Weiss, Charles R., Chief Engineer, Chain Division, Link-Belt Company.

Wilson, H. A., Application Engineer, Texrope Drive Department, Allis-Chalmers Company.

PREFACE

This book is written for those people in industry who are responsible for organization, design, construction, operation, and maintenance.

Experience over the years has shown the need for a book that could be used to solve the day-to-day problems of industry. This book is a compendium of industrial know-how and presents in compact form material that appears in greater detail in specialized reference works. It is not intended to replace the usual type of engineering handbook; it is to supplement and extend.

The book deals with industry's consumption and conservation of basic resources, with management engineering, with industrial construction, fire protection, maintenance, with industrial power and its uses, with air handling, materials handling, and the handling of services. It deals with the more specialized subjects of instrumentation, bearings and lubrication, engineering materials, and mechanical power. It covers many other subjects vital to efficient industrial and institutional operations.

The book was written by men with broad training and experience, selected from forty-six of the leading industrial organizations and five of the foremost educational institutions in the United States. These men have had complete freedom of expression.

WILLIAM STANIAR

WILMINGTON, DEL.
May, 1950

ACKNOWLEDGMENTS

"Plant Engineering Handbook" is a product of American industry and knowledge. The idea of such a book was conceived during 1943 and now has become a reality through the generous cooperation and assistance of the leading industrial organizations and universities of America. The Editor-in-Chief desires to acknowledge with deep gratitude the willing cooperation of these institutions.

The Editor-in-Chief is most fortunate in having had the friendly encouragement, support, and assistance of a great many people and therefore acknowledges a real debt to his authors, critics, and others whose combined efforts built this handbook. He particularly desires to thank the following:

Dr. Sydney Steele of the Fischer and Porter Company for the editing of manuscript and his generous technical assistance in many phases of the project.
Dr. John H. Perry, Chemical Engineer, E. I. du Pont de Nemours and Company, for his guidance in the preparation of initial data.
Dr. A. A. Potter, Dean of Engineering, Purdue University, for his advice, interest, and encouragement.
A. B. Wason, Assistant Manager, Air Conditioning Department, Sturtevant Division, Westinghouse Electric Corporation, for his many valuable suggestions.
George J. Martin, formerly, Superintendent of Maintenance, Brown Company, for his interest and helpful suggestions.
Martin J. Bergen, Chief Draftsman, E. I. du Pont de Nemours and Company, for his encouragement and assistance given in obtaining authors from the Massachusetts Institute of Technology.
F. A. Miller, Materials Handling Consultant, E. I. du Pont de Nemours and Company, for the editing of the sub-section on conveyors, elevators, pallets, and fork trucks.
D. F. Hollingsworth, Lubrication Consultant, E. I. du Pont de Nemours and Company, for his valuable suggestions on the subjects of lubrication and special lubricants.

For the editing of manuscript and their constructive criticisms the author also wishes to thank:

W. D. Bailey, Chemical Engineer, E. I. du Pont de Nemours and Company.
Joseph Segel, Mechanical Engineer, retired.
R. F. Hibner, Power Consultant, E. I. du Pont de Nemours and Company.

II Basic-cost reduction

BASIC INDUSTRIAL COSTS AND COST REDUCTION*

BY SYDNEY STEELE, B.A., M.A., PH.D. (CANTAB.)

Sales Promotion Manager, Fischer & Porter Co.

BASIC INDUSTRIAL COSTS

When you figure your costs, do you think only in terms of dollars, pounds sterling, pesos, cruzeiros, francs, or other national currencies? Is money the only criterion used in making the profit-and-loss statement for your industry, or your plant, or your business? Have you considered *basic costs*, and do you make a man-power, materials, and utilities balance sheet for your enterprise? The real success of a business depends primarily on the efficient use of those basic-cost elements, which are actually any country's fundamental resources.

In this section basic costs, not dollar costs, have been determined for many United States industries and have been put in tabular form. By basic costs are meant the man-hours of labor, kilowatt-hours of electric energy, weights of raw material, etc., per unit of production of goods or services. For the most part, these costs are shown for the calendar years 1929, 1933, and 1939. Complete data were not available for all the years, however, and figures for other years are used for some industries. The costs were calculated from Census of Manufactures and Bureau of Labor Statistics data, supplemented by information from several trade associations, the Minerals Yearbook, and other sources. The Bureau of the Census 1939 classification of industries was used as a guide in assembling the tables of basic costs for manufacturing industries, and data for some nonmanufacturing industries are also included. It is regrettable that no census of manufactures for the United States has been made since 1939 and that data on man-hours of labor are sketchy prior to 1933. Reasonably complete figures should eventually be available for the calendar year 1947 and for subsequent years.

Since almost every enterprise depends to some extent upon the efforts of the engineer, he has a continuing responsibility for the economical production, distribution, and use of goods and services. No less important and closely related are his responsibilities in the personnel field— to promote and maintain harmonious relations with those to whom he reports and with those who work with and for him. In the broader view, he should also bend his efforts toward improving his company's standing in the community. Good personnel and public relations form a favorable climate in which the engineer can make his greatest contributions to industrial advancement, and the engineer himself can do much to create the climate in which his efforts can flourish.

Unless the engineer knows the basic costs of the operations under his charge, he is severely handicapped. Without comparable national-average data he may have difficulty in setting realistic goals of improvement toward which to work. And without data covering a wide span of years, there is no reliable criterion of industrial progress. In the long run, no enterprise can succeed if its basic costs are excessive.

In order to measure industrial performance and to make possible comparisons

---

* The author's thanks are due Richard S. Witmeyer, of the du Pont Company, for considerable assistance in preparing and checking the tables of basic costs. The author is also indebted to Edmond E. Lincoln, du Pont Company economist, for helpful comments and suggestions and to G. M. Read, du Pont Company chief engineer, for permission to reproduce Fig. 1-3.

Information on work being done on interindustry relations by Professor Leontief at Harvard and in the Bureau of Labor Statistics under Marvin Hoffenberg was obtained through the office of Senator C. Douglass Buck.

The author also acknowledges with thanks the cooperation of officers of many trade associations in furnishing pertinent information or helpful suggestions in connection with data shown in the tables of basic costs.

between industries, standards of reference must be set up which are adequate for the purpose and for which a reasonable amount of data is available.

The national currency is frequently used in this kind of work, but the practice has some defects, notably the following:

1. Changes in the intrinsic worth of a national currency make comparisons between different calendar years misleading, if not meaningless. As anyone who has experienced 20 years of economic life can testify, even the comparatively stable dollar has fluctuated considerably in intrinsic worth. Roughly twice as many dollars, for example, must be given in exchange for automobiles and radios in 1947 as in 1940 and almost three times as many for some basic food products.
2. If it is difficult to make comparisons between different calendar years in terms of one national currency, the problem of translating from one national currency to another over a period of years is well-nigh insurmountable.
3. Even within national boundaries, the unit cost of similar items entering into a given industry, measured in terms of the national currency, may vary with the geographical location. An example of this is the lower unit cost of man-hours which, some years ago, was a factor in the migration of textile and other industries to the southern United States which still continues.

Also used in measuring various aspects of industrial activity are a great many indexes. Usually some year, or period of years, is selected as a base, or 100, and data for other years are shown as percentages of the base period. Not all indexes have the same base period, and the base periods are changed from time to time Furthermore, the items taken into consideration in setting up the indexes sometimes vary. This necessitates a recalculation of data and recorrelation of data between indexes

In measuring industrial performance, the engineer thinks first in terms of man-hours of labor, kilowatt-hours of electric energy, tons of coal, cubic feet of gas, gallons of water, weights of raw materials used, etc. His measures of production are equally concrete: number of articles produced, weight of products made, ton-miles of freight handled, etc. These are the true criteria of industrial performance, and they are independent of currency variations. They enable direct and meaningful comparisons to be made between any number of years for which adequate data are available Moreover, these basic costs translate directly into the units used by other countries, and the conversion factors do not vary from year to year.

Most industries may be considered as separate entities, drawing on and consuming the resources of the country and producing in return goods and services. Among the resources consumed are man power; electric energy, fuels, and water; minerals, agricultural products, output from other industries; etc. The figures presented later in this section were prepared with this point of view in mind.

Determining consumption of resources, or basic costs of those industries which turn out a single product, such as flour, cement, or cigarettes, presented little difficulty. For others with a variety of products the following general procedure was adopted. The primary purpose of the industry was considered. For example, the wholesale meat-packing industry produces edible animal products for sale in the grocery stores, the supermarkets, the delicatessens, and for export. The total weight of these items alone is taken as the industry's production. From the over-all point of view no distinction is made between steaks, lard, lamb chops, sausage, and canned meats and this industry's other products for human consumption. Along with these items are manufactured by-products such as dog and cat food, livestock feeds and fertilizer, oils, hides, etc., which testify to the efficiency of the industry in its use of raw materials. These are not included in the production figures for the industry.

A different type of analysis is used in the transportation field. United States class I railroads and air-transport data are based on thousands of "traffic units," a traffic unit being defined as ton-miles of revenue freight plus three times revenue passenger-miles.

Use of the Tables

The tables of basic costs (pages 6 to 21) may be used in several ways, among which are the following·

1 They present United States national-average basic-cost data for selected industries to serve as a yardstick in measuring performance of individual producing units and for setting goals of improvement

2 By multiplying the basic costs given in the tables by the price of man-hours, utilities, and raw materials at any geographical location, an estimate of these costs in terms of any currency can be obtained

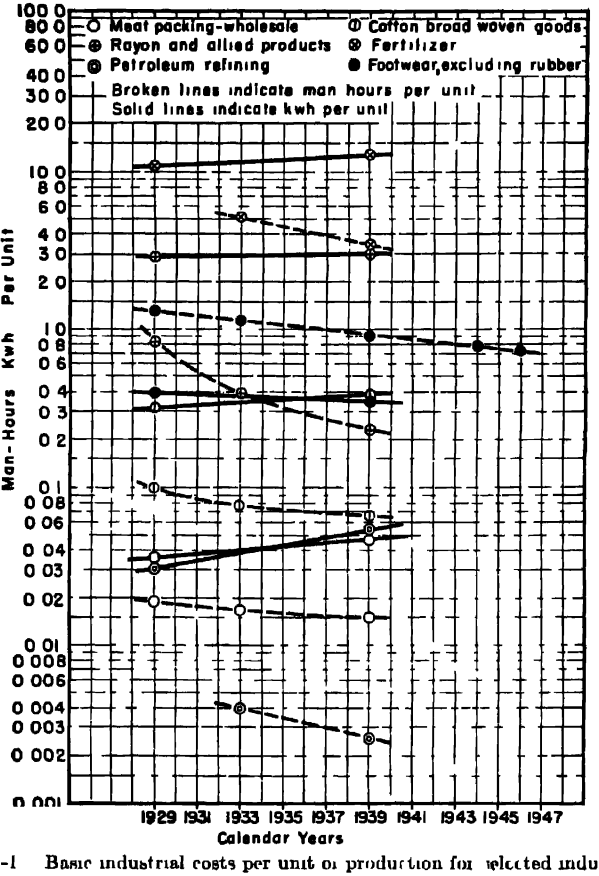

Fig. 1-1 Basic industrial costs per unit of production for selected industries

3 For those planning to broaden their business interests the tables provide information that can be used to estimate the major resources which will be required in setting up a new enterprise

4 Technological changes over the years are shown by altered consumption or substitution of basic resources and by changes in utility requirements

5 Changes in man-hours per unit of production reflect changes in productivity of labor brought about by worker efficiency changes in management, equipment, and procedure per cent utilization of equipment, and other factors

It is clear from the above that the tables reflect technological changes and variations in labor requirements * These are the only two factors that affect basic costs

---

* When more complete data are available for all major industries tables of this sort can be used in studies of interindustry relations See Leontief Dr Wassily A New Approach to the Problem of Market Analysis, American Management Association Marketing Series No 5) 1945 and Cornfield Jerome W Duane Evans and Marvin Hoffenberg Full Employment Patterns 1950, Bureau of Labor Statistics Serial No R 1868 1947

in any industry, and they are difficult, if not impossible, to follow in terms of unconstant, though indispensable, currencies

In Figs 1-1 and 1-2, man-hours, kilowatt-hours, and other basic costs per unit of production in several industries are plotted on a calendar-year base to demonstrate trends (The complete data are given in the tables that follow Fig 1-2) In spite of the fact that data for so few years were available, distinct trends can be observed

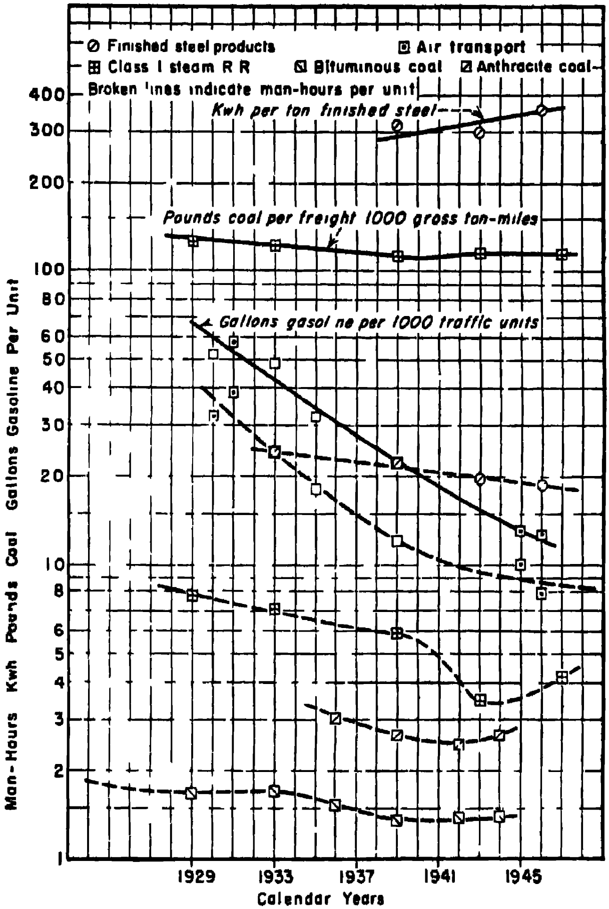

Fig 1-2 Basic industrial costs per unit of production for selected industries

In general, man-hours per unit are decreasing while kilowatt-hours per unit tend to remain constant or increase It will be noticed that the "youngest" industries for which data are plotted, the air-transport and the rayon and allied products industries, show the most marked rates of change *

Following the tables is a brief discussion of basic-cost reduction and of the methods that can be used to achieve this end

* This may have interesting philosophical implications The reader is referred to E R Dewey and E F Dakin "Cycles" Henry Holt and Company Incorporated New York 1947 and in particular to p 49 Fig 8 where various American industries are located with approximate accuracy on a basic industrial growth curve

BASIC INDUSTRIAL COSTS

1-20	20 Miscellaneous Industries[a]	None	

Nonmanufacturing Industries

Table	Classification	Industries for Which Data Are Presented	Page
1-21	21 Transportation	Air Transport Class I Steam Railroads	19
1-22	22 Coal Mining	Anthracite Coal Mining Bituminous Coal – Mining and Markets	19
1-23	23 Utilities	Electric Power and Light Manufactured Gas	20, 21

[a] Tables omitted. Satisfactory data not currently available (1948).

GENERAL NOTES. The many gaps in the tables which follow suggest that an extension of industrial and governmental thinking along basic cost lines may be timely. It is regrettable that in the welter of statistical information gathered and disseminated (at high man-hour cost) there is comparatively little that can be used to determine the rate at which we are depleting our basic resources. The following symbols are used throughout the tables:

* To indicate that data are unavailable from sources checked.

† To indicate author's estimate.

LIST OF TABLES

Manufacturing Industries

Table	U.S. Bureau of the Census (1939) Group No. and Title	Industries or Products for Which Data Are Presented	Page
1-1	1 Food and Kindred Products	Bakery Products Candy and Other Confectionery Products Cane-sugar Refining Creamery Butter Flour and Other Grain Mills Ice Cream and Ices Meat Packing, Wholesale	7-9
1-2	2 Tobacco Manufactures	Cigarettes Cigars	9
1-3	3 Textile-mill Products and Other Fiber Manufactures	Cotton Broad-woven Goods Rayon Broad-woven Goods	10
1-4	4 Apparel and Other Finished Products[a]	None	
1-5	5 Lumber and Timber Basic Products[a]	None	
1-6	6 Furniture and Finished Lumber Products[a]	None	
1-7	7 Paper and Allied Products	Paper and Paperboard Mills Pulp Mills	10-11
1-8	8 Printing, Publishing, and Allied Trades[a]	None	
1-9	9 Chemicals and Allied Products	Fertilizer Industrial Chemicals Not Elsewhere Classified Ammonia, Anhydrous Caustic Soda Hydrochloric Acid Nitric Acid Soda Ash Sulfuric Acid Rayon and Allied Products	11-13
1-10	10 Products of Petroleum and Coal	Beehive Coke Petroleum Refining	14
1-11	11 Rubber Products	Automotive Tires and Inner Tubes	14
1-12	12 Leather and Leather Products	Footwear, Excluding Rubber	15
1-13	13 Stone, Clay, and Glass Products	Flat Glass Glass Container Portland Cement	15-16
1-14	14 Iron and Steel and Their Products, except Machinery	Finished Steel Products	16
1-15	15 Nonferrous Metals and Their Products[a]	None	
1-16	16 Electrical Machinery[a]	None	
1-17	17 Machinery, except Electrical	Tractor	17
1-18	18 Automobiles and Automobile Equipment	Passenger Car	17
1-19	19 Transportation Equipment, except Automobiles	Cars and Car Equipment Locomotives	18
1-20	20 Miscellaneous Industries[a]	None	

Nonmanufacturing Industries

Table	Classification	Industries for Which Data Are Presented	Page
1-21	21 Transportation	Air Transport Class 1 Steam Railroads	19
1-22	22 Coal Mining	Anthracite Coal Mining Bituminous Coal—Mining and Markets	19
1-23	23 Utilities	Electric Power and Light Manufactured Gas	20-21

[a] Tables omitted. Satisfactory data not currently available (1948).

GENERAL NOTES. The many gaps in the tables which follow suggest that an extension of industrial and governmental thinking along basic cost lines may be timely. It is regrettable that in the welter of statistical information gathered and disseminated (at high man-hour cost) there is comparatively little that can be used to determine the rate at which we are depleting our basic resources. The following symbols are used throughout the tables:

* To indicate that data are unavailable from sources checked.

† To indicate author's estimate.

BASIC INDUSTRIAL COSTS

Table 1-1. Food and Kindred Products (*Cont.*)

Industry	CANE-SUGAR REFINING			
Basic unit	Short Ton			
Year	1929	1933	1937	1939
Units produced	5,115,307	3,938,000	4,515,582	4,126,508
Labor, man-hr/unit	*	*	6.1	6.7
Electric energy, kwh/unit	17.2	*	*	48.9
Principal raw materials, short tons/short ton				
Raw sugar treated	1.04	*	*	*

Industry	CREAMERY BUTTER		
Basic unit	Pound		
Year	1929	1933	1939
Units produced, $\times 10^6$	1,650†	1,763[a]	1,782[a]
Labor, man-hr/unit	*	0.023†	0.024
Electric energy, kwh/unit	0.089†		0.103
Principal raw materials, lb/lb			
Milk[a]	20		20
Refined cane sugar			0.008

[a] Data from U.S. Department of Agriculture, "Agricultural Statistics."

Industry	FLOUR AND OTHER GRAIN MILLS		
Basic unit	Hundredweights of Flour, Meal, Feed, Etc.		
Year	1929	1933	1939
Units produced	404,363,690	307,933,770	324,819,032
Labor, man-hr/unit	*	0.17	0.17
Electric energy, kwh/unit	1.45†	*	2.09
Principal raw materials, lb/cwt			
Wheat	81.05	86.05	93.85
Corn	12.98	8.20	11.50
Oats	4.31	1.17	1.63
Rye	1.43	1.46	1.42
Barley	1.41	0.86	1.04
Buckwheat, rice, etc	0.30[a]	0.09[a]	0.58
Sugars, shortening, enrichment, etc	*	*	0.65
Other and mixed grains	0.29	0.21	*
Total accounted for	101.77	98.04	110.67

[a] Buckwheat only.

Industry	ICE CREAM AND ICES			
Basic unit	Gallon			
Year	1929	1933	1937	1939
Units produced, $\times 10^6$	279.8	166.4	300.0	278.0
Labor, man-hr/unit	*	0.22	0.15	0.14
Electric energy, kwh/unit	0.94†	*	0.88†	1.07
Principal raw materials, lb/gal				
Milk	13.6	13.4	14.0	16.3
Refined cane sugar	*	*	*	0.47

* Data unavailable from sources checked. † Author's estimate.

BASIC INDUSTRIAL COSTS

Table 1-1. Food and Kindred Products (*Cont*)

Industry Basic unit	MEAT PACKING WHOLESALE Pounds for Human Consumption[a]		
Year	1929	1933	1939
Units produced $\times 10^6$	16 852	15 221	17 046
Labor man hr/unit	0 019	0 017	0 015
Electric energy kwh/unit	0 036†	*	0 047
Principal raw materials lb on the hoof/lb			
Cattle	0 53	0 56	0 64
Calves	0 05	0 06	0 07
Sheep and lambs	0 08	0 10	0 10
Hogs	0 73	0 75	0 63
Total accounted for	1 39[b]	1 47[b]	1 44[b]

[a] Fresh cured and canned meats canned and other sausage and sausage casings lard

[b] Part of the excess represents dog and cat food, livestock feed and fertilizer animal skins, wool, hair etc

Table 1-2 Tobacco Manufactures

Industry Basic unit	CIGARETTES Thousands of Cigarettes Weighing Less Than 3 Lb/1 000				
Year	1929	1933	1937	1939	1944
Units produced[a]	122 392 381	114 874 217	169 969 320	180 666 824	323,583 888
Labor man hr/unit	*	*	0 29	0 28	*
Electric energy kwh/unit	0 31†	*	*	0 30	*
Principal raw materials lb/1 000 cigarettes					
Leaf tobacco[a] unstemmed equivalent[b]	2 83	2 84	2 82	2 81	2 84
Sugar	*	*	*	0 15	*
Licorice	*	*	*	0 06	*
Total accounted for	2 83	2 84	2 82	3 02	2 84

[a] Data from U S Treasury Department annual reports of the Commissioner of Internal Revenue

[b] Stemmed leaf and scraps etc converted to unstemmed equivalent on the basis of 3 lb stemmed to 4 lb unstemmed

Industry Basic unit	CIGARS Thousands of Cigars Weighing More Than 3 Lb/1 000				
Year	1929	1933	1937	1939	1944
Units produced[a]	6 518 533	4 300 015	5 303 369	5 197 627	5 198 670
Labor man hr/unit	*	*	19 5	18 1	*
Electric energy kwh/unit	2 6†	*	*	5 6	*
Principal raw materials lb/1 000 cigars					
Leaf tobacco[a] unstemmed equivalent[b]	23 15	24 18	24 11	23 49	24 89
Sugar	*	*	*	0 025	*
Licorice	*	*	*	0 01	*
Total accounted for	23 15	24 18	24 11	23 525	24 89

[a] Data from U S Treasury Department annual reports of the Commissioner of Internal Revenue

[b] Stemmed leaf and scraps etc , converted to unstemmed equivalent on the basis of 3 lb stemmed to 4 lb unstemmed

* Data unavailable from sources checked † Author's estimate

BASIC INDUSTRIAL COSTS

Table 1-6. Textile-mill Products and Other Fiber Manufactures

Industry Basic unit	COTTON BROAD WOVEN GOODS Yards of Material 36 In Wide		
Year	1929	1933	1939
Units produced $\times 10^6$	8 512	8 089	9 045
Labor man-hr/unit	0 10†	0 077†	0 066
Electric energy kwh/unit	0 32†	*	0 38

Total accounted for	*	*	0 3122
Average wt/yard 36 in wide lb	0 277	0 263	0 274

Industry Basic unit	RAYON BROAD WOVEN GOODS Linear Yards of Material over 12 In Wide
Year	1939[a]
Units produced $\times 10^6$	1 341
Labor man hr/unit	0 099
Electric energy kwh/unit	0 32
Principal raw materials (lb/yd)	
Raw cotton short staple	0 028
Long staple	0 012
Rayon staple	0 030
Shorn and pulled wool etc scoured wt	0 00026
Cotton noils and mill waste	0 0017
Raw silk other fiber etc	0 00037
Total above items	0 07233
Total yarn consumed	0 2345
Average wt/lin yd lb	0 2104

[a] Data comparable with 1939 not available from sources checked for years 1929 to 1933

Table 1-7 Paper and Allied Products

Industry Basic unit	PAPER AND PAPERBOARD MILLS Short Tons of Paper and Paperboard[a]		
Year	1929	1933	1939
Units produced	11 140 235	9 190 017	13 509 612
Labor man hr/unit	*	20 0	17 2
Electric energy kwh/unit	630†[b]	*	670[b]
Principal raw materials short tons/short ton			
Wood pulp	0 565	*	0 64
Manila stock	0 0116	*	0 0047
Rags	0 066	*	0 035
Waste paper	0 345	*	0 32
Straw	0 052	*	0 038
Other fiber (cotton etc)	0 0045	*	0 0086
Casein	0 0017	*	0 0013
Clay	0 042	*	0 032
Rosin	0 0034	*	0 0027
Rosin sizing	0 009	*	0 007
Other nonfibrous materials alum starch etc	0 022	*	0 042
Total accounted for	1 1222	*	1 1312

[a] Newsprint groundwood book cover text writing wrapping tissue absorbent building and other papers and boards

[b] A considerable amount of power is used direct from the prime mover without putting it into the form of energy *e g* grinders connected directly to water wheels

* Data unavailable from sources checked † Author s estimate

BASIC INDUSTRIAL COSTS

Table 1-7. Paper and Allied Products (*Cont*)

Industry Basic unit	PULP MILLS Short Tons of Wood Pulp		
Year	1929	1933	1939
Units produced	4,862,885	4,276,204	6,993,334
Labor, man hr/unit	*	9.7	7.9
Electric energy, kwh/unit	[a]	[a]	[a]
Principal raw materials cd of wood/short ton			
Yellow pine southern	0.21	0.37	0.55
Spruce domestic and imported	0.64	0.48	0.35
Hemlock domestic and imported	0.27	0.26	0.32
Other woods slabs and mill waste	0.45	0.43	0.33
Total accounted for	1.57	1.54	1.55

[a] No electric-energy data available for pulp mills as distinguished from paper and paperboard mills.

Table 1-9 Chemicals and Allied Products

Industry Basic unit	FERTILIZER Short Tons of Fertilizer (All Types)		
Year	1929	1933	1939
Units produced	9,320,000	5,196,000	10,161,606
Labor man hr/unit	*	5.23	3.43
Electric energy kwh/unit	11.0†	*	12.9
Principal raw materials short tons/short ton

Steam, lb			20 000	2 700
Water, lb			*	18 000
Refrigeration tons			0 9	
Reburning fuel, Btu				13 000 000
Soda ash (58 per cent) lb			50	2 900
Salt, tons			1 6	
Lime make-up as 90 per cent CaO lb				160
Sulfuric acid (66° Bé) lb			200	

[a] Production figures from 1939 government census Basic cost data from Chemical and Metallurgical Flowsheets" 1944 4th ed

[b] Electrolytic process

[c] Lime-soda process

[d] Basic costs per ton 76 per cent NaOH plus 1 750 lb chlorine and 8 750 cu ft hydrogen (50 lb hydrogen) (electrolytic process)

[e] Basic costs per ton NaOH in 11 per cent solution produced in plant of 100 tons per day capacity (lime-soda process)

Chemical Basic unit	HYDROCHLORIC ACID[a] Short Tons of 100 Per Cent Acid (HCl)		
Year	1939	1944[b]	1944[c]
Units produced	140 338	*	*
Labor man-hr/unit	*	16 5	9 9
Electric energy kwh/unit	*	280	5 6
Other basic costs per unit of production	*		
Water, gal		9 012	1 550 3 100
Salt, lb		3 263	
Sulfuric acid, 100 per cent lb or		2 937[d]	
Niter cake, lb		8 173[e]	
Coal, lb		2 300	
Chlorine, lb			1 920
Hydrogen			60

[a] Production figures from 1939 government census Basic cost data from Chemical and Metallurgical Flowsheets' 1944 4th ed

[b] Salt process [c] Synthetic process [d] Process also produces 3,915 lb salt cake

[e] Process also produces 8 825 lb salt cake

Chemical Basic unit	NITRIC ACID[a] Short Tons of 100 Per Cent Acid (HNO_3)	
Year	1939	1944
Units produced	167 7[illegible]0	
Labor man-hr/unit		1 0
Electric energy, kwh/unit		270
Other basic costs per unit of production		
Anhydrous ammonia lb		575
Platinum-catalyst loss (some plants) †		0 012

[a] Production figures from 1939 government census. Basic-cost data from Chemical and Metallurgical Flowsheets," 1944, 4th ed

* Data unavailable from sources checked † Author's estimate.

BASIC INDUSTRIAL COSTS

Table 1-9 Chemicals and Allied Products (*Cont*)

Chemical Basic unit	SODA ASH[a] Short Tons		
Year	1939[b]	1939[c]	1944[d]
Units produced	2 012 804	132 897	*
Labor direct	*	*	2 0
Repair and maintenance	*	*	2 6
Electric energy kwh/unit	*	*	*
Other basic costs per unit of production	*	*	
Cooling water gal			15 000–18,000
Salt tons			1 50–1 75
Limestone tons			1 20–1 35
Coke tons			0 095–0 11
Coal boilers tons			0 25–0 5
Dryers tons			0 16–0 25
Ammonia loss as $(NH_4)_2SO_4$ kg			2–4
Carbon dioxide cu ft			1 000–1 200
Sodium sulfide lb			2 4

[a] Data from *Statistical Bulletin* 1947 published by Edison Electric Institute

[b] Preliminary figures

[c] Excludes generation by wood and waste fuels

[d] Average for all stations. It should be noted that the current power shortage (1946–1948) has made it necessary to operate all stations old and modern. As new stations come into operation and older stations are shut down this ratio will decrease appreciably below 1.29. The best plants today (1948) are producing a kilowatthour on 0.75 lb of coal and the best designs will make it for 0.7 lb. One system is now using 1 lb of coal per kwh. It has been estimated that the national average in three years will be 1.2 lb coal/kwh and in 12 years will be 1 lb coal/kwh.

The average Btu per pound of coal burned by the utilities in 1945 was 13 100. According to company reports the figure now varies from a low of 9 000 Btu/lb to something over 14 000 Btu/lb and averages perhaps closer to 12 000 than to 13 000 Btu/lb. This may be a temporary situation, which could improve in a few years.

* Data unavailable from sources checked † Author's estimate.

BASIC INDUSTRIAL COSTS

Table 1-23. Utilities (*Cont.*)

Industry	MANUFACTURED GAS[a]							
Basic unit	Thousand Cubic Feet (550-Btu Gas)							
Year	1932	1933	1936	1939	1942	1945	1946	1947
Units produced	265,138,000	244,743,000	238,553,000	241,405,000	291,718,000	358,876,000	377,132,000	398,805,000
Labor, man-hr/unit	0.63	0.67	0.65	0.60	0.44	0.32	0.32	0.31
Principal raw materials, lb/1,000 cu ft.								
Solid fuels, anthracite, bituminous, and coke[b]	84	86	86	77	74	66	62	57
Oil, gal/1,000 cu ft[b]	2.3	2.2	2.2	2.6	2.6	2.6	2.8	3.1

---

[a] Data from "Gas Facts, 1945–1946," and other publications of the American Gas Association, Bureau of Statistics. By-products are coke, tar, light oil, briquettes, etc. Between 0.65 and 0.75 lb of coke is produced per pound of coal carbonized.

[b] Average Btu content of fuels used:

Anthracite	12,500–14,000 Btu/lb
Bituminous	11,700–15,300 Btu/lb
Coke	12,300–13,000 Btu/lb
Light industrial oil	145,000 Btu/gal
Heavy industrial oil	155,000 Btu/gal

* Data unavailable from sources checked. † Author's estimate.

BASIC-COST REDUCTION

The Second World War forced belligerents and nonbelligerents alike to use up the world's basic resources at an unprecedented rate. We now face the problems created by depleted soil and drastically reduced reserves of oil, iron, copper, and other commodities on which our present civilization is based. There is also a marked, although possibly temporary, shortage of technically trained personnel, without whom it will be difficult to maintain, still less improve, standards of living in all countries. Basic-cost reduction is therefore an urgent necessity.

The first basic-cost reduction should be the elimination of waste all along the line from source to ultimate consumption or use. The toll of basic resources taken as result of carelessness and indifference is particularly inexcusable—soil erosion accelerated by poor soil management, pollution of streams, lakes, and rivers, forest fires started through carelessness, and the losses of food through spoilage and waste in the average home are typical examples. The same pattern of waste appears in many industries, in some to a lesser extent than in others. In general, unless there is (1) a continuing improvement in quality or (2) a reduction in the amount of raw materials consumed per constant unit of production, (3) a substitution of more plentiful for scarce raw materials or (4) an increase in the weight or number of useful by-products from the same weight of raw materials, the industry probably stands in need of technological improvement. The engineer can contribute to quality improvement and elimination of waste in industry and should cooperate in curtailing losses in other fields.

Not only are materials wasted, but countless man-hours are lost for a variety of reasons. Among these are poor personnel relations and failure to make the most of the individual employee's talents, training, and inclination; inefficient management, featherbedding, and disputes between labor and management; accidents and illness; failure to plan and execute the job properly the first time; and bureaucracy and pressure groups. In these matters the engineer is frequently out of his depth, although his responsibilities are no less marked here than in the field of raw-material conservation.

If only part of these losses in raw materials and man-hours were eliminated, much higher material standards of living would be achieved.

In addition to raw-material and man-hour losses, excessive use of utilities (electric energy, steam, water, etc.) frequently occurs. In fact, it is exceptional to find an industrial plant where a reduction of utilities consumed per unit of production cannot be made. Of course, it should not be forgotten that increases in utility consumption are sometimes justified, *e.g.*, an increase in electric energy to reduce physical effort and to make possible a higher output per man-hour.

The many ways in which industrial-engineering know-how and procedures can be applied to basic-cost reduction were presented by G. M. Read[*] in a paper read before the American Management Association in 1940. Read's tabulation is reproduced in Fig. 1-3 and needs no elaboration.

No discussion of cost reduction would be complete if limited to engineering methods. Among others which have proved successful are the following:[†]

1. *Quantity output,* which permits overhead expenses and the various fixed charges to be distributed over a very large number of units so that a low selling price can still allow for a reasonable profit margin.

2. *Specialization* in the manufacture of a commodity or commodities for which a plant is best fitted. Closely related is *standardization* of both operations and types of goods produced, the first leading to methods simplification and the second to elimination of unprofitable lines.

3. *Utilization of by-products* is one of the most effective means by which costs can be reduced. It sometimes leads to a new industry or industries and frequently permits the main product to be sold at a lower price.

---

[*] Now chief engineer, E. I. du Pont de Nemours & Co., Inc., Wilmington, Delaware (see American Management Association, Production Series No. 122, 1940).

Analyses of operations and equipment arrangement to effect motion economy
INCENTIVE-WAGE APPLICATION
Consultation on wage payment plans, installation of new systems, and development of multifactor wage-payment plans
MATERIALS HANDLING
Studies on materials handling, transportation, and shipment
MACHINE DEVELOPMENT
Development of special and automatic machines and special gauges and instruments
PLANT REARRANGEMENT
Studies to effect consolidation of operations to reduce handling improve supervision and reduce plant investment.
MATERIALS COST REDUCTION
POWER CONSERVATION
Development of rational power standards and studies to improve generating efficiency power and fuel costs, and contracts
PACKAGING
Selection of most economical packages and containers
WASTE MATERIAL RECOVERY
Development of equipment and processes for reduction of material losses
WATER TREATMENT
Studies to determine most economical treatments of water for process and power use
TRADE WASTE DISPOSAL
Development of processes to treat trade wastes in compliance with laws and for recovery of valuable materials
YIELD IMPROVEMENT
FIELD ENGINEERING
Studies of plants and processes to reduce unit manufacturing costs
INSTRUMENTATION
Application of instruments gauges etc to improve process control
UNIT PROCESS DEVELOPMENT
Application of fundamental developments in unit processes such as mixing heat transfer fluid flow, etc
PROCESS CONTROL
Studies in manufacture distribution and use and general exchange of information on improvements in equipment and processes
REDUCED INVESTMENT
EQUIPMENT DEVELOPMENT
Development of most economical equipment for each company process
PLANT DESIGN
Incorporation of all industrial engineering knowledge in new plant design
LOW DEPRECIATION RATE
MATERIALS OF CONSTRUCTION
Studies to provide the most suitable construction materials
MAINTENANCE SYSTEMS
Application of modern maintenance systems to reduce maintenance costs
MECHANICAL POWER TRANSMISSION
Specification and standardization of facilities for mechanical power transmission
LUBRICATION
Standardization to reduce unit purchase price and specifications for lubricants to increase equipment life
PRODUCT QUALITY
IMPROVED EQUIPMENT
MACHINE DEVELOPMENT
Development of special machines for improving quality of product
INSTRUMENTATION
Application of control instruments to improve product quality
MATERIALS DEVELOPMENT
Specifications on materials of construction to reduce product contamination
NEW PROCESSES
ENGINEERING DEVELOPMENT
Development of new information and equipment to improve product quality including semiworks operation leading to plant scale design
UNIT PROCESS DEVELOPMENT
Application of fundamental information on distillation absorption filtration etc for product improvement
SALES SERVICE
Adapting specialized engineering information to sales problems
RAW MATERIAL IMPROVEMENT
PROCESS CONTROL
Improvement in process and equipment for the manufacture of raw and semifinished materials
WATER PURIFICATION
Specifications on water treatment for special uses requiring water of high quality

FIG. 1-3. Industrial engineering applied to basic-cost reduction.

4. *Integration* of industrial processes under one management can reduce production costs through control of raw materials, and selling costs through elimination of middlemen. (The benefits are not always passed along to the customer.) Integration is not an unmixed blessing, and, to name but one possibility, the increased capital* required may constitute a hazard.

5. If *stock turnover* can be increased, less working capital will be required, and unit costs can be reduced.

6. *Output per man-hour* is perhaps the most important single item in cost reduction and one in which labor's and management's interests should be parallel. Higher output per man-hour is a sound basis for increasing wages and should lead to lower costs and broader markets (see Figs. 1-1 and 1-2).

7. Closely related to (6) are *output per unit of equipment* and *elimination of bottlenecks*. The output of many a plant has been increased without additional facilities or man power, sometimes even with a reduction in these items, by bringing all units into production balance and by increasing the output per unit.

8. *Equipment utilization* has a direct bearing on unit costs. Taxes, depreciation, interest on investment, and many general and administrative expenses continue whether the equipment is fully utilized or not. The ideal is 100 per cent equipment utilization, although this cannot be attained in practice except for limited periods of time.

9. *Control of inventories* of raw materials, semifinished, and finished products is essential in a well-ordered business. Purchasing should be governed by business conditions and anticipated manufacturing requirements and inventories held at levels determined by current market demands. Speculation in inventory appreciation is hazardous and has no place in manufacturing.

Basic-cost reduction is the responsibility of all who profit from the use of the world's basic resources—consumer, labor, management, and government. Working in harmony, these four groups can raise material standards of living to new and higher levels. Working at cross purposes, it will be difficult to maintain present standards

---

* Capital in the economic sense is ordinarily thought of as the man-made instruments of production, such as mills, factories, plants, and commercial buildings, and their machines, tools, equipment, and furnishings.

ELEMENTS OF SUPERVISION AND TOOLS OF SUPERVISION

BY MARTIN JOHN BERGEN, B.S., M.S.

Chief Draftsman, E. I. du Pont de Nemours & Co., Inc.

ELEMENTS OF SUPERVISION

Supervision. A great deal of confusion surrounds the meaning of the term "supervision." This misunderstanding can be removed quickly when it is remembered that supervision is an act. It is the act of overseeing, inspecting, or superintending. It is an act performed by a person toward other persons.

Supervisor. From the above it is seen that a supervisor is one who oversees, inspects, or superintends the actions or results of others. The supervisor is a person who is responsible for the behavior, conduct, and activity of others. He, therefore, is a leader and gets results through others.

Many men who are responsible for materials, methods, or money consider themselves supervisors. In the true sense of the word, these men are not supervisors because they do not have responsibility for men. Since a supervisor is responsible for men, it is essential that the supervisor's duties, as well as his responsibilities, be clearly defined. It is necessary for the supervisor to know how to manage and guide the man power under his direction and control to achieve the most effective and least expensive results.

Authority. Authority is the legal or rightful power to command or to act. It is the power exercised by the supervisor by virtue of his office to supervise. This power is received by him from higher authority or management. In the case of a manager, such power is received from the owner of the business. Authority, being the power to act or to achieve a certain goal, is energy in the hands of a supervisor. It is therefore the supervisor's duty to direct this energy or authority into the proper channels to achieve the goal which he is responsible for reaching.

Responsibility. Another misunderstood term in industry is "responsibility." Since it comes into being at the time when the power to act is given a supervisor, it is often confused with the power to act.

Responsibility is not a power. It is the *state of being accountable or answerable for* the trust accorded one and which one is obligated to discharge.

Duty. A duty is that act which one is obliged or bound to do. It is plain to see, therefore, that one's responsibilities are very similar to one's duties.

Upon receipt of authority or power, a supervisor becomes accountable for this power vested in him. The act of transfer of power also becomes the act of creation of accountability for the power. A supervisor must understand this principle clearly, and it will be developed at length.

However, the important difference between duty and responsibility is that duty is an act which one is accountable for the performance of, or accountable to perform, whereas responsibility is the state of accountability.

Supervisor's Fundamental Duties. The supervisor's fundamental duties are organizing, deputizing, and supervising.

Organizing. Organizing is the act of planning work in order to achieve the desired goal, using the authority or power vested in the supervisor to achieve this end.

Deputizing. Deputizing is the act of using the best efforts of persons under a supervisor's control by giving to them a particular share of the power or authority vested in the supervisor and seeing to it that these persons use this power to their best knowledge and ability in assisting the supervisor to reach the goal he is responsible for attaining.

Supervising. Supervising has been defined under *supervision*

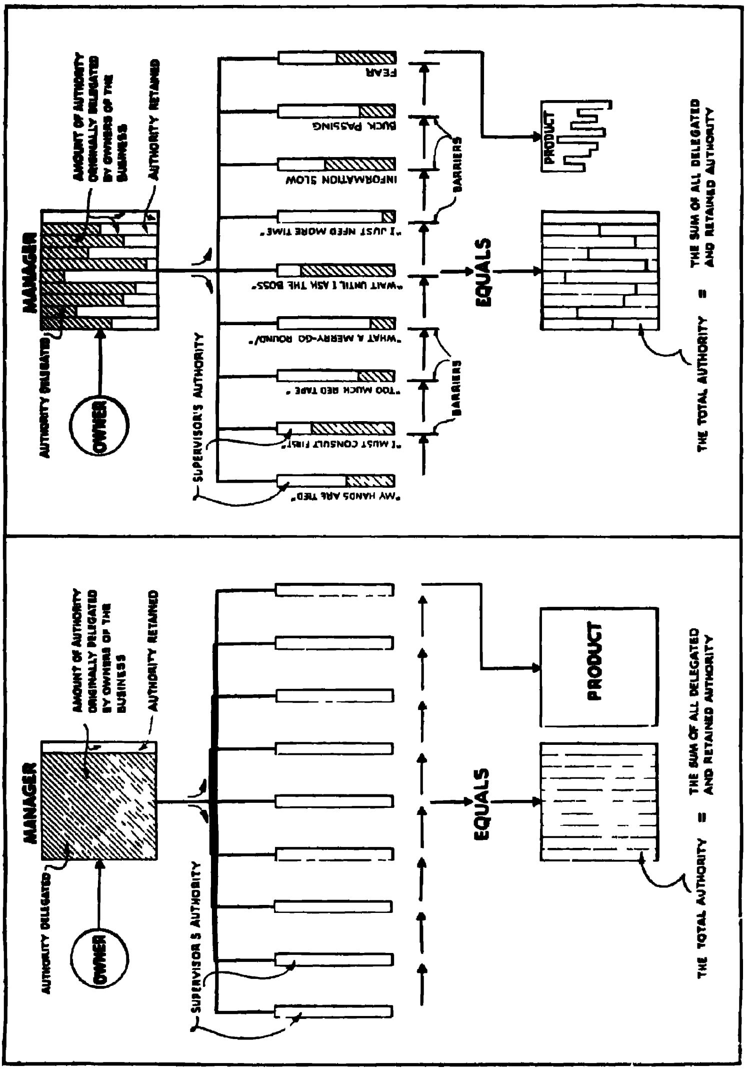
Figs 2-1 and 2-2. (*Above*) An organization which fully accepts its responsibilities (*Below*) An organization which evades its responsibilities—a buck-passing organization.

Delegation of Authority. The act by a supervisor of deputizing other people to act for him, and the vesting of these people with a portion of the authority the supervisor has, is called the delegation of authority (see Figs. 2-3 and 2-4)

Amount of Authority a Supervisor Should Delegate. How much authority should a supervisor retain, and how much should he delegate? A supervisor should delegate all the authority it is possible to delegate in order to get work done, reserving for himself the necessary remainder of authority to oversee, check, and direct the work of others. This is a fundamental principle of good supervision (see Fig. 2-4).



Figs. 2-3 and 2-4. (*Left*) The correct delegation of authority. (*Right*) The incorrect delegation of authority.

Creation of the State of Responsibility. The delegation of authority has been confused in a good many instances by the supervisor with the act of delegating responsibility. *Responsibility cannot be deputized or delegated.*

Responsibility must be created. When authority is accepted by a supervisor and, in turn, the supervisor delegates a portion of this authority, he does not delegate responsibility or accountability. He is fully accountable at all times to the source of his authority for his use of this delegated power. When the supervisor accepted the authority, he became fully accountable for its use and created in himself the state of responsibility for the authority received.

If it is necessary to delegate a portion of the original authority to get results, it becomes necessary, during the act of delegation, for the person accepting the authority to become responsible. By this act of becoming accountable, additional responsibility is created. Since the superior, who delegated the authority to the supervisor, is still fully accountable, it is plain to see that there is now more responsibility, when both men's responsibilities are added together, than the sum total of the authorities of the two men (see Fig. 2-5).

It is rather interesting to study the effect of this process of creation of responsibility. If we start off with a definite amount of authority, it can usually be measured in terms of dollars. There are a definite number of dollars' worth of authority to perform a certain task, a portion of which is parceled out from top management to each succeeding echelon in the supervisory line. Since the person who originally held and delegated the authority is fully accountable and since each person under him is fully accountable for the portion of the authority accepted by him, we find that the sum total of authority adds up to the full authority originally vested in the first person, but that the responsibility adds up to a far greater amount than the original responsibility (see Figs. 2-5 and 2-6).

Failure to understand this process of creation of responsibility has been at the bottom of a great deal of trouble for supervision, which has been called, for want of a better name, "buck-passing" supervision (see Fig. 2-2).

Organization. In order that a supervisor (1) use his authority, (2) discharge his duties, and (3) accept his responsibilities, he must have a common-sense series of methods, accepted by all concerned, when he performs these acts. The sum total of these methods and the efforts of people using them to reach the desired goal is called an "organization." It can readily be seen that an organization is the product or end result of a series of acts of organization. An organization is, as its name implies, an organism or structure that has been put together to accomplish a single or a series of continuing results. This structure has certain definite characteristics which are centered around the end or goal for which the structure or organization was constructed. This structure must be so clearly defined that each unit component can work in the structure with definite regard for

1. The flow of authority or power
2. The definite acceptance of responsibility
3. The effective performance of duties
4. Close regard for relations of these unit components

These unit components may be individuals or groups of people. The supervisor is an important unit component in this structure or organization.

Act of Organizing. In the process of structuralizing a business we have the act of organizing. It is necessary for supervision to segregate all duties of a similar nature and so combine these duties, or, as they are sometimes called, functions, to get the most effective effort from the people who are performing the duties.

In order to perform these duties effectively, the functions of various people must be clearly defined. In addition, where two or more persons are involved, relationships between these persons must also be clearly defined. In the process of definition, the supervisor will also have to determine the path and flow of authority to achieve the desired result. This path will be the path along which responsibilities will be created, accepted, and discharged. It will be, in addition, the path of duties which must be performed.

Development of an Organization. What constitutes an organization, and how can one be developed? An organization, being an operating entity with functionalized parts and with definite flow, can be compared in a manner of speaking with a mechanism. Each function or duty must be related to other functions or duties in order to have a smooth-running production machine. There cannot be rivalry or conflict between the functions of the mechanism, or the energy employed will be dissipated by other things than those for which it was originally to be used. Therefore, it is necessary to set down on paper, in an adequate manner, the fundamental channels of authority and methods by which these channels will be used for the flow and use of authority.

In so doing, it will be found that certain functions can be well defined and their use definitely prescribed. It will be found, also, that methods for checking the use

Figs. 2-5 and 2-6. (*Left*) Effective creation of responsibility. (*Right*) Failure adequately to create responsibility, resulting in only partial creation of same; insufficient to do a good job.

of these functions can also be laid down in detail. We call the first operation the setting up of a system by which the work can function and call the second operation the method of controlling the system through records.

System. System is nothing more nor less than an orderly habitual or routine method or methods by which the regular activities of a business or part of a business are carried on.

Control. Control is the process by which comparisons are made between the plan and the performance either during or after execution. Control relies on effective, complete planning and accurate, quantitative observation. It is the process of comparing these two operations.

In addition, it will be found necessary to have certain "do's" and "don'ts" clearly defined for the human beings who are going to use the structure we call an organization to obtain the desired ends of the business and the desired personal ends of the people employed in the business. These "do's" and "don'ts" are called policies, rules, and regulations.

Policies. Policies are broad directions of an authoritative nature laid down for the purpose of enabling all administrative and managerial decisions of the business to be properly determined and adequately carried out in the successful attainment of the goal or goals for which the business was organized.

Rules. Rules are standards or guides for performing specific operations or limiting the activities of people.

Regulations. Regulations are rules that are concerned with methods of activity or performance. Both rules and regulations are derived from the broader policies of a business.

The effective handling of an organization structure with its human participants calls for the exercise of the most important quality of supervision—that of leadership.

Leader and Leadership Defined. Leadership is a peculiar thing. A leader is a person who goes forth to guide or show the way: He precedes and directs. A supervisor, therefore, must show the way to the people he directs in order to be a leader. It might be interesting to know that leadership—the word "leader" or the word "lead"—has a very ancient meaning and comes from an Anglo-Saxon word that signifies "carrying the load." The leader carries the load. By this means he is able to attract, to direct, or to motivate, by his influence, the people under his control.

It is plain to see from the above that a supervisor must have a definite method or system of doing business because if he would carry the full load, instead of placing a load upon the shoulders of each individual under his jurisdiction, he would not only fail to supervise but would damage himself in the process. For this reason, supervision, when successful in delegating the necessary authority, operates on a rather interesting principle—sometimes known as the "exception principle."

Exception Principle. The exception principle is very simple. If a supervisor handles only the problems that are outside the scope of the authority he has delegated to others, he then handles problems within the scope of the residue of authority he has kept for himself. These problems are the exception rather than the rule for those who have a portion of the original supervisory authority. When this "exception principle" is adhered to, persons operating with delegated authority feel that they have more freedom of action and usually will be very much more willing fully to accept their responsibilities and discharge their duties. This fact explains why the "exception rule" is such a successful supervisory rule. Organizations where the "exception rule" is not used intelligently are usually in trouble.

Records as Supervisory and Control Tools. In the process of assisting the flow of authority, it is sometimes necessary to rely on written records instead of attempting to keep a multitude of details in one's head. For this purpose various forms and records have been established. However, these are merely supervisory and control tools and should be used as such and not as ends in themselves.

Results of Failure to Define Responsibility. Since responsibility is the state of being accountable to higher authority for certain acts or performance, it is necessary that such responsibility be clearly defined. Responsibility, poorly defined and hazy in the minds of the people concerned, is apt to create situations where people have been held accountable for acts of others over whom they have no control. When this is true, we have supervision, if it is held accountable for such acts, frustrated and out of sorts. It is necessary, therefore, that responsibility be very clearly defined. Once accepted by a person, that person should be held fully accountable until he is formally relieved of responsibility. Many industrial difficulties today are due primarily to (see Figs. 2-5 and 2-6)

1. The failure to recognize the fact that responsibilities are not clearly defined
2. The failure of people to accept their responsibilities fully in connection with the authority vested in them
3. People being held responsible without the authority or power to get results

Coordination. Coordination is the act of synchronizing various functions and duties to obtain a desired result. It is easy to see that, if methods and efforts are not synchronized, people act at cross-purposes with each other and desired goals cannot be reached. To prevent such failures of methods and to ensure that all efforts shall be in the same direction, we speak of coordinating these efforts or methods; *e.g.*, the process of delegation of authority, or delineation of duty in an organization, is a coordinating act.

Examples and Diagrams of Delegation of Authority and Creation of Responsibility. Authority was defined as power over people. It is finite in nature. Its delegation can be well illustrated by an example and by Figs. 2-3 and 2-4.

EXAMPLE: If the owners of concern A, which has 100 employees and 10 supervisors, wish to make $1,000,000 worth of product, the manager of the firm is vested with the power to spend this money in the performance of the necessary operations which convert this $1,000,000 into $1,000,000 worth of product. The manager delegates the necessary authority or power to each of his 10 subordinates to do the job effectively, retaining enough authority to supervise and control the operation. However, the manager is still fully responsible to the owners for the $1,000,000. Let us assume that he delegates to each of his subordinates $90,000. They accept the authority and become responsible for its use. They then proceed with the necessary tools, equipment, labor, and material, each to do his function in the manufacture of the finished product. It is interesting to note that, in this very simple example of manufacture of $1,000,000 worth of product, $1,900,000 worth of responsibility was created if each supervisor fully accepted his responsibility. This $1,900,000 worth of responsibility will be discharged fully only when each person has fully and successfully discharged his component responsibility, and not before (see Figs. 2-5 and 2-6).

Nature of Industrial Authority. Since each supervisor has power over men, methods, materials, and money limited in amount and kind, he must not mistake the strength of his power or its type. He is empowered to use this authority as effectively, justly, and conscientiously as he knows how in the prosecution of the business. By no stretch of the imagination is he empowered to arouse emotionally or frustrate people in the exercise of this power.

Abuse of Authority. When industrial supervision uses industrial authority in directions other than those in which it should be rightfully used, *viz.*, to get results through people without disturbing them or causing them to give more than can justly be expected from human beings for the compensation received by them, the effects of such abuse of authority are invariably bad for the individual, the supervisor, and the business. Conflicts, frustrations, demeaning attitudes, humiliation, and retaliation are potentially or actually present in employees where supervisors have incorrectly and unjustly abused their authority. Supervisors should never use their authority in a way that causes employees under their control to have such feelings aroused because employees with these feelings and attitudes are invariably less effective in the performance of their work.

The ineffective and unjust use of power denies the fundamental rights of the individual and defeats the aims of a business.

Functionalization. It is necessary to divide large groups into smaller functional groups to use most effectively the single or, at the most, the relatively few skills possessed by each person. The efforts of these groups of people must be directed by others—called supervisors—because few people are capable of performing every act in any business today. The operation that divides the structure of a business into component parts, with the units of each part having specific relationships to each other, is called the act of "functionalizing." The organization is the sum total of all these small functional segments properly related to each other.

Line Organization. In order most effectively to examine these segregated functions, assume a one-man business. John Doe, the owner, must procure raw material, machinery, and a space in which to work; he must manufacture his product, store it, and sell it, granting credit or depositing the cash in the bank. He continuously repeats this cycle of operations. Assume that John Doe's business grows to the point where he feels it necessary to add one or more other persons. He has the option of looking for another person like himself, who will perform every one of the duties he has been performing, or he has the option of looking for a person who can perform one or more of these duties. John Doe knows that it will be much more difficult to obtain a person with capabilities similar to his than it would be to take a person who can be trained to do one of these duties. John Doe finally decides to employ a person who does the manufacturing operation. As the business grows it becomes necessary to employ a number of such people to manufacture the product. It also becomes necessary for John Doe to employ another person to help sell the product. John Doe is so busy now that he finds it necessary to add a bookkeeper and a stenographer. In all this process of growth, the owner has exercised authority. The authority emanates from him and proceeds down the line to those people making his product and to the salesmen selling it. There is a clearly defined line of authority from John Doe, the owner. This is a typical example of a business operating on a "line" or "line-of-authority" basis. As this business grows, the owner would find it exceedingly burdensome, and beyond even the scope of his varied abilities, to take care of all details. He eventually would have to employ a supervisor who would look after the manufacturing operations. This supervisor would be a "line" supervisor, being in the direct line of authority to manufacture the product. John Doe would also employ a sales supervisor. This supervisor would be a "line" supervisor because his efforts are needed to distribute the goods.

Line-and-Staff Organization. Now assume that competition overtakes John Doe and that he must modify or improve his product. It becomes necessary to employ the services of experts who would work not in the line of authority, but auxiliary to it. These experts would advise the "line" supervision of the changes necessary to meet the competition. These specialists might be engineers, advertising men, packaging experts, etc. They are called "staff men." It is easy to see that, should they increase in numbers, a "staff" organization would develop. John Doe's organization has changed from a "straight-line" organization to a "line-and-staff" organization.

Most businesses today are line and staff in their organizational concept, with the amount of authority delegated to the staff functions varying within each organization. The line-and-staff organization is much more flexible than the straight-line organization defined above. There is a greater possibility of less effective direction in a line-and-staff organization than there is in a straight-line organization.

Taylor Functional Management. The line-and-staff organization is an outgrowth of the activities and research of Frederick Taylor, who was an exponent of fully functionalized organization. Taylor's concept of an organization was one where an employee had a supervisor for each function he was required to perform instead of a single "boss." Taylor's functional management finally reached the point where a man had eight people telling him

What to do
How to do it
Where to do it
And when!

Obviously, while this work of Taylor's contained the germ of a brilliant idea now used in industry as line-and-staff organization, it was unworkable because of the difficulty experienced in trying to get work done by the use of such an organization structure. People had too many bosses to work well and effectively.

Committee Management. A method of management sometimes used, but which has never shown any great promise, is that of "committee" management. Committee management is usually used where people are unwilling to delegate to any one person the necessary and requisite power to perform. By splitting this authority up and placing it in the hands of members of a committee, management is much slower and usually more dilatory than the line or line-and-staff management.

Recapitulation of Supervisor's Duties

1. The Supervisor Is an Interpreter of Basic Company Policies. It was brought out that policies add up to a system of regulative measures which are necessary for the proper conduct, direction, and progress of a business. Policies are usually broad in their scope and subject to a great deal of interpretation of meaning. The supervisor, being a person directly in charge of others, of necessity must be the one who interprets, clarifies, or makes detailed decisions (when within the scope of his authority) based on the general policy rules of his company.

It frequently happens that people otherwise skilled in the art or craft for which they are employed by the company do not have a ready command or comprehension of written policy rules. These must be explained and interpreted in a patient and friendly way to such employees.

2. The Supervisor Enforces Company Rules and Regulations. Specific rules and regulations are the outcome in some cases of policy interpretation in detail. These rules and regulations are usually a series of "do's" and "don'ts" which it is necessary for all employees to observe for the welfare, safety, well-being, and effectiveness of all employees. Part of the supervisor's duties is to see that these "do's" and "don'ts" are complied with.

Some of these rules and regulations in business involve the life or safety of employees and must be rigidly enforced. This enforcing process is called the supervisor's use of discipline.

3. The Supervisor Is a Trainer and Teacher. The supervisor finds it necessary to train the people under his control in order that they may effectively absorb the company's "know-how."

Estimates were made by people who had command of the facts that show that in the lower supervisory groups of assistant foreman, foreman, and chief foreman, training and teaching constituted 50 per cent or more of the supervisor's job, especially during the Second World War.

Many supervisors do not understand the principles of training or of learning. It is worth while to state them briefly.

What Training and Teaching are NOT:

1. Telling a man what to do is *not* teaching.
2. Showing a man what to do is *not* teaching.
3. Making a man do a job without either telling him or showing him is *not* teaching.

What Training and Teaching ARE: Teaching is a process that involves the following steps:

1. Tell a man what to do.
2. Tell him how to do it.
3. Tell him why he is doing it.
4. Show the man what to do.
5. Show the man how to do it.
6. Show the man why he is doing it.
7. Make the man tell what he is to do.
8. Make the man tell how he is to do it.
9. Make the man tell why he is doing it.
10. Have the man do the job.
11. Correct the man in a friendly way where he has performed erroneously until
12. The man is able to do the job perfectly, even though he does it very slowly and awkwardly.
13. Have the man repeat the performance of the job perfectly until he has by a sufficient number of repetitions acquired the necessary skill.
14. Check and review to make sure that all the above steps have been fully and successfully carried out.

The Learning Process. This procedure shows that there are two people involved in the teaching process—the teacher and the student. Obviously the student does not go through the teaching process but goes through another process called the "learning process."

A fundamental rule of the learning process is this: "*No one learns without doing.*"

Examination of this rule shows why practically nothing is learned when you tell a man; very little is learned when you show a man; and it is not until you allow the man to learn by a number of repeated efforts that you get any learning. For this reason, it can be seen that, while all the *above* steps in the teaching process are important, steps 10 to 13 are of paramount importance. It should be remembered that a supervisor who is a good teacher usually has well-qualified, highly skilled, and enthusiastic people under his jurisdiction, and both the supervisor and the company profit by his teaching.

4. The Supervisor Is an Inspector. The supervisor inspects the performance of the people under his jurisdiction.

This duty should not be confused with the formal process of inspection. Rather this duty is one of general oversight in order that the supervisor *may* keep himself fully acquainted with the activities of the employees under his control.

5. The Supervisor Is a Disciplinarian. This was taken up under 2. A more specific statement of the supervisor's role as a disciplinarian is necessary. The supervisor uses disciplinary force fairly and effectively—and only when necessary. *Discipline* is the process of subjecting people to control, training, or education. It is easy to see from the above that discipline does not have to be either harsh or unjust but should be fair, impartial, and moderate in determination and application.

6. The Supervisor Is an Arbitrator. The supervisor handles grievances that occur among the employees under his control and arbitrates the disputes between personnel under his jurisdiction. In some cases he also referees the settlement of differences between men under his and other supervisors' jurisdictions.

The Supervisor Handles Grievances. The handling of grievances is a very important duty of a supervisor. In the process the supervisor must be an open-minded listener until he has obtained all the facts.

There are three kinds of grievances:

a. Frequently employees who are improperly trained or instructed will have grievances due to misunderstanding. Patient and friendly explanation will usually be sufficient to eliminate grievances of this nature.

b. Impatient "brush-off" methods of handling this type of grievance will cause it to change into another, more serious, type of grievance—one where the employee's feelings are deeply involved. Grievances of this nature create a class of employees who are called "problem children." Such employees are usually disappointed, disgruntled, poorly trained, improperly indoctrinated people, with either resentful or fearful attitudes toward their supervision and toward the company for which they work. It is the supervisor's undivided responsibility to keep the number of such employees at a minimum. This can be done if a supervisor understands the fact that the behavior and speech of all supervisors are of paramount importance in the handling of every personnel situation. The supervisor must realize that employees are other human beings like himself, with cares, worries, and responsibilities similar to those which he possesses.

c. A third class of grievances stems from troubles, worries, or cares of a personal or domestic nature, which every employee has confronting him at some time or other. Worries and cares of this nature are not left at the time clock, at the gate, or taken off with the employee's coat when he goes to work. They are carried around inside him all the time he is present on the job. Frequently the supervisor can do little about this type of grievance, except to be a sympathetic and friendly listener, allowing the employee to "get it off his chest." Sometimes this affords complete relief for the employee. Other times specialized industrial agencies, other than the supervisor, may have to be employed in straightening matters out.

The supervisor should understand that people under his jurisdiction are entitled to their feelings but are circumscribed in their behavior. For example, it is better to say, "I know you feel angry, Joe, but I have full confidence in the way you will handle this matter," rather than to say, "Now don't get angry, Joe, you know that isn't the right thing to do." Employees will have more regard for supervision that shows it understands that people are entitled to their feelings. Such supervision confines its control to the employee's behavior.

A fundamental rule in the handling of all grievances by supervision is as follows: Employees should not be subjected to, or remain in, continuously frustrating situations. If the situation is caused by the business policy or procedure, such policies or procedures should be changed, if possible. If it is necessary for an employee to remain in a frustrating situation, he should fully comprehend why and be given free choice as to whether or not he wishes to continue in the situation. The basic attitude will prevent grievances due to frustration from becoming a major problem.

The Supervisor as an Arbitrator. In the handling of disputes between personnel under his jurisdiction and in the settling of differences between men under his and other supervisors' jurisdictions, a supervisor must again be a good listener and get all the facts. He must realize that "word battles" between two employees are an indication of a feeling of anger between these two employees. It is not sufficient for the supervisor to give them both a tongue lashing and make them shake hands and make up—rather the supervisor should tell both parties that he realizes they are both angry. Furthermore, he should state that they are entitled to feel angry and should then let them talk the situation out until both parties have ventilated a sufficient amount of anger to settle their differences on a logical and amicable basis. If this is done, there will be no stale emotion overhanging employees under a supervisor's jurisdiction.

In the settlement of disputes between personnel in two sections, the same strategy and tactics should be employed by both supervisors. These supervisors should agree on the methods used. Remember: Most fights have to be fought out to a finish. If this is not allowed, feelings will smoulder inside an employee and become the gathering point for other resentments, which are usually turned against a supervisor who fails to allow proper ventilation of these feelings.

7. The Supervisor Is a Planner. The supervisor plans how work, for which he is responsible, shall be done.

If the supervisor is a member of a large organization, he has the aid of a good many "staff" men. If the supervisor is in a small organization, he may have the problem of doing a great deal of planning in order to accomplish effectively what he is responsible for doing.

8. The Supervisor Is an Executive. The supervisor carries out the company's plans and basic instructions from higher management. He executes, in detail, both the company's and his plans for effective work.

9. The Supervisor Is the Friend of All Employees under His Control. The supervisor is usually the counselor and father confessor for these same employees. He sees to it that their side is well, clearly, honestly, and adequately represented to management and that management is well, clearly, honestly, competently, and fully represented to the employees under his jurisdiction.

If the supervisor feels that he knows his employees a whole lot better than the employees know themselves and, therefore, attempts to tell his employees how to live and conduct themselves both on and off the job—if the supervisor does nothing but tell the employees of their shortcomings and never recognizes their good performances; if the supervisor is arrogant and superior—rest assured that he will neither be a friend to his employees nor have a friend among them.

The supervisor who is honest, fair, just, temperate in his dealings with his people, and loyal both to his company and to the people working for him is a better supervisor than one who is arrogant, unfair, irresponsible, and always ready to shift the blame.

10. The Supervisor Is a Salesman of His Company to the Employees under His Jurisdiction. It behooves every supervisor to speak well of his company to the employees under his control. His example will undoubtedly be imitated, and his actions will be copied. In the process of selling the company to the employees, it is never necessary or wise to be either untruthful or insincere. The company should be sold to its employees on truth alone.

It is necessary for a supervisor always to realize that in a good many cases he represents the company to the people under his jurisdiction. His attitude, conduct, and demeanor are, therefore, the attitude, conduct, and demeanor of the company as far as the employee is concerned. Frequently, the management of a company is astounded to learn that the unfriendly and antagonistic attitudes of employees were created by supervision, which neglected or failed to behave as the management of the company wished it to behave.

11. The Supervisor Is a Counselor. The best counsel that a supervisor can give an employee is given by the supervisor being a good listener. If, in a 20-min interview with a supervisor, where an employee is seeking counsel, the supervisor talks for more than 4 min, he is *talking too much.* No supervisor should counsel any employee on how to govern his life—that is the prerogative of the individual. No individual should be told

What to do
Where or how he should do it

when such advice involves the employee's spare time. He should never be told

What to buy
Or whom to marry
Or how to spend his money

These are individual rights and should be respected as such. In these areas, involving the personal rights of an individual, a supervisor has no authority or right to interfere.

Improper counseling sometimes elevates the supervisor, *in his own mind,* to a position where he is superior to the average run of people. When this occurs, the supervisor has lost his effectiveness. He becomes a hazard to the business or industry with which he is connected.

12. The Supervisor Is a Student. Supervision is too prone to think that it has no more learning to do. Some people are so constituted that they will instinctively find better ways to do work. Some mental and a great many manual operations are improved by employees possessing this kind of instinctive coordinating skill. The supervisor should be open minded—looking, listening, and learning from the employees under him. It is usually true that a supervisor who is a good teacher is also a good student and willing to be shown—willing to learn.

A great deal of assistance can be rendered employees and supervisors by the use of some excellent short training courses such as

Job-instruction Training
Job-relations Training
Job-management Training

These courses were codified and published for wartime use. The material has been adapted for peacetime training of supervisory personnel. Its study by supervision will pay excellent dividends.

13. The Supervisor Is a Human Being. The only difference between supervisors and people under their control is the power or authority that is vested in the supervisor. The supervisor is the same kind of individual as those working for him.

If the supervisor fails to realize that human beings are mental, physical, and emotional creatures and that he is such a being, poor human relations will exist in the business or in the component of the business under the supervisor's direction.

If the supervisor has a proper realization of his make-up and the make-up of the people under his direction—if the supervisor conveys this understanding to those under him and insists upon the understanding of these fundamentals by those above him—he will be a successful supervisor.

TOOLS OF SUPERVISION

It is not the intent in this subsection to do more than describe and indicate the fundamental ideas behind the following supervisory tools:

1. Office methods
2. Cost-control methods
3. Quality-control methods

The literature is voluminous in these fields. It should be consulted when solving specific problems involving these supervisory tools. However, the strategic principles involved in handling such problems should be clearly understood.

Office Methods

Office methods, for a supervisor, are not ends in themselves but means to an end. They enable a supervisor to discharge his duties effectively in a systematic way. Office methods have as their foundation

1. Systems
2. Forms
3. Records
4. Procedures

System. Basically, a system is a combination of items in an orderly arrangement, according to some common or accepted rule, to make a coherent whole or unit.

Form. A form is an orderly, standardized arrangement of the area of a paper sheet. It is used to record facts systematically and precisely. When facts are recorded on a form, they can be sent from one place, or person, to another. When used this way, a form is a fact-transmitting vehicle. Forms are usually printed but do not necessarily have to be.

Record. The writing of authentic factual data accounting for, or otherwise explaining, the transactions involved in doing business is the act of recording. The resulting compilation of facts on paper is called a "record." It should be noted that recording in business is usually performed on forms, but this is not always true.

What a Supervisor Should Expect from a Record. A supervisor wishes to know what the results of the controlled actions of the people for whom he is responsible are. Therefore, records, as supervisory tools, must show a supervisor *how, when, where, why, and how well* he has performed his duties and discharged his responsibilities.

Procedure. A procedure is a detailed orderly method of passing from one step or operation to the next succeeding step or operation in any transaction involving the conduct of a business. For convenience, procedures are sometimes written, but it is not necessary that they be so recorded.

When procedures are written, they are sometimes recorded on forms in order that standardized systematic methods of recording them be used. This again is a matter of convenience which increases the effectiveness in the use of the procedure. However, it is not necessary that procedures be recorded in this manner.

Symbol. In the process of recording, and in the use of the record thereafter, it is usually found convenient and timesaving to use symbols instead of writing voluminous and wordy descriptions of the items being recorded. A symbol, therefore, is a mark, sign, character, or groups of characters representing something else. It is used as an abbreviation for that which it represents. These abbreviations may and do represent ideas, items, people, activities, etc. They may be composed of alphabetical, numerical, geometrical, pictorial, or meaningless components, or a combination of these components when representing that for which they stand.

Classification. The act of classifying is that of arranging and segregating persons, items, or ideas having similar characteristics of rank, order, time, dimension, or principle into orderly related groups.

Reason for Classification of Data. Data should be classified to save time and simplify their use.

It is essential to determine how the recording of items (called "data") can best be performed. A little thought will usually show the basis of similarity which will cause items to be grouped together naturally or normally. For example, some items will group on a geographical or location basis. Other items will group on a time basis, while still others will group on a basis of similar characteristics, such as materials of the same composition, parts of the same shape, assemblies used for the same purpose, etc. Such sequences or groups are given the more familiar names of *pay rolls, buildings, departments, job numbers, projects, lot numbers, parts, etc.* Classifying data into such groups enables a supervisor to make his activity more effective.

Method of Classifying Data. All the above looks rather formidable and complicated. The operation of classifying can be simplified by a clear realization on the part of the supervisor as to the use, as a supervisory tool, to which he wishes to put the record. All records must conform to two very simple principles. The consistent use of these principles will greatly simplify the act of classification, the art of recording, and the use of the record.

The record must tell the supervisor a story. The story can be that of a series of happenings one after the other in time, or it can be a story of a series of related happenings, items, or characteristics which have occurred or are present at a specific time.

Journal Type of Record. If items are recorded one after the other in a time sequence, it is a journal type of record.

Ledger Type of Record. If items possessing similar characteristics are all grouped together to make clear a situation as it exists *at a particular time*, it is a ledger type of record.

METHOD OF DERIVING A LEDGER-TYPE RECORD. It is clear that, if a journal type of record is made, it is easy to extract from it items possessing similar characteristics. If this process of extraction is performed at stated intervals and a new record is made of all the items possessing similar characteristics, a new record will be derived or made from the original journal type of record. This new record is the ledger type and gives a picture of the situation concerning the items involved at a particular time. If the two simple principles summarized below are understood,

1. Record the data in some journal sequence.
2. Derive ledger-type records by extraction.

If reasonable common sense is used in classifying items, records can and will tell a time-flow story if they are of the journal type.

If records are of the ledger type, they tell a story of the situation at a particular time.

EXAMPLE: Take the problem of recording a series of jobs which can be called making up "job orders." As time goes on and business is transacted, it becomes necessary to do one job after the other. Each job is written up on a job order as the necessity for the performance of the job comes to pass. Job orders, therefore, differ in age (or time).

It would be easy to take a sheet of paper, calling it the job-order journal, and, by serially numbering each job, set down in job-order-number sequence a record of all the job orders issued. This job-order journal becomes a running record in time of all jobs involved.

Now, assume that these jobs are done by different departments. By going through the job-order-journal record and extracting all jobs pertaining to departments A, B, C, etc., setting each one of these extractions up on a sheet devoted to the specific department, a ledgerized record is obtained from the original journal. However, in this case this ledgerizing or classifying segregates *only* by departments.

A further examination of these new records will show that each one is a *new departmental job journal*. If, within department A, it is desired to segregate types of jobs by machine, the ledgerizing or classifying process can again be used, and by the process of extraction, a new derived record will be obtained. It is interesting to note that the ledgerizing process can and may create new journalized types of records.

SUMMARY OF STEPS IN DERIVING LEDGER-TYPE RECORDS.

1. Record in journal sequence.
2. Classify.
3. Extract.
4. Rerecord the new data, using the classifying characteristic on which the extraction was made.
5. Repeat steps 2, 3, and 4 if necessary.

Failure on the part of the person constructing records clearly to understand and perform these fundamental operations is at the bottom of most record trouble. Records that are not constructed in accordance with these principles are usually ineffective when interested parties wish to use them.

The Dynamics of Recording. In addition to the strategy of classifying described above, it is necessary to understand clearly that records, and the symbols contained thereon, must stand in a definite relationship to the items they represent. Such records must indicate all (or at least the essential) activities concerning the recorded items. In any operation or series of operations, materials that eventually comprise components of the product must have a certain *flow* velocity. The principle of industrial flow, of which recorded data are the symbol, will now be described.

1. *The Flow of Authority.* Authority or power to produce results must flow through the necessary recognized channels in order that the results may be obtained. This is amplified under Elements of Supervision.

2. *The Flow of Decision.* In the exercise of industrial authority, it becomes necessary to decide

1. What to do
2. Where to do it
3. How it is to be done
4. When it is to be done
5. Who is to do it
6. In what quantities product is to be made

The decision involving the above items will pass from one person to another when these persons are involved in the various operations. These decisions are the visible and audible exercise of industrial authority. The process of passing these decisions is called the "flow of authority."

3. *The Flow of Material.* Material, as it is operated on, will flow in channels corresponding to those channels defined by the flow of decision.

4. *The Flow of Paper.* Assume that, as material flows, a paper symbol flows along a path corresponding to, and in some cases identical with, the path of material flow. This symbol, in the shape of a paper record, can be used to acquaint those who are responsible with what is happening to the material without direct examination of the material. The movement of this paper symbol or record is called the "flow of paper."

5. *The Flow of Recorded Data.* If the symbol or record described above carries the recorded data in sufficient detail and with adequate clarity, it will perform two most useful functions—that of assisting in the control of the flow of material and that of controlling the operations performed on this material during the process of flow.

Coordination of Flow of Records—How Many Records to Keep, How Detailed Should They Be. From the above, a logical conclusion can be drawn. Records and data must flow in synchronism with the flow of

1. Authority
2. Decision
3. Material
4. Personnel

A further conclusion is that there should be no more records than are necessary to control adequately and effectively the flow of these items. Furthermore, records should have no more and no less data than are necessary for the regulation and control of this same flow of authority, decision, material, and personnel.

When records are set up on the basis described above, with due regard for the fundamentals of flow, they become very effective supervisory tools. With them, supervisors can achieve the desired ends of supervision, *viz.*, making the necessary product or rendering the necessary service, by effectively controlling the people and material under their jurisdiction and completely and adequately discharging their responsibilities.

Records that do not flow correctly, as described above, rapidly lose their effectiveness.

Records which are extreme in detail, redundant in data, and which stagnate are the basis for the creation of excessive "red tape."

Cost-control Methods

Cost. A cost is a price paid. In a business, costs are

1. The prices paid during the process of converting the component materials to a finished product

2. The expenses incurred in getting this finished product into hands of consumers

Types of Costs. There are five types of costs incurred by business in the process of manufacturing goods or rendering service:

1. Capital Cost. Capital cost is the price paid for the use of the capital and goods, such as buildings, machinery, and equipment.
2. Labor Cost. Labor cost is the price paid to all people directly or indirectly responsible for the manufacture of goods or for the rendering of service to those directly or indirectly responsible for the manufacture of the goods.
3. Material Cost. Material cost is the price paid for all materials that enter into the manufacturing process, whether or not they appear in the final product.
4. Overhead Cost. Overhead cost is the expenses which, although necessary for producing the manufactured goods, cannot be charged directly to the product and which must, therefore, be allocated or distributed.
5. Sales Cost. Sales cost is the price paid for the distribution of the product and the placing of it in the hands of the consumer.

Cost Control. Cost control is the regulation of the component operations of a business in order that the prices paid by the business for the various operations or services involved in the manufacture of the product and its distribution be kept to a minimum. It can be seen that cost control involves

1. Decision
2. Guidance and direction
3. Measurement of performance
4. Effective action

Supervision's Authority and Responsibility with Respect to Cost Control. Line supervision's authority, in lower echelons, and responsibility with regard to cost control are usually limited to authority over and responsibility for

1. Labor
2. Material
3. Operations performed by labor on material

Prime Cost. The costs of labor and material, when taken together, are sometimes called the "prime cost" of manufacture. Lower line supervision is currently said to be responsible for prime cost.

Cost Records. Ample records of the various elements entering into the cost of labor, material, and the operations performed by labor on material must be kept in order that supervision exercise adequate control over the manufacturing process. Such records, called "cost records," also have an added use by becoming storehouses of performance information when new jobs or operations are in the planning stage. Such records show the difference in worth between various employees and also show such things as the amounts of materials used and the amounts of time used in individual or groups of operations.

Cost control endeavors to keep waste material and ineffective use of labor at a minimum. One specific procedure by which cost- and production-control records minimize waste is called "quality control."

By using quality-control records, supervision making production and cost-control decisions and acting on these decisions has at its command powerful new instruments for cost reduction.

Quality-control Methods

For many years, industrial operations were governed by the process of inspection. If an operation was performed and, by some measuring means, the material on which the operation was performed was measured, the measurement could and would become an index of the acceptability of the product and the operation. With the increase in complexity of manufacturing operations, the process of making sure that the product conformed to the necessary detailed specifications during each operation and met the requirements demanded of satisfactory finished product became a very expensive one when methods that involved the inspection of every part, piece, subassembly, or batch were used.

In some industries it was thought necessary for such inspection operations to be performed on every part or batch. Because of the staggering cost of such inspection, studies were made to determine the fundamental principles underlying the control of industrial operations.

The important result of such studies was the creation of a new concept of control, called "quality control," and new records used for control, called "quality-control charts."

Inspection. Inspection is the act of subjecting to careful, quantitative scrutiny parts or components of parts, batches of product, or even the finished product itself. In this scrutiny the process of measurement must be used and comparisons with predetermined standards made. If the measurement, after being compared with the standard, lies within prescribed limits, the part, component of the part, operation, or other item under inspection is said to be within the tolerance allowed and passes inspection as a satisfactory or acceptable unit.

By implication, it is seen that inspection might be construed to be an operation that would have to be performed on every part or batch going through the operation under inspection.

A further implication lies in the assumption that there is nothing further to be done should the inspection be satisfactory and all inspected parts lie within the prescribed tolerance.

If, under this type of procedure, the inspector finds parts or material that do not conform to the standards, these items become "rejects" or "defectives." However, until this situation comes to pass, nothing of a preventive nature is done, usually, to avert such industrial waste. It can be seen that even 100 per cent inspection will not ensure the production of good material or prevent the production of defective material.

Quality Control. Quality control is defined as a philosophy that aims at using mathematical, statistical, and inspection techniques to control the characteristics, attributes, dimensions, or physical or mechanical properties of materials within definite, known limits. This operation of control is performed on such a basis that preventive techniques can be used in order to

1. Lessen the cost of inspection to the lowest safe and economical amount
2. Make the maximum amount of acceptable product of the desired standard
3. Make the minimum amount of rejected product by preventing defects which cause the product characteristics to fall outside the tolerance limits

Foundation on Which Quality-control Practice Is Based. Quality control is based on a mathematical and physical foundation. This foundation can be illustrated by the following example:

> If a large number of similar objects be examined and any characteristic of these objects be measured, it will be found that these measurements of the same characteristic will differ among themselves by small amounts.
>
> In other words, if the diameters of 100 small cylinders, which were turned and cut off in an automatic screw machine, were measured with micrometer calipers and the measurements tabulated, differences between individual measurements would be found. Some measurements would occur more frequently than others. If a "tick" sheet of the dispersion of these measurements were made, it would appear similar to that shown in Fig 2-7.

Variation. The extent to which these measurement readings differ, scatter, or disperse is called the "variation" in the measurement.

Sources of Variation. 1. Some of this variation may be due to the inherent characteristics of the machine itself or to variation in the characteristics of the machine.

2. Some of the variation may be due to the activities of operator of the machine.

3. Some variation may be due to defective measurements by the inspector.

4. Other variation may be due to causes outside those named above.

The causes of variation under 2, 3, and 4 are called "assignable causes" and can usually be tracked down. When these causes are isolated, correction in operation or process can be made. By making such corrections, variation due to assignable cause is eliminated from the operation or process.

Types of Variations. There are two types of variation:

1. That which is *normal and inherent in the process, material, or machine* and to which *no assignable cause can be given*
2. That which is *abnormal and not inherent in the process* and for which *an assignable cause* may be *found*

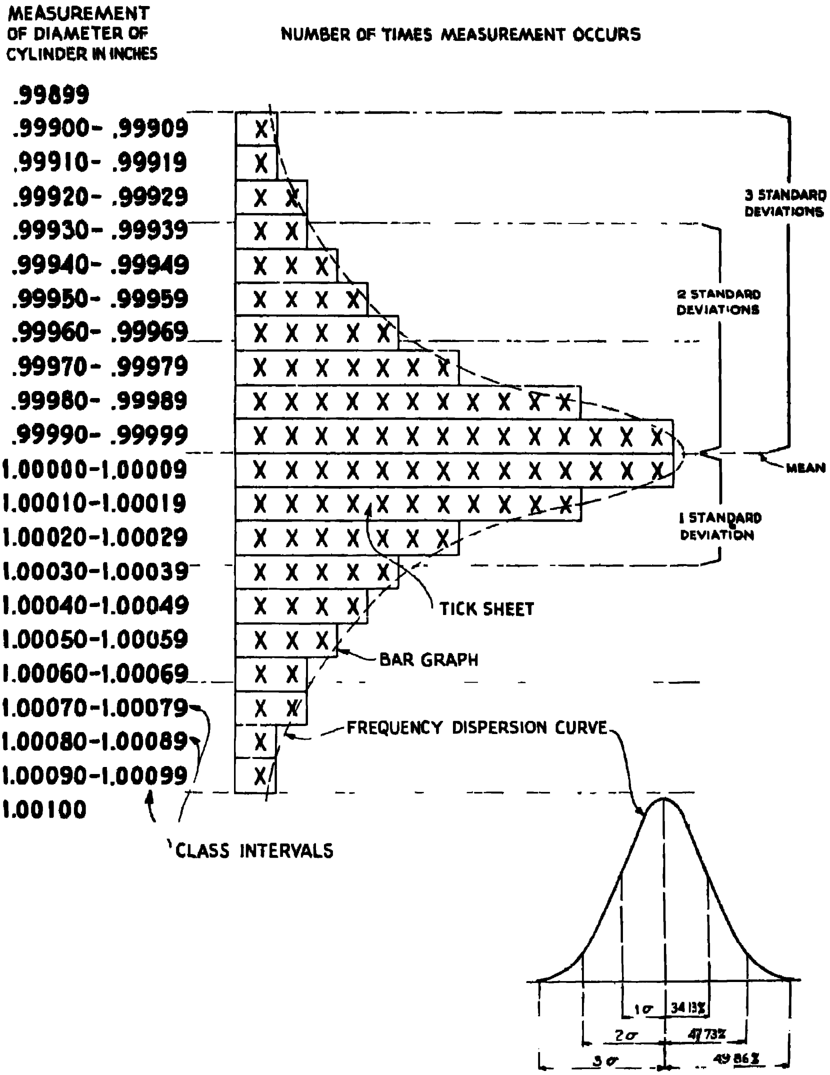

Fig. 2-7. Typical construction of "tick" sheet, bar graph, and frequency-dispersion curve.

Illustration of Sources of Variation and Their Detection. From an examination of the data that were made into a frequency-dispersion "tick" sheet in Fig. 2-7, it will be seen that all the measurements were within the prescribed tolerance. However, if these measurements are plotted in the time sequence in which

COLUMN 1 MEASURED DIAMETER IN THOUSANDTHS OF AN INCH		COLUMN 2 NUMBER OF READINGS IN EACH INTERVAL f	COLUMN 3 DEVIATIONS FROM AVERAGE VALUE $x - \bar{x}$	COLUMN 4 FREQUENCY X DEVIATION COL.2 X COL.3	COLUMN 5 FREQUENCY X DEVIATION SQUARED COL.3 X COL.3 X COL.2 σ

1.00070	1.00079	2	+ .00075	+ .00150	0000011250
1.00080	1.00089	1	+ .00085	+ .00085	0000007225
1.00090	1.00099"	1	+ .00095	+ .00095	0000009025
1.00100"					
SUM		100		0	0000132900

① IN COMPUTING THE DEVIATIONS FROM THE MEAN, ASSUME ALL READINGS IN THE INTERVAL TO BE AT THE MID POINT OF THE INTERVAL.

② THE SUM OF COLUMN 4 EQUALS ZERO

③ THE SUM OF COLUMN 5 DIVIDED BY 100 EQUALS THE SQUARE OF THE STANDARD DEVIATION

④ THE STANDARD DEVIATION $= \sqrt{\frac{.0000132900}{100}} = .000349$

⑤ THIS MEANS THAT 68 4% OF THE MEASUREMENTS WILL LIE WITHIN A TOLERANCE OF ONE STANDARD DEVIATION i.e

DIAM. = 1.000"± .00035"

⑥ THIS ALSO MEANS THAT 95 46% OF THE MEASUREMENTS WILL LIE WITHIN A TOLERANCE OF TWO STANDARD DEVIATIONS i.e.

DIAM. = 1000"± .00070"

⑦ THIS ALSO MEANS THAT 99.73% OF THE MEASUREMENTS WILL LIE WITHIN A TOLERANCE OF THREE STANDARD DEVIATIONS i e.

DIAM. = 1.000"± .001"

FIG. 2-8. Typical computation of standard deviation.

each one occurred, a chart resembling Fig. 2-9*D* would be obtained. It can be seen that there is a definite trend, as each new part is made, for the measured diameter to approach the upper tolerance limit. A probable assignable cause for this variation would be the dulling of the tool (see Fig. 2-9*D*).

From a preventive point of view, it would be desirable to make the change to a newly sharpened tool before this trend had reached the point where defective parts were made. If this were the only *assignable* cause for this particular operation, it would be necessary only to inspect a few pieces at stated intervals, plotting the results and watching the trend. This method of inspection would be far more economical and would produce products lying within the specified standards at as high or even a higher degree than full piece inspection. Furthermore, the preventive attitude, inculcated in operating personnel by the use of such a chart, would cause them to make tool changes before spoilage occurred.

Average. An average is the "mean" or middle point of a series of data. It has the symbol $\bar{X}$. If, in the example given above, all the readings of the measurement of the diameter be added together and this sum be divided by the number of readings, 1.000 in. will be obtained as the average value. It is important that this average value be examined and its reliability checked by determining its standard deviation (see Fig. 2-8).

Deviation of Individual Readings. If the difference between each reading and this average value be ascertained, this difference can be called the deviation of each observed value. It has the symbol $(X - \bar{X})$. It can be seen in the example that some of these deviations are positive and others are negative. If the deviations are added up, with due regard for signs, the sum would equal zero (see Fig. 2-7).

Standard Deviation. If, however, these deviations are squared, the squares can then be added together. If this sum is divided by the number of readings and the square root of this quotient is extracted, the result is a measurement called the "standard deviation." This standard deviation has the symbol σ and is called sigma. *The value of sigma does not equal zero* (see Fig. 2-8).

WHAT THE STANDARD DEVIATION MEANS. The standard deviation of an average tells how good the average is (see Fig. 2-8).

1. An amount of one standard deviation on each side of the average, or mean, will include 68.26 per cent of all readings composing the average.
2. An amount of two standard deviations on each side of the average, or mean, will include 95.46 per cent of all readings composing the average.
3. An amount of three standard deviations on each side of an average, or mean, will include 99.73 per cent of all readings composing the average.

Effect of Arbitrarily Tightening Tolerances. Going back to the original example involving the measurement of the diameter of the 100 small cylinders, assume that somebody decided to attempt to increase the quality of these cylinders by arbitrarily tightening the tolerances from plus or minus three standard deviations (see Fig. 2-9*A*), which represent the limits of variation inherent in the operation, to plus or minus two standard deviations.

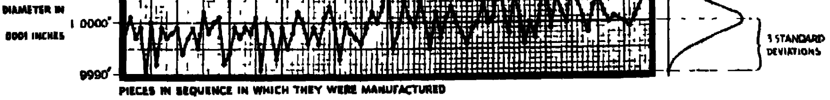

FIG. 2-9*A*. Quality-control chart—correct tolerancing of operations.

The new tolerances, positioned at the plus or minus two-sigma limits, are shown in Fig. 2-9*B*. These tolerance lines are now inside the lines of the three-sigma limits, and arbitrary spoilage now shows up.

Figure 2-9*C* shows a further arbitrary tightening of tolerances to the plus or minus one-sigma limits, with a consequent sharp increase in the number of rejected pieces.

It can be seen that, with the tolerances set too tight by arbitrary means, a needless amount of rejection will take place and that no amount of inspection will cure the variation which is inherent in the operation. This is a situation which can be corrected only by the improvement of the machinery or operations constituting the process or by changing the tolerance limits back to more realistic ones than those which were arbitrarily set. The records shown in Figs. 2-8, 2-9*A*, 2-9*B*, 2-9*C*, and 2-9*D* are called "quality-control" charts of the simplest kind. Such records enable supervision to control processes realistically. The intelligent use of these records will prevent the manufacture of defective material without recourse to 100 per cent inspection.

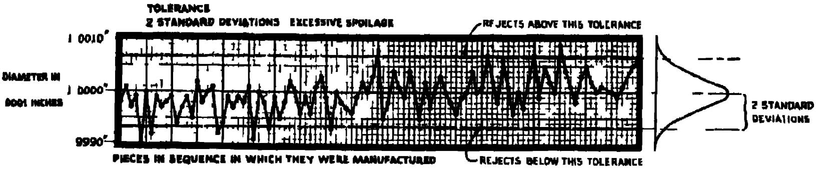

FIG. 2-9*B*. Quality-control chart—excessive spoilage due to tightening tolerances arbitrarily.

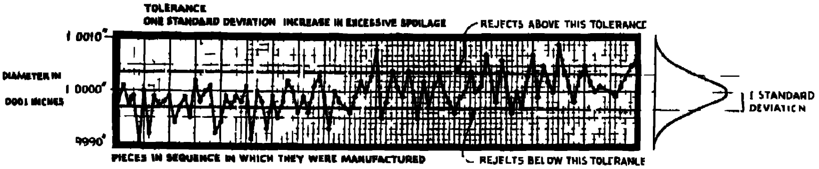

FIG. 2-9*C*. Quality-control chart—increase in spoilage by arbitrary increase in tightening of tolerances.

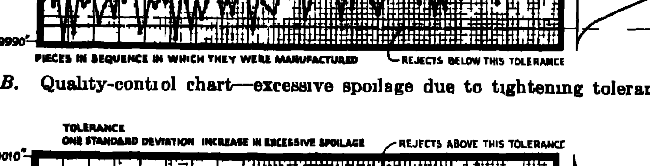

FIG. 2-9*D*. Quality-control chart—a trend of measurements due to probable assignable cause.

Mistakes Avoidable through Quality Control. The quality-control charts and quality-control philosophy enable supervision to avoid two very costly types of inspection mistakes. They are:

1. The process of looking for trouble when none exists and when the variation is the normal amount inherent in a process operation of material.
2. The failure to look for trouble, when it does exist, soon enough to prevent defective material or product being made or faulty operations being performed.

Quality-control Literature and Consultation. While the quality-control literature is scattered and highly technical, some acquaintance with this literature by supervision is extremely profitable. The advice and consultation of engineers versed in quality control or of statistical men connected with a supervisor's organization will help to clarify the more technical sections of this subject for line supervision. Consultation with these men is definitely recommended.

WORK SIMPLIFICATION*

BY MARVIN E. MUNDEL, PH.D.

Professor of Industrial Engineering, Purdue University, Lafayette, Ind.

Work simplification or motion study is used to analyze production and work methods so as to

1. Eliminate unnecessary steps
2. Arrange the necessary steps in the best order
3. Make each step as easy and economical as possible
4. Determine the easiest and most economical over-all pattern for the job
5. Place the method information in such a form as to facilitate its being carried into practice.

The development of a better way of doing the job, the development of a better method of production, and the development of an efficient method of doing new work are almost always the results of the application of a logical procedure consisting of the following steps:

1. Analysis of the details of the known method or methods of performing the work
2. Application of known general and specific principles of improvement
3. Formulation and detailing of the resulting suggested method of performing the work
4. Preliminary analysis of the suggested method of doing the work
5. Testing of the improved method by application and possible time measurement
6. Final application of the standard method

The main body of knowledge in work simplification consists of

1. Procedures for analyzing jobs into units possessing known characteristics
2. Check lists of desirable and undesirable features applicable to these analyses
3. Procedures for describing the new method prior to performance
4. Procedures for checking, prior to performance, the desirability of the new method
5. Procedures for setting down job methods in such a manner as to aid in training operators to follow the desired job method

Table 2-1. Possible Classes of Change through Motion Study

Class of change	Hand and body motions	Tools, workplace, and equipment	Process	Product	Raw material
1	New	Minor changes	Same	Same	Same
2	New	New (radical)	Same	Same	Same
3	New	New	New	Same	Same
4	New	New	New	Modified	Same
5	New	New	New	Modified	New

NOTE. The word "modified" appears in the product column to emphasize that this is only a modification rather than a different product for a different purpose Also in any row the item farthest to the right undergoing change indicates where the change must usually be initiated

The particular procedure used for analysis is a function of how far the analyst thinks desirable, or feels able, to carry the improvement Altogether, five classes of possible changes exist as shown in Table 2-1 Note that, as the complexity of change increases, more and more items are changed The higher the class of change, in most cases, the longer it takes to achieve, the more authority required, and the more people affected.

---

* This section is abstracted from M E Mundel, "Systematic Motion and Time Study," Prentice-Hall, Inc., New York, 1947 All rights are reserved by Prentice-Hall Inc

The class of change finally sought is the main factor that determines which group of analysis procedures the procedure used will be chosen from.

The class of change sought is a function of

1. How much volume is there, or expected, and how often does the job occur?
2. How long will the job exist?
3. How much time per unit is spent on the job?
4. How much time is available for working up the change?
5. How much equipment is already invested in the job?
6. How much analysis time will be required?
7. How much loss of production would occur during a change?
8. How much retraining would be required?
9. What is the possible saving by means of the improvement?
10. What is the position of the analyst in the organization?
11. What is the nature of the organization and the personalities involved?
12. Is the product production or consumer goods? Will the change affect marketing?

The importance of each factor will vary from case to case. Their particular order as given here does not indicate their necessary relative importance. The analyst must weigh and evaluate them for each situation.

For class 1 and class 2 changes the following work-simplification techniques emphasizing man analysis are used:

1. Process chart—man analysis
2. Operation charts
3. Man and machine charts
4. Multiman charts
5. Multiman and machine charts
6. Micromotion study
7. Stop-watch time study (This last is mainly used as a means of determining expected performance, although it may be used as an aid to methods improvement.)

For class 3, 4, and 5 changes a work-simplification technique emphasizing product analysis is used. The one commonly used is

8. Process chart—product analysis

DEFINITIONS

Process Charts—Product Analysis. Process charts—product analysis—are a graphic means of portraying the separable steps of the procedure involved in performing the necessary work required to modify a product from one stage of completion to another.

Process Charts—Man Analysis. Process charts—man analysis—are a graphic means of portraying the step-by-step procedure a person goes through in doing a job and are particularly useful when the job involves moving from place to place.

Operation Charts. Operation charts are a graphic means of portraying the work a person does when performing a job that takes place essentially at one location. The operation chart usually involves a breakdown into steps of the work performed by each of the body members engaged in the task. This usually means the right and left hands. Where the feet or eyes are important factors, they may also be charted

Man and Machine Charts. Man and machine charts are a graphic means of portraying the work a person does when working with a machine or machines when the work of the machine or machines is a controlling factor.

Multiman Charts. Multiman charts are a graphic means of portraying the work of a crew, with or without machines, when the work involves coordinate work of the crew and not work in sequence.

Micromotion Study. Micromotion study is a technique that involves the use of a motion-picture camera and a timing device for the analysis of man activity. Any of the above man-analysis techniques may be used for a graphic presentation of the data, or a simo chart may be used with time as a factor and the motions broken down into therbligs.

How the man-analysis technique is selected is indicated in Table 2-2.

Table 2-2. Selecting the Analysis Technique for Man Analysis

Job characteristics	Technique recommended	Equipment required	Notes
Person moves from place to place while accomplishing job	Process chart—man analysis	Paper and pencil. Watch is sometimes used but not necessary	Rapid analysis
Person does job at one place	Operation chart	Paper and pencil. Watch is sometimes used but not necessary.	Rapid analysis
Man operates one or more machines. Machine time is an important factor	Man and machine chart	Paper, pencil, and watch are desirable	Rapid analysis
Several men work coordinately as a crew without or with machine or machines	Multiman chart and multiman and machine chart	Paper, pencil, and watch are desirable	Rapid analysis
Any job of any type of sufficient volume and duration to afford analyst's time. First choice on long-run short-cycle operations or where detailed training material is required. Is not suitable for one-time, short-lived jobs	Micromotion study	Moving-picture camera, filming equipment, timing device, and projection equipment	Analysis takes some time but is less costly for detailed analysis and where much methods work is done

CONVENTIONS

Tables 2-3 through 2-7 give the conventions used on the various types of charts.

Table 2-3. Symbols for Process Charts—Product Analysis

Symbol	Name	Used to represent
◯	Operation	A modification of a product which takes place essentially at one location
○	Movement	A change in location of a product from one place to another, not changing the product's characteristics
▽	Controlled storage	Storage of a product under controls such that a requisition or receipting is needed to withdraw it
⛛	Temporary storage	The storage of a product under conditions such that it may be moved or withdrawn from storage without a requisition, *i.e.*, material banked on skids at a machine
□	Quantity inspection	The verification of the quantity of a product against a standard
◇	Quality inspection	The verification of the quality of a product against a standard

Table 2-4. Symbols for Process Chart—Man Analysis

Symbol	Name	Used to represent
◯	Operation	The doing of something at one place
○	Movement	Change in location moving from one place to another
▽	Delay	Idleness or time spent either waiting or moving If the movement was not part of the job could have been spent in waiting
□	Quantity determination	A special form of operation involving the person determining the quantity of an item present
◇	Inspection	A special form of operation involving the person comparing an attribute of a product with a standard

Table 2-5. Symbols Used on Operation Charts

Symbol	Name	In gross breakdown used to represent	In fine breakdown used to represent
◯	Suboperation	Body member doing something in one place such as placing assembling turning, bending etc	Body member doing something at one place, such as taking hold, lining up, assembling etc
○	Movement	Get (reach for take hold of, and move to change location except if lever—reach for and take hold only) or aside (same as get but for the purpose of disposing of an object)	A movement of a body member toward an object or changing the location of an object
⛛	Hold	Body member maintains an object in a fixed position	Same as in gross breakdown
▽	Delay	Body member is idle	Same as in gross breakdown

Table 2-6. Symbols Used with Man and Machine Time Charts and Multiman Charts

Symbol	Name	With man activities is used to represent	With machine activities is used to represent
■	Suboperation	Body member or operator doing something at one place	Machine working
▩	Movement	Body member or operator moving toward or with an object	Not used
▧	Hold	Body member maintaining an object in a fixed position	Not used
□	Delay	Body member or operator is idle	Machine idle (down)

PROCEDURES

The step-by-step procedures for making the three simplest and most commonly used types of analyses follow:

Process Charts—Product Analysis

1. A form or a blank sheet of paper may be used.
2. The analyst should actually observe the production process if possible. If the product is not in process or if direct observation is inconvenient, a scale floor plan should be used. Actual observation is usually desirable inasmuch as deviations between what is supposed to be the process and what actually is the process are not uncommon.
3. Pick a convenient starting place for the analysis.
4. Classify the first step into the proper category by means of Table 2-3.
5. On the first line of the chart place the proper symbol and description. If the step is a movement, pace off the distance or measure it by some means. If the time for the step is desired, time the step with an ordinary watch or stop watch or consult the file of standard times if they are available.
6. On the second line place the proper symbol for the second step, etc.
7. Every time the product moves from one workplace to another, waits, is inspected or worked on, a separate entry should be made. However, movements on a workplace in the course of which the product is worked on should not usually be separately noted.

Process Charts—Man Analysis

1. A form or a blank sheet of paper may be used.
2. The chart may begin at any point in a cycle of work, considering a cycle as the complete set of movements necessary to bring a unit of the product to the degree of completion typical of the process. However, it is usually most convenient to begin with the first movement of the operation connected with a particular unit of the product and end on the last movement before the next similar unit is worked on.
3. The first work step should be carefully classified according to the categories of Table 2-4 and the symbol, explanation, and, if the step is a movement, the distance entered on the first line of the chart. The distance may be paced, estimated, measured on the actual factory floor, or scaled from a drawing. The explanation should be as brief as possible.

Table 2-7. Therblig Definitions and Symbols

Therblig	Symbol	Color	Eagle pencil	Definition
Select	ST	Light grey	734½	Begins when hand or body member touches several objects. Consists in locating an individual object from a group. Ends when the hand or body member has located individual object.
Search	SH	Black	747	Begins when hand or body member gropes or hunts for part. Consists in attempting to find an object. Ends when hand or body member has found location of object.
Grasp	G	Lake red	745	Begins when hand or body member touches an object. Consists in gaining control of an object. Ends when control is gained.
Transport empty	TE	Olive green	739½	Begins when hand or body member begins to move without load. Consists in reaching for something. Ends when hand or body member touches part or stops moving.
Transport loaded	TL	Grass green	738	Begins when hand or body member begins to move with an object. Consists in hand or body member changing location of an object. Ends when hand or body member carrying object arrives at general destination or movement ceases.
Position	P	Blue	741	Begins when hand or body member causes part to begin to line up or locate. Consists in hand or body member causing part to line up, orient, or change position. Ends when body member has part lined up.
Pre-position	PP	Sky blue	740½	Same as position except used when line up is previous to use of part or tool in another place.
Assemble	A	Heavy violet	742	Begins when the hand or body member causes parts to begin to go together. Consists in actual assembly of parts. Ends when hand or body member has caused parts to go together.
Disassemble	DA	Light violet	742	Begins when hand or body member causes parts that were integral to begin to separate. Consists in taking objects apart. Ends when hands or body member has caused complete separation.
Use	U	Purple	742½	Begins when hand or body member actually begins to manipulate tool or control. Consists in applying tool or manipulating control. Ends when hand or body member ceases manipulating tool or control.
Release load	RL	Carmine red	744	Begins when hand or body member begins to relax control of object. Consists in letting go of an object. Ends when hand or body member has lost contact with object.
Inspect	I	Burnt ocher	745½	Begins when hand or body member begins to feel or view an object. Consists in determining a quality of an object. Ends when hand or body member has felt or seen object.
Hold	H	Gold ocher	736½	Begins when movement of part or object which hand or body member has under control ceases. Consists in holding an object in a fixed position and location. Ends with any movement.
Unavoidable delay	UD	Yellow ocher	736	Begins when hand or body member is idle. Consists in a delay for other body member or machine when delay is part of method. Ends when the hand or body member begins any work.
Avoidable delay	AD	Lemon yellow	735	Begins when hand or body member deviates from standard method. Consists in some movement or idleness not part of method. Ends when hand or body member returns to standard routine.
Plan	PN	Brown	740	Begins when hand or body members are idle or making random movements while worker decides on course of action. Consists in determining a course of action. Ends when course of action is determined.
Rest for overcoming fatigue	R	Orange	737	Begins when hand or body member is idle. Consists in idleness necessary to overcome fatigue from previous work which is part of cycle. Ends when hand or body member is able to work again.

4. If the time for the step is desired, time it with an ordinary watch or stop watch.

5. The subsequent steps should be entered on subsequent lines, placing the information in such a way that the symbols, explanations, etc., form separate columns for easy reading.

6. Care should be exercised to make one entry for every separable phase of the work. Each time the worker moves from one place to another, an entry should be made. Each time the worker works at a workplace, an entry should be made. In some cases, two distinctly separate activities may follow each other at a workplace without an intervening movement, and two operation symbols, one after the other, may be convenient.

7. The steps should represent the activities of the worker, what he does to the product, and where he goes rather than what happens to the product.

Right- and Left-hand Operation Charts

1. They are best prepared by actual observation of a worker, although they may be prepared from a proposal for a method.

2. A form or a blank sheet of paper may be used.

3. Although the chart may begin at any point in the work cycle, it is usually most convenient to begin with the hand that makes the first movement in the cycle.

4. The first and last cycles of a work spell may be different from the other cycles. It is usually most desirable to chart the most typical cycle.

5. The first step of the hand that begins the cycle should be classified into the proper category according to Table 2-5 and an entry made on the first line of the chart. The symbols are usually drawn freehand.

6. All the steps of this hand should then be properly classified and plotted in order. It may be necessary to observe a considerable number of cycles in order to accomplish this and to check the completeness.

7. The other hand should then be plotted, care being taken to place each step for this hand opposite the step of the other hand during which it occurs.

8. Since step 7 often involves the squeezing in of lines and items to coordinate the chart properly, it is frequently necessary to redraw it so as to make it easily legible. However, since the chart is mainly an aid to the understanding of the method, excess draftsmanship is purely a waste of time and should be avoided.

CHECK LISTS

The check lists for application to the three simplest and most commonly used analysis techniques follow:

Check List for Process Charts—Product Analysis

1. Who could most conveniently do the job?
2. What does the job really accomplish?
3. Why is it done?
4. Where is it done?
5. Where could it be done?
6. Can the job be eliminated?
   a. As unnecessary
   b. By changing the order of work
   c. By slightly changing the product
   d. By changing the raw-material specifications
7. Should the job be combined with another?
   a. By new tools or workplace
   b. By new equipment
   c. By a new order of work
   d. By slightly changing the product
   e. By changing raw-material specifications

Check List for Process Charts—Man Analysis

1. Can any operation be eliminated?
   - *a.* As unnecessary
   - *b.* By changing the order of work
   - *c.* By new or different equipment
   - *d.* By changes in the layout
2. Can any movement be eliminated?
   - *a.* By leaving out operations
   - *b.* By shifting some operations to another job into which they fit more conveniently
   - *c.* By changing the layout
   - *d.* By changing equipment
   - *e.* By changing the order of work
   - *f.* By conveyors (Make sure they are economical.)
3. Can delays be eliminated?
   - *a.* By changing the order of work
   - *b.* By changing the layout
   - *c.* By new or different equipment
4. Can countings or inspections be eliminated?
   - *a.* Are they really necessary; what happens after they are done and the information obtained?
   - *b.* Do they provide unnecessary duplication?
   - *c.* Can they be performed more conveniently by another person?
   - *d.* Are they done at the best point in the sequence?
5. Can operations be combined?
   - *a.* By changing the order of work
   - *b.* With new or different equipment
   - *c.* By changing the layout
6. Can movements be combined?
   - *a.* By changing the order of work
   - *b.* By changing the layout
   - *c.* By changing the quantity handled at one time
7. Can delays be combined?
   - *a.* By changing the order of work
   - *b.* By changing the layout
   - *c.* If they provide rest, can they be grouped better?
8. Can countings or inspections be combined?
   - *a.* By changing the order of work
   - *b.* By changing the layout
9. Can any step be made safer?
   - *a.* By changing the order of work
   - *b.* By new or different equipment
   - *c.* By changing the layout

It may also be possible to make various steps easier. However, several other types of analyses are of greater help here. Hence, questions concerning easier ways of performing single steps do not appear in this check list.

Check List for Operation Chart

1. Can a suboperation be eliminated?
   - *a.* As unnecessary
   - *b.* By a change in the order of work
   - *c.* By a change of tools or equipment
   - *d.* By a change of layout of the workplace
   - *e.* By combining tools
   - *f.* By a slight change of material
   - *g.* By a slight change in product
   - *h.* By a quick-acting clamp on jig if jigs are used

2. Can a movement be eliminated?
   - *a.* As unnecessary
   - *b.* By change in the order of work
   - *c.* By combining tools
   - *d.* By a change of tools or equipment
   - *e.* By a drop disposal of finished material
3. Can a hold be eliminated (holding is extremely fatiguing)?
   - *a.* As unnecessary
   - *b.* By a simple holding device or fixture
4. Can a delay be eliminated or shortened?
   - *a.* As unnecessary
   - *b.* By a change in the work each body member does
   - *c.* By balancing the work between the body members
   - *d.* By working simultaneously on two items
   - *e.* By alternating the work, each hand doing the same job but out of phase
5. Can a suboperation be made easier?
   - *a.* By better tools
   - *b.* By changing leverages
   - *c.* By changing positions of controls or tools
   - *d.* By better material containers
   - *e.* By using inertia where possible
   - *f.* By lessening visual requirements
   - *g.* By better workplace heights
6. Can a movement be made easier?
   - *a.* By a change of layout, shortening distances
   - *b.* By changing direction of movements
   - *c.* By using different muscles

     Use the first muscle group in this list that is strong enough for the task
       - Finger
       - Wrist
       - Forearm
       - Upper arm
       - Trunk
   - *d.* Making movements continuous rather than jerky
7. Can a hold be made easier?
   - *a.* By shortening its duration
   - *b.* By using stronger muscle groups such as those of the foot in operating vises

STOP-WATCH TIME STUDY

Definition. A stop-watch time study is used to find the amount of time necessary to accomplish a unit of work, using a given method, under given conditions of work, by a worker possessing a specified amount of skill on the job and a specified aptitude for the job, when working at a pace that will produce, within a unit of time, a specified physical effect upon him.

Uses

1. As a basis for setting schedules
2. To determine supervisory objectives
3. To determine operating effectiveness
4. To set labor standards
5. To determine the number of machines a person may run
6. To balance the work of crews working coordinately or in a production line
7. To compare methods
8. As a basis for computing standard costs
9. To determine equipment and labor requirements
10. To determine synthetic times
11. To provide a basis for the setting of piece prices or incentive wages

Components. The activities required for taking stop-watch time studies may be grouped under five heads:

1. Determination of objective
2. Recording of method
3. Timing of an individual
4. Rating and adjusting
5. Allowances

Objective. The first step in the setting of time standards requires the substitution of some definite adjective for each use of the word *specified* in the generic definition previously given, such as:

A stop-watch time study is used to find the amount of time that will be necessary to accomplish a unit of work, using a given method, under given conditions, by a worker possessing sufficient skill to do the job properly, as physically fit for the job, after adjustment to it, as the average person who can be expected to be put on the job and working at the maximum pace that can be maintained day after day without harmful physical effects, to which 30 per cent has been added. (An infinite number of variations on this definition are possible.)

Definitions of Terms in Objective. The time obtained from a stop-watch time study will be called the standard time.

Skill is the ability to do a job in the proper manner; the ability to repeat a definite muscular pattern. The higher the skill, the faster the possible pace before the muscular coordinations fail.

Aptitude is the physical fitness for the job.

Physical effect is the muscular and mental deterioration as a result of work.

Method Record. There is considerable agreement in the field concerning the requirements of the method record. It must be complete. Any of the work simplification techniques may be used to describe the method or it may be described in paragraph style.

The essential criteria of any method description are

1. Is it sufficient so the job could be reproduced from it?
2. Is everything the worker has to do recorded?

The method record should also include

1. Products and material specifications
2. Workplace layout
3. Surrounding environmental conditions
4. Tools
5. Equipment
6. Feeds and speeds of machines, welding currents, etc
7. Services in the way of machine and tool maintenance, delivery and materials handling rendered to or required of the worker
8. The name and clock number of the operator observed
9. The date and time the time study is made
10. The department in which the job exists
11. Any other pertinent information

The method record should be broken down into elements which are as small as possible and yet large enough to time adequately The elements should be chosen in accordance with the following requirements·

1. Well defined as the first motion of the element, what it involves and where it ends
2. As small as is convenient to time
3. As homogeneous as possible
4. Hand time should be separated from machine time
5. Constant elements should be separated from variable elements
6. Regular and irregular elements should be separated

Timing. Times for stop-watch time studies may be obtained with any one of three devices:

1. Stop watch
2. Marstochron
3. Motion picture camera

Stop Watch. Stop watches may be used in one of three ways:

1. Continuous
2. Repetitive or snapback
3. Accumulative

Continuous. In the continuous method of using a stop watch the watch is started at the beginning of the first element of the first cycle being timed, and allowed to run continuously throughout the study. The times for each element are obtained later by successive subtractions.

Repetitive. In the repetitive method the watch is simultaneously read and snapped back to zero at the completion of each element.

Accumulative. In the accumulative timing two stop watches are used and the time is alternately accumulated on the two watches. When one is started the other is stopped and before starting again it may be snapped back to zero or merely restarted from the stopped position.

NOTE: In many places in the literature a method called *cycle-timing* is described. This method consists of timing the elements in groups of one less than the number in the cycle. It is followed by a mathematical procedure for the determination of the individual element times. This method does not produce the correct element times and it should not be used. It involves the assumption that the average value for each element computed on the basis of a small sample of cycles will be the same as the average value for each element, computed on the basis of a sample $(x - 1)$ times the size of the original sample, with x equal to the number of elements in the cycle. A huge number of recordings would be necessary for this to be a reliable assumption.

Marstochron. The Marstochron is an instrument which draws a narrow tape of paper at uniform speed under a set of finger-actuated pencils. By depressing these pencils at intervals corresponding to the terminal points of elements, the time for each recording may later be found by measuring the length of paper between successive pencil marks. This method may be highly accurate.

Motion-picture Camera. Recent practice in taking stop-watch time study has involved the use of a constant speed, one frame per second, motion-picture camera. This permits simultaneous recording of the method and time to a degree of preciseness not obtainable by other methods The reliability of the record is also enhanced.

Recent thinking in the time-study field suggests that some of the statistical quality-control techniques should be applied to time studies to ensure that the average values which are used as representative of each element are reliable averages. Reference should be made to standard works on statistics.

Whatever the timing device used, most present-day practice involves the determination of an average or mean value for each element.

Rating and Adjustments. To the preceding values, obtained by any one of the means given, some correction factor must be applied to relate the value observed to that called for by the definition or objective. Such an adjustment factor is called a rating.

Rating procedures may be divided into one of three groups:

1. Mathematical
2. Fully subjective
3. Semisubjective

Mathematical. No accurate, reliable mathematical means of performing the rating procedure is at present known.

Fully Subjective. Fully subjective techniques usually involve comparison by the time-study man of the pace of performance he observes to his concept of proper pace of performance for the job, and as such, is subject to the typical errors of unanchored human judgment. Commonly described procedures may involve a rating of skill, effort, conditions, and consistency; skill and effort; or effort alone.

Semisubjective. Semisubjective methods may involve comparison of observed rates of activity or pace of performance to recorded paces portrayed on endless loops of motion-picture film. Some such systems rate all jobs to a single pace and correct later for the nature of the job. **Present indications are that such procedures offer more reliable bases for performing this step.**

Allowances. Allowances added to a time study are usually percentages of time, or increments of time per hour, added to the base time for the job so as to give the worker personal time, time for tool or material handling, etc. Allowances may be accurately determined by means of *ratio delay* studies which are based on a sampling procedure or by recording sufficient values continuously to provide an accurate estimate of the time required by the activity for which the allowance is made.

INCENTIVE WAGE METHODS

BY CARROLL J. BROWN

Assistant Professor of Business Management, Massachusetts Institute of Technology, Cambridge, Massachusetts

OBJECTIVES

> The human donkey requires either a carrot in front or a stick behind to goad it into activity. It is fashionable at the moment to argue that the carrot is the more important of the two: "incentive" is the watchword, and all classes of the community are busy arguing that if only they are given a little bit more in the way of incentive (at the expense of the rest of the community) they will respond with more activity. From miners to company promoters, the basic argument is the same. And no doubt, within limits, it is quite correct: a bigger carrot would make the donkey move a bit faster.[1]*

It is evident that the emphasis has shifted during the past 60 years from punishment for disobedience, defective work, and loafing to reward for skill, effort, ingenuity, and competence. It is also evident that the method of reward—*viz.*, the wage-incentive plan—has frequently been ill-conceived, unfair, inaccurate, and misused.

> . . . the use of carrots as bait for the donkey has neither universally nor permanently solved all of the knotty problems in the relationship between the driver and the cart's prime mover, although the device may have served useful on many occasions. Likewise, wage incentives have been used with success under proper circumstances, but they have not proved to be a panacea for industrial ills.[2]

The theoretically simple principle of permitting maximum use of skill and effort and rewarding accordingly has had many pitfalls in actual practice. The decade preceding the Second World War saw considerable advancement in correcting the evils. Top management took increasing interest in wage-incentive plans, and organized labor demanded sound and fair incentive plans. Today, the value of the wage-incentive plan which achieves higher rate of output with lower unit cost and higher employee earnings is no longer questioned. The problems are those of determining the goal of industry in the matter of wage-incentive coverage and establishing the type of wage-incentive plan, if any, best suited for each set of conditions.

The application of wage-incentive plans should be restricted to those operations where both management and labor mutually benefit from the application of the incentive plan. The sound incentive system should not be installed to quench a fire kindled by labor dispute. It should be used only after methods have been highly developed and standardized. It should be used only after consideration is given to the wage rate and incentive relationship of the workers covered by the proposed installation to other workers in the department or workers performing similar work elsewhere in the company or area. It should be used only after consideration is given to the feasibility of placing the workers covered by the proposed installation on incentive. It should be used only after joint discussion with labor representatives and the employees affected of the need for and the type of incentive installation. It should be used only after the incentive standards have been accurately developed, the degree of accuracy depending largely upon their use. It should be used only when the development and application of the whole incentive plan is simple and understood by the employees affected. No incentive plan is far better than one poorly conceived and poorly maintained.

In the past, many types of wage-incentive plans have been developed to meet varying conditions. An analysis of the major classifications of wage-incentive plans will indicate guiding principles to be used for their development and installation.

DEFINITION OF TERMS

Definitions of terms, particularly wage-rate terms, vary considerably from industry to industry and from company to company; therefore, no attempt has been made to be all-inclusive.

Actual Hour. An actual hour is a unit of time taken to perform a given amount of work.

Standard Hour. A standard hour is a unit of time allowed to perform a given amount of work at a rate of output that a worker or group of workers qualified for, and skilled in, the particular work may be expected to attain for reasonable wage-incentive pay, given good supervision and supplied with an unlimited amount of work, and to maintain over long periods of time without physical or mental impairment.

Operating Performance, or Productive Efficiency. Operating performance is the ratio of standard hours to actual hours. It is generally expressed in per cent.

One Hundred Per Cent, or Expected Operating Performance. One hundred per cent operating performance is that level of operating performance attained when standard hours equal actual hours (or actual production equals standard production).

Occupational or Evaluated Rate. The occupational rate is the prevailing hourly rate for fulfillment of minimum requirements of a job. It is frequently determined by job evaluation and an appropriate rate curve, with due consideration given to rates paid for similar occupations in other departments and the community and to rates paid in the past. It is the rate that would be paid for the job without wage incentive. In many industries, the *base rate* is synonymous with the occupational rate.

Guaranteed Rate. The guaranteed rate is the minimum rate paid for a job and is generally the occupational rate.

Pay Performance. Pay performance is the ratio of actual hourly earnings to the occupational rate. It is generally expressed in per cent.

Expected Pay Performance, or Expected Earnings. Expected pay performance is that level of pay performance attained when operating at 100 per cent operating performance. It is a level of earnings at a specified percentage amount above the occupational rate.

Earning Curve. The earning curve graphically represents the relationship between pay performance and operating performance.

EARNING CURVES

Purpose of Earning Curves. The relationship between reward and effort, or amount of wages earned and production, is of primary importance, and for any wage-incentive plan this relationship can be represented graphically or expressed in formula or tabular form. Formula or tabular form is used in actual wage calculations for convenience and accuracy; the graphic form, however, is more satisfactory for development and comparison purposes. In graphic presentation, pay performance (actual hourly earnings in per cent of occupational rate) is scaled on the vertical axis, and operating performance (actual production in per cent of standard production) is scaled on the horizontal axis. The percentages permit the use of one curve to represent the relationship for jobs of varying occupational wage rates and production units; whereas the use of actual occupational wage rates and production units would require a family of curves.

In the following classification and analysis of wage-incentive plans by earning curves, the strong and weak incentive features of each type are indicated by the slope of the curve. They range from the strong wage incentive with the steeply sloped curve to the weak wage incentive with the flat curve. The flat curve approaches the horizontal axis along which earnings are constant regardless of production.

Classification by Earning Curves. There are various classifications of wage-incentive plans by their earning curves. One of the simplest classifications makes the distinction between straight-line (constant-sharing) and curved-line (variable-sharing) plans, with a breakdown of the straight-line group into three subdivisions: curves parallel to the horizontal axis, straight-line curves originating at the origin, and all other straight-line curves. In actual practice, however, the earning curve is frequently more complex because it is composed of a combination of segments of curves taken from the straight- and curved-line groups. In addition, step curves are occasionally used. In illustrating various major types, whenever convenient, the names and curves of a few of the more noted plans are used as being representative of their particular type. These plans usually bear the name of the engineer by whom they were developed.

Time-rate plans, represented by the horizontal line, have been included for the sake of completeness, although they are not considered a wage incentive as earnings are constant, regardless of production (Fig. 2-10). With the differential time-rate plan, however, earnings are related to production to the extent of the step or steps. As the number of steps in the differential time-rate plan increases, the shape of the curve approaches those of the constant- or variable-sharing types. A variation of the differential time-rate plan is called "measured day work." Under this plan, an individual hourly wage rate is composed of an occupational rate plus an incentive rate which is based on past individual operating performance. To determine the incentive portion, a long period (1 or 3 months) of past individual operating performance is reviewed. The incentive portion of the rate is developed, and a new individual hourly wage rate is established and used until the next periodic review (Fig. 2-11).

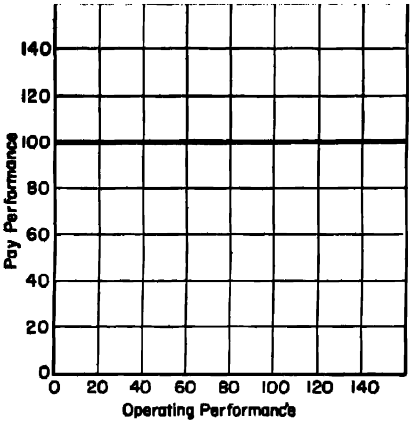

FIG. 2-10. Time-rate plan.

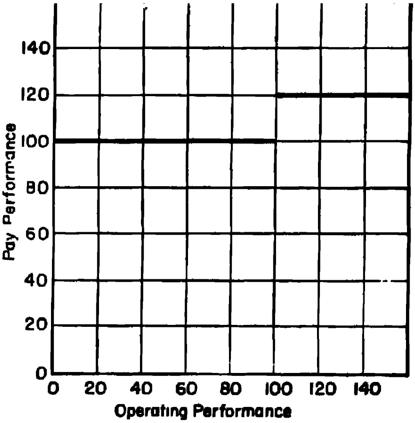

FIG. 2-11. Differential or step time-rate plan

The piece-rate plan is of the constant-sharing type where the earning curve passes through the origin; it is generally considered separately, however, because of its extensive use (Figs. 2-12, 2-13, 2-14, 2-15). Earnings under the constant-sharing plan may be considered to be made up of two portions—a time portion and an incentive portion. The area between the horizontal axis and a line parallel to it which crosses the vertical axis at the same point as the earning curve, when extended if necessary, may be considered the time or nonincentive portion (this area is zero for the piece-rate plan); while the portion between this line and the earning curve is the incentive portion and remains as constant sharing per unit of production throughout the production range (this area is zero for the time-rate plan). With constant-sharing plans, the (50-50) or (75-25) figure frequently shown indicates the point at which the straight-line curve, when extended if necessary, would cross the vertical axis (Figs. 2-16, 2-17, 2-18).

One classification of the earning curves of variable-sharing wage-incentive plans has been by the geometric form of the curve, such as hyperbolas and parabolas; further classification as to direction of concavity (upper or lower side), however, probably is more enlightening (Figs. 2-19, 2-20). Most variable-sharing curves are used in combination with constant-sharing curves (Figs. 2-21, 2-22). The straight-line curve frequently takes the form of the time guarantee for low levels of production, when used either with the constant- or variable-sharing curves or with some combination of them.

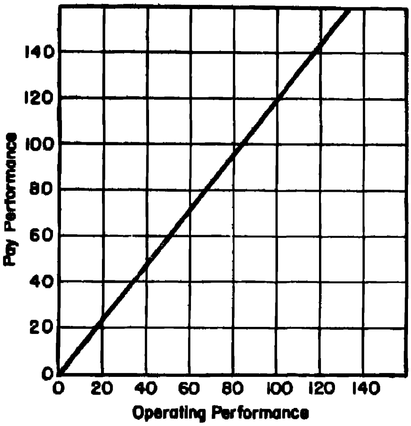

Fig. 2-12. Piece-rate plan.

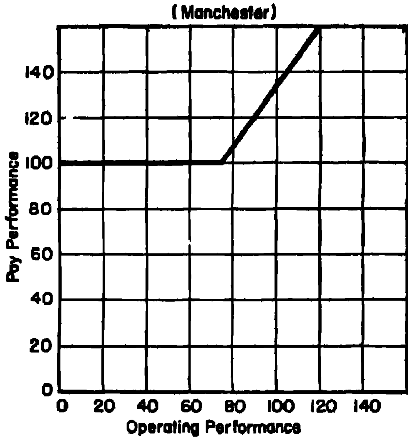

Fig. 2-13. Piece-rate plan with time guarantee.

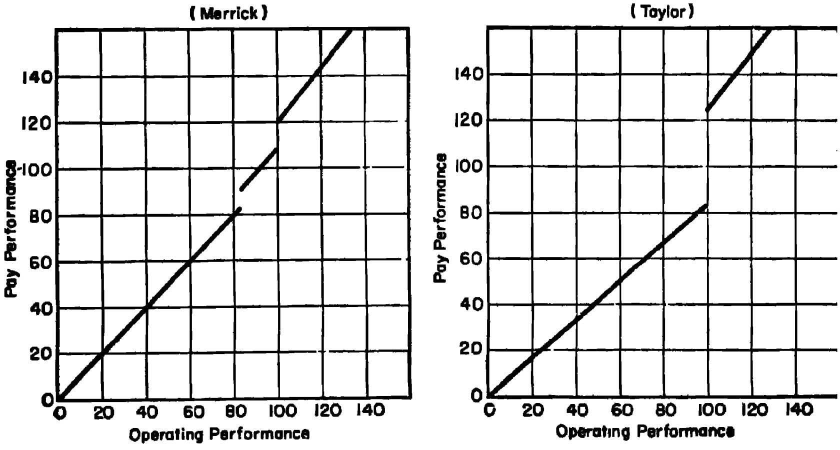

Fig. 2-14. Differential or step piece-rate plan.

The guaranteed and occupational rates, the slope or slopes of the curve, and steps in the differential type of plan vary according to the results desired and conditions surrounding a particular plan. Principles outlined under Guaranteed Period and Rate, Expected Earnings, and Analysis of Earning Curves indicate the normal range of earning curves.

Expected Earnings. In the discussion of the various classifications of wage-incentive-plan earning curves, no detail was given on slope or relative position of the earning curve. Determination of these factors is a question of policy as they must be established somewhat arbitrarily. Consideration should be given to the surrounding conditions and purpose of the plan, such as desired wage-incentive strength and other factors given under Analysis by Earning Curves. So many factors affect operating performance that isolation of the effect of one factor—the financial incentive—is exceedingly difficult. It is known that its effect is different under each set of varying conditions, if not even with each individual. Therefore, until better methods are devised for such determination, past performance is our chief guide. In actual practice, expected earnings, *i.e.*, earnings at expected or 100 per cent operating performance, range generally from 120 to 130 per cent pay performance. In recent years the trend has been toward the higher figure. In other words, 20 to 30 per cent bonus is considered as the necessary additional compensation to encourage workers materially to increase effective effort above normal nonincentive pace. When the definition

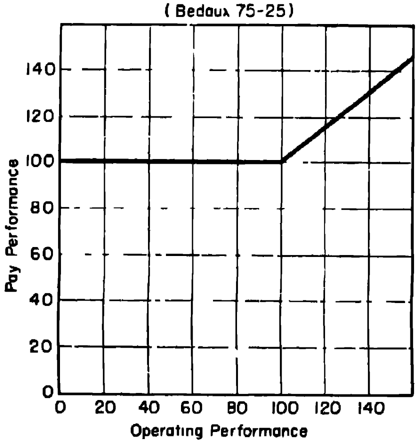

FIG. 2-17. Constant-sharing plan with time guarantee (expected operating performance 133).

of a standard hour is different from that defined above, the expected operating performance is not 100 per cent (*example* Bedaux).

Guaranteed Period and Rate. Some of the illustrations of earning curves shown include guaranteed rates (Manchester, Gantt, Halsey, Bedaux, Diemer, Baum, Emerson, Wennerlund, Knoeppel, Bigelow, and Rowan plans), whereas others do

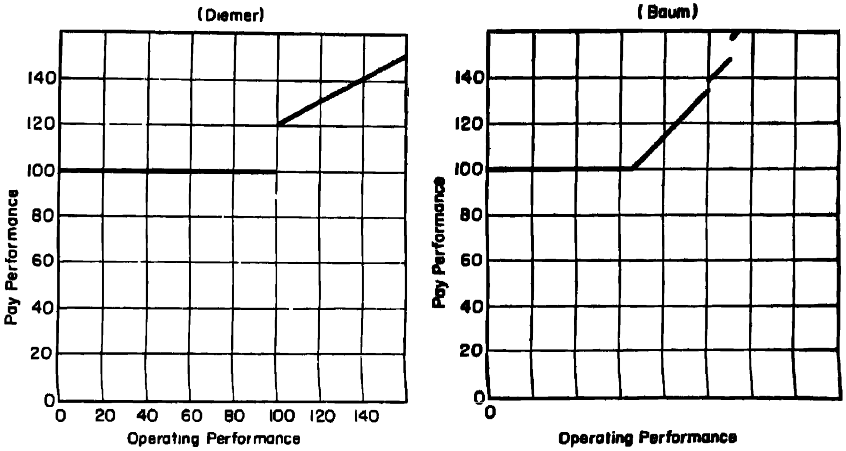

FIG. 2-18. Differential or step constant-sharing plan with time guarantee.

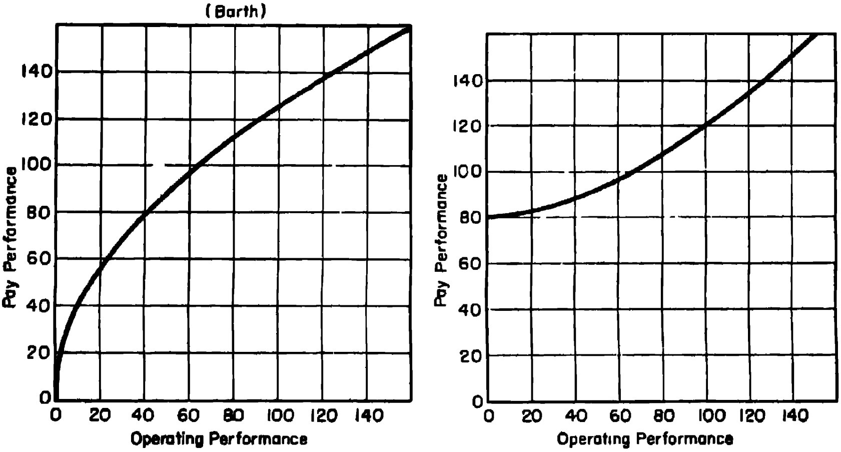

FIG. 2-19. Variable-sharing plan.

not (straight piece, Merrick, Taylor, and Barth plans). Theoretically, the lower the guarantee, the stronger the incentive. Nevertheless, in actual practice, the guarantee of occupational rates for incentive workers has become accepted. This guaranteed rate has become a standard feature because of the legal, social, and psychological requirements of a wage-payment plan. The guarantee is generally unconditional, assuring the employee his occupational rate for the hours worked regardless of the reason for the low output. In addition, present union contracts may call for guarantees above the occupational rate when earnings are affected by conditions beyond the employee's control.

The length of the guaranteed period depends upon the circumstance surrounding each installation. The job, day, or pay period (1 or 2 weeks) is the period for which the guaranteed rate is generally satisfactorily applied. Within reason, the shorter the period for which the guaranteed rate is applied, the stronger the incentive. For supervisory employees working under wage-incentive plans and for plant-wide plans, the guaranteed period is a month or more.

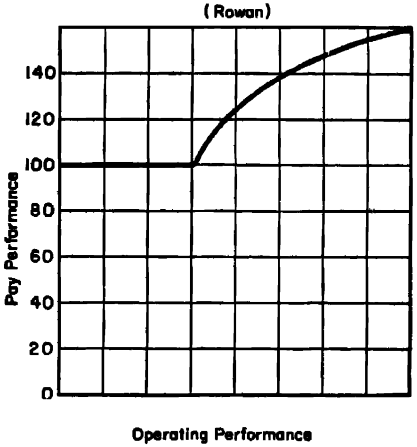

FIG. 2-20. Variable-sharing plan with time guarantee.

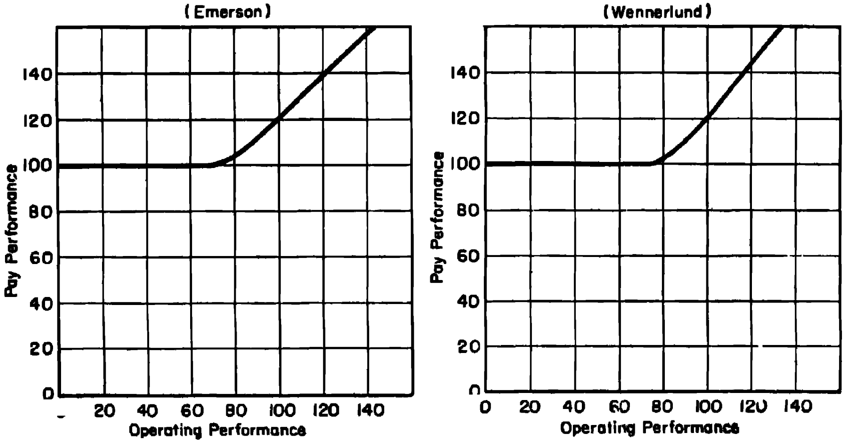

FIG. 2-21. Combination constant- and variable-sharing plan with time guarantee.

Analysis by Earning Curves. The rate of premium, or sharing ratio, on all production above the prescribed production level should be based upon the directness of the relationship between production in terms of the standards determinants and the skill, effort, and other factors affecting production over which the individual or group on incentive has control. Where the degree of control is relatively high, earnings should be in direct proportion to production.

There are no specific rules for use in selecting the best wage-incentive plan for a given set of conditions. The conditions surrounding each proposed installation cannot be defined in absolute terms but must be considered in relation to conditions of other wage-incentive installations. Analysis of these conditions, as factors affecting the selection of the earning curves, is a matter of degree. Selection of a proper wage-incentive plan is based upon the relative importance of each factor making up a given set of conditions to other factors in the same set and other sets of conditions. Those factors which appreciably influence selection of the earning curve and their effect on the earning curve follow.

Strong wage-incentive plans with steep earning curves are usually installed when one or more of the following conditions exist:

1. When standards for measuring performance can be accurately and practically established
2. When operating performance can be readily obtained
3. When job and methods are highly developed and standardized
4. When work is routine or at least elements of the work are repetitive

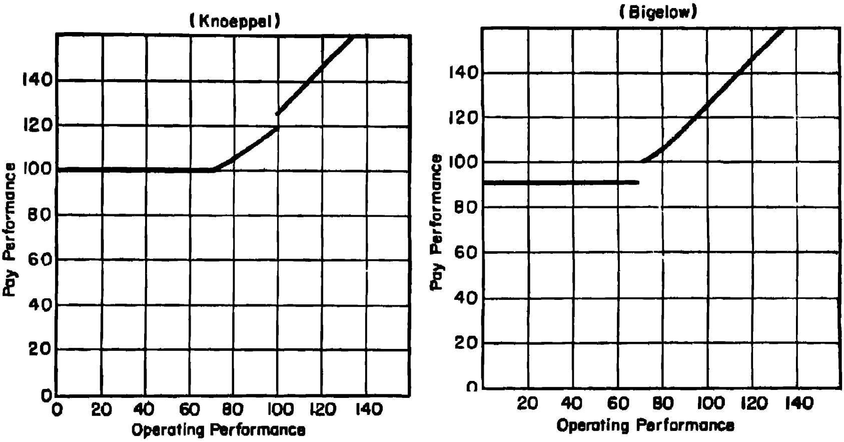

FIG. 2-22. Differential or step constant- and variable-sharing plan with time guarantee.

5. When operator has considerable control over production
6. When operating conditions and equipment are satisfactorily maintained to minimize delays, breakdowns, etc.
7. When ample backlog of work exists
8. When overhead costs are high in relation to labor costs so that emphasis is on production

Weak wage-incentive plans with flatter earning curves or time rates are usually installed when one or more of the following conditions exist:

1. When standards for measuring performance cannot be accurately or practically established
2. When skill and effort do not necessarily have a direct effect upon production
3. When considerable fluctuations in earnings might result from wide fluctuations in production uncontrollable by the employee
4. When job and methods are not developed or standardized
5. When work performed is not a key operation in controlling rate of production but is of a paced or service nature
6. When work is temporary in nature
7. When there is possibility of considerable unavoidable delay, breakdowns, and nonstandard work
8. When operating performance is low (minimum-wage guarantee)
9. When work is highly technical
10. When used to pay for delays, nonstandard work, etc. (occupational rates)

Wage-incentive plans with step earning curves or a combination curve which is weak in certain areas and strong in others are installed when the condition exists in which it is desirable to maintain production at a certain point, or area, above which little or no increase is desired.

INDIVIDUAL OR GROUP PLAN

The individual type of wage-incentive plan is used where one employee works independently; the group type of plan is used when two or more employees work on a common unit or group of units. The individual type is generally considered a stronger incentive because reward is directly associated with individual performance. With the group type, the earnings of one employee may be affected by performance of another, as each employee of the group shares the resulting earnings in proportion to his actual hours worked and his occupational rate. Under certain conditions, however, measurement of individual performance is not practical and so the group type of plan is used. Naturally, the smaller the group, the stronger the incentive. Historically, considerable success has been obtained with groups ranging from two to ten or fifteen employees. The effect of one's effort on larger groups is so diluted that it is generally considered to have little incentive value. The success of any group plan depends largely upon the degree to which the individuals can be mutually helpful, the teamwork of the group, their common interest, and the group spirit. Also, the work load must be properly and uniformly balanced among all members of the group.

There is no direct connection between the use of the individual or group plan and the earning curve. The principles governing the selection of earning curves apply equally for the individual or group type of plan. The formulas for the two types are frequently different, however, because of the man-hour-control feature of many group plans. Such a condition occurs when the size of the group is not necessarily constant and when group actual and standard hours are used instead of total of the individual hours.

In recent years there has been limited application of the group plan on a broader scale with group composition covering a department or even a whole plant. Under such an installation, particularly for a larger group, the additional earnings are frequently of the profit-sharing or Christmas-bonus type, in contrast to the physical type of wage-incentive plan where man performance is directly measured, and reward is made accordingly. When bonus earnings are based on such determinants as dollars of sales, per cent of net profit after or before taxes, and length of service, the factors influencing the amount of the bonus are so remote from the performance of an individual that the effect of the plan as an incentive is negligible. Other financial types based on dollars of sales per man-hour, dollars of sales per pay-roll dollar, actual per cent compared to standard per cent of labor cost to sales, or dollars of sales weighted by type of product per man-hour are a decided improvement over those totally lacking in man-hour control. In these an attempt is made to connect the bonus with total man-hours or labor cost. Many of these plans have claimed success where the department or plant is not too large and the group spirit strong. One advantage of many group plans—particularly department or plant-wide plans—is that they are easier to administer than individual plans; although even the plant-wide plan requires extensive service work.

DIRECT OR INDIRECT WORKERS

The same principles that apply to the determination of the earning curve and the use of individual or group type of plan for direct workers also apply to the development of incentive plans for other types of workers. In fact, the classification of employees as direct, indirect, clerical, supervisory, skilled, or semiskilled workers, to mention a few, has little or no bearing upon the general features of a wage-incentive plan. The type of operation performed by the workers is the important consideration.

Historically, management has been production-conscious; so, naturally, tools to implement production, such as wage incentives, would appear for direct workers first, especially in consideration of the fact that measurement of the performance of direct workers is generally more practical than measurement of the other classes. Gradually, other groups have been increasing their demand for wage incentives because semiskilled direct workers on wage incentives frequently receive higher wages than skilled indirect, clerical, or supervisory workers. The need for increasing the skill and effort of the indirect, clerical, and supervisory classes is probably as great as it is for the direct workers, if not greater. Management recognizes this need. However, it does not consider the wage-incentive tool, with the exception of the plant-wide plan, practical for most indirect, clerical, and supervisory workers.

Wage-incentive installations may be made for indirect workers when the functions of the indirect workers are not closely connected with direct operations. This group may include general maintenance workers, storeroom workers, and receiving and shipping workers. When standards can be accurately developed and practically maintained for these indirect operations, the indirect workers are paid on their own individual or group performance. Under such conditions, incentive development and application for indirect workers is identical to incentive development and application for direct workers.

Wage-incentive installations may also be made for indirect workers when the economical use of the indirect workers is second in importance to their influence on the performance of the direct workers. In this group may be included crane operators, transportation workers, assigned maintenance workers, assigned inspectors, and setup men. In establishing this type of indirect service workers' wage-incentive plan, the performance of the direct workers and the utilization of the indirect workers are important. Incentive payment of the indirect workers is made on the basis of the performance of the direct workers, provided a man-hour control establishing the ratio of direct to indirect workers is used. The indirect man-hours should be correlated to a measurable unit, such as direct man-hours or production. Whenever feasible, however, indirect workers should be solely or partly paid on their own individual or group performance. Payment to indirect workers of a bonus based solely on the performance of the direct workers without measurement of the productivity of the indirect workers amounts to a wage increase and destroys the value of the direct workers' incentive plan The relationship between performance and reward for indirect workers, as for direct workers, must be direct or else the value of the incentive is lost.

Thus, the standard objections to wage incentives under each of the above conditions is (1) the cost of development, maintenance, and application of incentive standards for most indirect jobs not closely connected with operations exceeds the value received, and (2) the performance of indirect workers servicing direct workers can have little direct effect upon production. The importance of the first objection diminishes, however, as operations become standardized and routine, and the importance of the second objection diminishes when an increase in man performance results in increased production and possibly in a decrease in service hours expended.

Learners and apprentices are protected by minimum guaranteed rates, and generally no additional wage-incentive features are considered necessary. However, when learners and apprentices are members of a group whose incentive earnings are determined as a group, the earnings of the other members of the group will be affected by inclusion of learners and apprentices in the group. Under such conditions, an allowance may be permitted the other members of the group.

Wage-incentive installations for clerical workers are based on the same principles as those for direct workers. Performance of some clerical workers, however, is difficult to measure as there are frequently many factors affecting performance, the relative importance of each of which is difficult to determine. Even more difficult to measure is the performance of technical workers. About the only incentive application that may cover this latter group is a plant-wide plan.

In consideration of the difficulty encountered in measuring performance of hourly rated employees, either in the shop or office, even more caution should be exercised in attempting to measure the performance of supervisory employees for wage-incentive purposes. When used, wage-incentive installation for supervisory workers is based on the same principles as those used for indirect service workers. The major difference lies in the standards and the guarantee period. The guarantee period is a month or longer, such as 3 months or a 3 months' moving average. Standards may be based solely on the performance of the employees supervised but more frequently include all factors over which the supervisor has control, such as maintenance expense, utilities, yields, quality, nonproducing labor, etc. Standard cost or variable budgetary-control standards are used frequently as the basis for such wage-incentive standards. Thus, the supervisor's performance is determined by the standard cost performance of the department or departments over which he has control.

Another type of worker frequently covered by wage-incentive plans is the salesman. In the past, by far the great majority of standards for measuring the performance of salesmen have been set by nonscientific methods. These sales standards, or quotas, as they more frequently have been called, were established by estimates of executives or based on past performances, sales records, or established by estimates of salesmen. A more scientific approach would include a thorough analysis of all factors that may have an effect upon the standard. The importance of the various factors may vary from industry to industry, or even from company to company, and what is practical to analyze in one situation may not be in another. The important thing is to achieve the greatest possible accuracy for those factors which have the greatest influence. A list of factors would include past sales experience, general business conditions, potential market, changes in sales policies, and competition.

SOME CHARACTERISTICS OF OPERATION AFFECTING PLAN

Unavoidable Delays. Delays should be reduced to a minimum before incentive development and installation are undertaken. Even after extensive precautions have been taken, employees on incentive occasionally are required to spend time waiting for material to be brought to them, for machinery to be repaired, for machinery to be adjusted, for resumption of work after power failures, or other unusual conditions which are no fault of their own. The type of delay will depend upon the nature of the work and the conditions that surround it, and only to a minor extent will the experienced operator, through better planning, have fewer such delays than the poor operator. As such unavoidable delays adversely affect the earnings of the employees, payment is generally made for all or part of the time the employees are delayed. Theoretically, such delays are an indication of poor management, and payment for them weakens the wage incentive.

For convenience, specified unavoidable delays of short duration are included in the standards because continual recording and approving of 2- and 3-min delays would require excessive foreman time for approval of payment for the delayed time. No additional payment is made for this type of delay. For delays of a long duration, allowances for which have not been included in the standards, payment is made on an actual occurrence basis. The length of the delay time to be included in the standards, the length to be paid for, and the rate of pay are determined in part by the nature of the delay. They vary considerably in actual practice. Some plans call for payment on an occurrence basis for the full duration of the delay, whereas others call for payment of the delay time beyond a specified period, such as 15 or 30 min. Under no conditions should the full delay time be paid for delays during this specified period because this would make it advantageous to the worker to prolong delays that are shorter than the specified period. A definite procedure should be established for payment of allowable delays, preferably at occupational or base rate, whether they are included in, or excluded from, the standard.

The higher the hourly rate used for payment during the delay period, the weaker the incentive. As this rate approaches average hourly earnings, a condition is reached where number and length of delays have no effect on earnings, thereby defeating one purpose of the incentive plan. The occupational or base rate is the most widely accepted rate. Some use has been made, however, of rates above the base rate, such as average earnings or a specified percentage of average earnings.

When part of the equipment operated by an individual is idle, such as one or more of a bank of machines, the determination of its effect on performance is difficult and generally impractical, and little or no attempt is made to obtain an accurate analysis. An arbitrary or developed adjustment may be made in the standards or rate allowed.

Man versus Equipment Performance. In operations where machines are used, the operator is frequently idle or at attention during part or all the machine elements. Ideally, this time is kept at a minimum through proper arrangement of equipment and operations. In actual practice, considerable idle or attention time occasionally exists. Where automatic machine time with set feeds and speeds is extensive, the operator should utilize his time during the machine elements on other equipment or at other operations. This frequently involves the operating of two or more machines by one operator. Where the operating cycle is short, manual elements usually overlap machine elements, and attention time is negligible. When the capacity of the equipment is greater than man's capacity, the standards are based largely on man performance; when man's capacity is greater than the capacity of the equipment, the standards are based on equipment utilization. A combination of man and equipment performance standards is frequently used when both conditions exist for a particular job. In the United States, because of a high wage level, emphasis is on full utilization of the man's time. The strength of the wage incentive is directly proportional to the degree of utilization of man's time.

Quality and Defective Work. Theoretically, an employee at fault should not be paid for defective work, and when payment is made it weakens the incentive plan. General practice has been to require an employee to correct the defective work, whenever possible, on his own time in order to receive payment, when the identity of the employee at fault could be established. When the defect could not be corrected, the employee was paid for acceptable product only. Frequently, the identity of the employee producing the defective work cannot be established, and payment for all product is made. However, many plans where such payment occurs claim to pay for acceptable product only. An employee should be paid for work on defective products resulting from faulty materials, etc., only when he is not responsible for the cause of the rejection.

In some industries there now appears to be a tendency to include incentive payment for all products, regardless of the reason for rejection. The trend away from expectation of highest quality, regardless of specifications, toward requirement of quality within specified limits, has caused a shift in thinking about payment for quality and defective work. With the present subdivision of work, better control of materials, and equipment, the feeling prevails that control over quality is management's responsibility and that no quality control should be tied in with the wage incentive. The poorer employees, after reasonable training and trial periods, should be transferred or released

A definite procedure should be established governing the payment for defective work. The rate, if any, used for defective-work payment varies with the surrounding conditions. The theoretically sound wage rate for time spent by an employee at fault working on defective material is zero, and the farther the actual rate deviates from the theoretical, the weaker the incentive. In present practice, the occupational rate is used frequently in payment for the time spent on defective work; under conditions where the employee at fault corrects the defect or where the identity of the employee is lost, payment is made through application of regular incentive standards. When the employee is not at fault, average earnings, approximate average earnings, or other rates above the occupational rate are used and justified on the basis that the employee should not be penalized for conditions beyond his control.

Nonstandard Time. Wage-incentive-plan installations are considered desirable for employees wherever accurate incentive standards can be practically established and maintained. Ideally, standards should be available prior to commencement of work for all the elements of work performed by an employee on incentive. Practically, however, certain work elements occur for which accurate standards development is impossible or not feasible. The time spent by an employee performing work for which no standards have been developed is considered as nonstandard time and arises either when an employee is temporarily assigned to a special job other than his regular job or is temporarily assigned to a regular job for which standards have not been developed. Naturally, the amount of nonstandard time should be kept to a minimum as the strength of the incentive varies inversely with the amount of such time.

Method of payment for nonstandard time varies considerably in actual practice. The proponents of a relatively high rate, such as average earnings, hold that the workers should not be penalized for conditions over which they have no control. On the other hand, the proponents of a relatively low rate, such as occupational rate, hold that the higher rates weaken the incentive because earnings are maintained regardless of performance on nonstandard work. With the lower rate, there is an incentive to get back to work covered by standards. When an employee is temporarily assigned to a special job, the reason for the transfer has considerable bearing upon the rate used. If there is no work available on the regular job when the transfer to the nonincentive job is made, the nonincentive rate is generally used. If the transfer is made because of the immediate need for an operator on the nonincentive job, although there is still regular work available, then average earnings probably would be the rate used for payment on the nonincentive job. When an employee is temporarily assigned to a regular job for which standards have not been developed, the issue is not so clear-cut. Generally, an attempt is made to use the occupational rate, although there is a recognized tendency to pay average earnings, a specified percentage above base, or a specified percentage of average earnings.

Equipment or Method Change. It is an almost universally accepted rule that standards will not be revised unless there is a change in method, equipment, or product. When there is such a change, the time for only those elements of the job which are affected is revised. Also, good faith on the part of management requires that method changes be legitimate and not deliberately sought because of an error in the standards. It is considered essential that standards be revised after a change whether the change was proposed by management or labor. If standards are revised only when management instigates a change, the rate structure soon becomes distorted. Employees proposing worth-while changes should be compensated by other means for their suggestions. The theoretically simple rule of revising standards for changes in method, equipment, or product is difficult to apply in actual practice. Minor changes which require an endless amount of servicing for proper rate maintenance are continually occurring. The practical limits to which one may go in making rate and standards changes vary for each set of conditions. Under present practice, an attempt is made to revise standards if the change has made an appreciable effect upon earnings, such as 5 per cent or more. When method changes occur, which require a lapse of time for the new methods to become standardized and proposed standards to be developed, payment is frequently based on temporary standards or average earnings.

The department responsible for maintaining standards is frequently not notified when minor changes occur. Even though aware of the changes, they often do not know the exact conditions before and after the changes and, consequently, the effect of the change. Even when these two conditions are known, the proposed standards are often subject to bickering, and the change leads to discontent. Revision is exceedingly difficult when standards are based on equipment utilization. Also, revision is made difficult when incentive payment is being made for low levels of man performance, thus introducing the problem of definition of a "fair day's work." Considerable attention has been given by industry to devising a method of routine revision of base rates and standards. Use of such a method would assure adequate payment for additional work or decreased work resulting from technological change. At present, there is no adequate solution to the problem of revision.

STANDARDS

Performance Measurement. Although systematically measured performance standards are associated most frequently with incentive compensation, there are other uses now being made of such standards. A brief recapitulation will illustrate some of the more important uses.

1. They serve as a basis for wage-incentive standards so that the compensation is contingent upon accomplishment.

2. They serve as a basis for developing the operating budgets. These in turn give rise to more orderly production planning and better production control.

3. They serve as a basis for developing standard costs. These in turn give rise to more accurate product costs, cost control, and estimating cost of new product.

4. They give the supervisors, as well as the workers, a yardstick for evaluating the worker's performance. Workers will be able to detect their own deficiencies; supervisors will be able to spot low performance efficiently and take corrective action, as well as spot creditable performance.

5. They supply required data for redesigning plant layout, equipment, method, and product.

Ideally, the same basic standards would be used for all purposes, whether they be for managerial control, cost control, or for wage payment. Here we are concerned only with the use of standards as a basis for wage payment.

When an employee is hired, whether he is hired as president or janitor, there should be available to him a description of the duties of his job and beside each specific duty there should be an indicated means of measuring performance. The subordinate, as well as his supervisor, should be able to answer the question, "How am I doing?"

There is no doubt that a comparatively accurate analysis and description of most jobs can be made, but the question of performance measurement is more difficult. Two main problems are encountered in performance measurement; these are the ability to measure and the practicality of attempting measurement. Any analysis of these two points will yield a wide divergence of opinion and a host of conclusions. Circumstances that make measurement practical in one industry may be totally lacking in another industry. Conditions are dynamic—what is practical today may not be tomorrow. The practicality of measurement will have to be governed by the conditions surrounding a given case.

As our performance-measurement techniques improve, our ability to measure performance more accurately will increase. Certainly, the most widely accepted performance-measurement technique today is the time study. It has, however, many recognized and unrecognized limitations. Some of the time-study techniques are not equal to the occasion. That we have overstepped the bounds of the practical use of time study in many instances in the past is obvious. Witness the lack of uniformity among the time-study men in the handling of allowances for fatigue and delays or in the handling of time-study ratings. What few definitions there are of a "fair day's work" or "average operator" or "average conditions" are vague and dissimilar. Results of going beyond practical limitations can be seen in the numerous examples of wild incentive earnings of 200 or 300 per cent bonus, although such earnings frequently result from lack of proper analysis and method improvement prior to measurement. Wage inequities frequently result where plans are applied without the knowledge of a fair rate of production or where the work load for a particular individual has been changed but where the individual is paid on the basis of group performance. More time should have been taken in the majority of the cases to correct operating conditions first and then develop, sell, install, and maintain sound standards.

Standards Development. In addition to the two basic requirements for standards development and application, the ability to measure performance and the practicality of attempting performance measurement, other requirements for successful application would include

1. A study involving the use of methods-improvement techniques. The methods should be highly developed and standardized prior to standards determination.

2. Establishment of fair, consistent, and accurate standards by time-study techniques. Development of uniform time-study practices and standards-development procedures will do much to achieve the desired consistency as the proper relationship is frequently more important than absolute value.

The technique of time study depends upon a clear-cut division of an operation into its component elements which can be recognized, measured, and eventually used for synthetic determination of standards. The first consideration in time and motion study is the studying of an operation by studying its elements. The finer the breakdown into elements, the better each individual element lends itself to close analysis; therefore, an operation should be broken down as minutely as is consistent with accuracy and practicality of describing the element and making the observation. Where there are many rapid movements to be timed, any one of which is too short to be observed and recorded by stop-watch time study, the technique employed in "micromotion" study involving the motion-picture camera provides an accurate means of observing and recording such times. The next step is determination of the necessary elements, their proper sequence, and where, how, and by whom they should be performed. It is only after such analysis leading to standardization with proper methods that wage-incentive standards should be developed.

Established time-study procedure should be followed in order to achieve the most consistent standards possible. Conditions under which the study is made should be specified. Stop-watch techniques, including type of watch and method of recording elemental readings, delays, missed elements, foreign elements, elements out of sequence, and unusual conditions should be uniform. Although what constitutes a representative number of elemental readings is difficult to establish, good practice calls for continual assembly of data to determine when sufficient information has been obtained. Within reason, the greater the number of observations, the more intelligently will the engineer be able to determine the standard time. For practical purposes, the influence on incentive earnings of a given standard should be directly proportional to the accuracy in its determination.

The next consideration is that of leveling or time-study rating. After the proper methods and conditions have been established, there are still factors that affect output, *viz.*, the skill, or proficiency, at following a given method and effort of the worker. As effective effort varies among workers, it is necessary to evaluate to a common level of skill and effort the various recorded elemental time values. The common level most frequently chosen is called 100 per cent, average, or expected performance. There are numerous definitions of average performance, such as "that rate of output which the average, skilled worker, qualified for the occupation, given good supervision, and allowed adequate rest, should be capable of maintaining for an extended period." Other definitions of average performance include considerable detail as to the qualifications of the average worker, such as average skill, effort, physique, and intelligence with respect to other workers doing the same type of work. Leveling is usually accomplished by estimating the percentage of performance of the worker in relation to average performance and adjusting the actual time by the estimated per cent. For machine elements, average performance may be defined as the rate that a machine unit attains when operating at established feeds and speeds. The leveling factor, as well as the selection of average conditions under which the operation is to be performed, are considered nonscientific parts of the time-study technique because the factor of human judgment is present. As they are a matter of personal opinion, training and experience in their application are essential in order to achieve the required consistency. To minimize error in leveling, time-study practice calls for the selection of as near average workers as possible because the farther away from average the performance of the worker under observation becomes, the more difficult it is to determine reasonable leveling factors. The maximum practical range for leveling calls for performances within approximately 25 per cent of average.

The normal time represents the time in which a worker may be expected to perform the designated elements without any interruptions. Separation of "variable" from "constant" elements aids in the determination of normal time. Time for constant elements, which may be constant with respect to turn, job, setup, or piece, is generally obtained by averaging. Variable elemental times are most easily analyzed by means of graphs. In the determination of a normal value for an element, all readings for the element are examined and the abnormal readings excluded. Many statistical and graphical methods for determining the normal value are used, but the straight average is the most common. Here, as in leveling, the selection of the readings to be used and the method of determining the normal is subject to opinion.

To the normal time must be added a certain amount of time to provide for personal needs, fatigue, unavoidable delay, and miscellaneous work elements. The category of unavoidable delay includes machine and electrical breakdowns, power failure, material delay, interference, and crane delay. Fatigue incident to an operation is influenced by the physical and mental requirements of the operation and the environment in which the operation is performed. Personal allowances include time for trips to the washroom, etc. Separate elemental consideration of miscellaneous work elements such as minor setup elements, cleaning machine, grinding tools, and machine adjustments, which are nonrepetitive and occur infrequently, is impractical. Allowances for unavoidable delays and miscellaneous work elements are determined by time study, whereas allowances for fatigue and personal needs are usually arbitrarily established. All are expressed in per cent and applied to the normal elemental values to give standard elemental values. Total allowances generally fall within the 10 to 20 per cent range. The factors included, however, vary considerably.

Table 2-8. Typical Allowances

Personal	3- 5%
Fatigue	5-15%
Unavoidable delays	0- 5%
Crane delays	2%
Mechanical and electrical	1%
Miscellaneous work elements	0- 5%
Clean machine	2%
Grind tools	2%

Standards Presentation. The presentation of standards in the form most convenient for application must be so clear that there is no chance for misinterpretation. This requires an operation description of each standard shown in the incentive plan. Such detail is particularly necessary when the individual elemental standard times have been grouped for presentation. To simplify application, those individual elements which always occur together should be grouped together. Whether they are constant or variable elements has no effect upon the grouping, since an element that may be considered constant for a given repetitive operation frequently is a variable element under nonrepetitive conditions. The more repetitive the nature of the work, the greater the degree of grouping individual elemental standards, the fewer the number of standards presented in the incentive plan, and the simpler the application. For highly repetitive work, the individual elemental standards are grouped for presentation into a few job standards; whereas for nonrepetitive work, the individual elemental standards are presented separately. Obviously, the standards for nonrepetitive work need to be developed to cover a complete range of sizes, weights, or types.

Standards for variable elements are expressed in graphic, formula, or tabular form because of the necessity for covering a whole weight, size, or type range for a given operation. The development and use of graphs and formulas minimizes the need for studying similar operations performed for a whole range on a single or several similar pieces of equipment. Also, standards so developed tend to be more consistent. Equipment specifications are frequently used in conjunction with time study to develop elemental times. For variable elements expressed in tabular form, it is desirable to have the time values broken down to a uniform per cent difference or a preferred number series. For presentation of standards, tabular form is preferred to graphic form as it permits more consistent and accurate application.

When the standards are expressed in monetary values, the time per unit, if it exists, is multiplied by the expected earnings rate per hour for the occupation to give the standard in dollars per unit. From a control standpoint, standard-hour plans are more desirable than monetary plans as operating performance is automatically obtainable.

Temporary Standards. Whenever possible, predetermined standards (standards determined before the start of work on an operation) should be applied. When existing standards do not apply to an operation, standards for it may be estimated by a member of management or developed directly from time study or elemental comparison with similar jobs, standards for which have been set by time study. Under these conditions, temporary standards are frequently used until regular ones can be established. The purpose of temporary standards is to increase incentive coverage. Temporary standards may be set on new jobs for which methods are incompletely developed or on jobs for which methods are temporary. Some temporary standards are applied to small orders which occur infrequently. Such temporary standards remain in effect until conditions warrant establishment of a revised temporary standard or a regular standard.

LABOR PARTICIPATION IN INCENTIVE PROBLEMS

General Labor Attitude. Opposition to wage incentives is a traditional part of the attitude of some unions. The prevalent notion that restriction of production will *temporarily lengthen employment has frequently proved to be true. However, it is* well known that such a *practice keeps prices high, a condition that invites competition* and thus defeats the practice in the long run. Opposition directed at the malpractices of the wage-incentive system rather than at its use has also occurred. The attitude of the workers will change as the malpractices are corrected and as the workers realize that management is honestly trying to develop and advance them and improve their standing, thus benefiting both management and the workers.

Some unions have abandoned their unfriendly attitude toward wage incentives and are moving toward cooperation and a correction of the malpractices. Van Dusen Kennedy, in a recent book,[3] indicates the willingness of the United Steel Workers of America to approve incentives:

> The United Steel Workers of America . . . does not take an official position against any and all incentives. It has many grievances against various wage methods in specific situations, but its policy is to work for correction of abuses and for protection of workers through participation in the regulation of such methods; it considers complete abolition of incentives from the steel industry an unrealistic aim.

Some unions, such as the United Electrical, Radio and Machine Workers of America, have strongly advocated the use of wage-incentive systems. The UE has published a book on wage-incentive systems,[4] stating in part that:

> Effective industrial unions can turn incentive systems from detriments to benefits for their members by securing for them a share in the financial benefits which accrue from the employee's increased productivity.

Some unions, such as the International Ladies' Garment Workers Union, have set up their own management-engineering department to assist in improving methods, in determining fair occupational rates, in training union representatives in sound time-study techniques, and in the development of standards for the industry. Gomberg, Director of Management Engineering Department, ILGWU, writing on labor's frequent objections to wage-incentive plans stated that[5]

> The principal technical barrier . . . is the shortcomings of the time study itself. It is not my objective to deny the usefulness of the time study but to point out the limitations of its accuracy. Thus far, no alternative method of measuring or estimating a reasonable day's work has appeared. Hence, the time study must stand until a better technique is found. Unions which denounce time study and refuse any participation in its use must either furnish a superior alternative method of measurement of a day's work or appear completely irresponsible.
>
> Acceptance of time study, however, does not mean acceptance of all the claims of its partisans, practitioners, users, and abusers. The profession, unfortunately, has failed to police itself. It has been content to denounce malpractice in general.

Fear of wage incentives on the part of the workers results from many beliefs, such as fear that the standards require a pace that will be injurious to health, that the standards will be cut, that failure to meet standards will bring criticism, that incentives will cause unemployment, and a general lack of understanding of standards development and incentive-pay determination.

Management has been reluctant to relinquish to labor its right to set and install standards. This is recognized by most unions; however, labor reserves the right to question standards through grievance procedure. Enlightenment on the part of both management and labor and the general labor movement toward cooperation will tend to alleviate both labor's fear of the incentive plans and the malpractices.

Negotiation and Grievance Procedure. The union contract that provides no grievance procedure for settling disputes arising during the contract term is now rare. Although a large and aggressive union usually has a more elaborate grievance procedure than a small union, discussion of grievance procedures in union contracts may be divided into four parts.

One part deals with the nature of the grievance. Most contracts specify the subjects that may be handled under the grievance procedure, such as differences arising over interpretation, application, or compliance with the provisions of the agreement or questions relating to hourly wages, wage incentives, or other conditions of employment. Such provisions are broad and permit discussion of almost any type of grievance except disputes involving demands for changes in terms of the agreement.

A second part deals with the manner in which the employee is to be represented. Agreements frequently differ in the extent to which the aggrieved employee participates in the processing of his grievance, although union representatives must by law be given an opportunity to be present. Frequently included are the number and method of selection of the union representatives, the protection allowed the representatives, such as seniority, and special features including remuneration and time allowed for processing disputes.

The third and most extensive part pertains to the procedure channels. Outlined in detail are the various steps for processing the disputes including the form and method of grievance presentation, the scheduling of time and place of meetings, the union and company representatives participating in each step of the procedure, and the channels to be followed in case of lack of settlement at any given point. Procedures usually call for four or five steps.

The fourth part covers the terminal point of the grievance procedure, which is almost always some form of arbitration.

Development and Installation. Joint discussion with labor representatives and the employees affected of the need for incentive application, the type of earning curve, the employees to be covered, and other important features including establishment and presentation of standards will bring about better labor acceptance of incentive wage-payment systems. Cooperation from labor should be obtained prior to the development of the plan. There seems to be a high degree of correlation between the extent of the standards presentation or willingness to deal with labor by the company and the freedom of management to set standards. Management is willing to explain new standards in great detail when assured of a receptive attitude on the part of labor and when assured that the proposed standards will not be subject to bickering, and vice versa.

The installation of an incentive plan is primarily a selling job and one which does not stop with top management or labor representatives but which must be sold to all workers affected. Before the workers will accept a plan, they must understand it, and therefore it must be simple enough to allow easy calculation of earnings by the workers themselves. Standards and sufficient explanatory data always should be available to each worker for calculation purposes.

Before a plan is made effective, it should undergo a considerable trial period in order to test its soundness, accuracy, completeness, and expectations. The results of such a trial run should be analyzed by both the workers and management. Regardless of the care taken in development, a trial-run period will usually indicate conditions not covered by the plan in its existing form. Although procedure is included in the plan for future revisions and additions, such additions and changes can be made more readily before a plan becomes effective. When revisions and additions are necessary, joint cooperation and understanding should be obtained to the same or greater extent than for original installation because of labor's fear of change.

Union-contract Incentive Detail. Because of labor's increasing participation in wage-incentive problems, the development and presentation of wage-incentive plans is becoming more formalized. The trend has been away from the inclusion of monetary piece rates in the company wage scale or the use of fly sheets to cover unusual conditions toward the use of a formal incentive-plan manual which includes, in addition to the standards, method of application, policies covering delays, equipment changes, etc. At present, practically all union contracts contain a section on rates which covers occupational rates and occasionally rates for delays and faulty materials, etc. A few of the more recent contracts include, in addition to rates, time-study procedure, allowances, use of temporary and regular standards, and changes in standards.

ADMINISTRATION OF JOB-EVALUATION PLANS

BY W. H. BRETT, III

*Industrial Engineer, The Aluminum Cooking Utensil Company,
New Kensington, Pennsylvania*

Job evaluation is a natural outgrowth of the development of scientific management. It is an attempt to reduce the complexities of an occupation to their fundamental components and to measure and weigh each component so that the sum will give the relative economic worth of that occupation. Let there be no mistake—no workable job-evaluation plan can measure a job as one may measure the dimensions of a room. One of the greatest causes of failure of these plans is a blind adherence to the system and the evaluations as they have been set up. In spite of the inaccuracies inherent in job evaluation (which will be pointed out later), it is still the most equitable method of dividing the pay roll which has yet been developed. If it does nothing else, it provides a framework for logical thought when assigning wage rates. Job evaluation is not an easy way to set wage rates, and there is no easy way to evaluate jobs. Painstaking and thorough research is required. Plans have been proposed as easy methods of job evaluation, but there is no easy cure for the inevitable disasters that will result from slipshod methods of analysis. No conclusions can be more accurate than the observations and data upon which they are based. If these are inaccurate or inadequate, the wage structure built from them will be intrinsically unsound and hopeless to administer.

The job components and their relative weights are of secondary significance to the care with which they are applied.

It is necessary in establishing a system of job evaluation first to define the objectives of the program. These objectives should be basically the following:

1. To describe and define completely the mental and physical requirements, the duties, and the responsibilities of every hourly rated occupation
2. To establish a ranking or grading of all occupations according to some breakdown of the skill, working conditions, and responsibilities that are required by each occupation
3. To establish certain key jobs with known market rates and from them to establish a wage-rate structure that will most equitably distribute the existent pay roll among the various occupations
4. To develop administrative procedures for evaluating new and changed jobs as changes occur and to maintain a close relationship between internal wage rates and the market-rate ranges for the same and similar jobs

Job descriptions are the heart of any program of job evaluation. It is that phase of job evaluation which is most frequently slighted and is most frequently a cause of future trouble. During the Second World War, especially, there was a tendency to establish these programs in a hurry. As a result, a great deal of job describing was done by filling out printed forms with short one-word answers. These forms generally follow the outline of the points in the actual job evaluation. Real job descriptions should be obtained by trained interviewers without a highly standardized list of questions to be asked. The interviews should be in the form of leading questions which encourage the worker to describe the true characteristics of his job. There are only a few general points to be covered, but they should be covered in detail. The resulting information should reveal what the worker does, what he has to know to do it, what material and equipment he must use to do it, what mental and physical exertion is required, and what his responsibilities are. These descriptions should be checked and rechecked for accuracy by foremen, supervisors, plant management, and industrial engineers. As they usually bring out phases of jobs that previously no one was aware of, the jobs will normally require a reorganization and possibly an elimination of certain phases of many jobs. Many jobs may be simplified, and some overlapping classifications should be entirely eliminated at this time. After this has been done, the evaluation plan to be used may then be selected.

The most popular type of plan today is the one which establishes a point valuation for the various predetermined job factors or characteristics. This type of plan is fairly easy to administer, and if the number of factors is fairly small, it is simple to explain and easily understood. The maximum number of factors which should be used is about eight. Some plans have been proposed that use as high as 20 different factors. Doing this does not add any real accuracy and in many cases only serves to remove attention from the important characteristics and to make agreement more difficult.

There are instances of some very successful plans which use no more than three factors. Table 2-9, which lists factors with their weighting, is a reasonable sample.

Table 2-9

1. Experience	21 %
2. Education . . .	18 %
3. Initiative and judgment	12 %
4. Dexterity and precision	12 %
5. Physical demand	12 %
6. Mental and visual demand .	6 %
7 Responsibility for equipment or process	12 %
8. Responsibility for others	7 %

When the plan to be used has been decided upon, certain key jobs are selected. These key jobs must have fairly definite market rates. They are evaluated and plotted on a chart of wage rate vs. point value. By statistical methods, a trend line is then drawn through these points. If some of the original key jobs are found to be too far out of line with the others, they should be discarded and others selected. When the other jobs have been evaluated, their wage rate or wage range will be established by this curve. The resultant wage structure should not cause a potential lowering of total pay roll or an appreciable increase in the present pay roll. This is based upon the assumption that the wage rates of jobs which fall above the curve will not be lowered immediately and those jobs whose rates fall below the curve will be raised to the proper level.

The foregoing is merely an outline of the general method of applying a job-evaluation plan. A great deal of literature is available on the actual methods of evaluation. However, very little has been written on the problems of administering such a system. Frequently, proponents of job evaluation prefer to ignore the existence of these problems. If job evaluation is to be utilized to its fullest advantage, these problems must be recognized and policies formulated to solve them. Poor administrative policies are responsible for the failure of more systems than a poor choice of factors or weighting of these factors.

MARKET RATES

One of the most important decisions to be made is determining the role of market wage rates. In some plans the effect of the labor market has been included as a factor to be evaluated. This procedure is not satisfactory in that it distorts the objective rating of job content or else it carries so little weight as to be of no value. It is also impossible to evaluate availability or market rates of skills that are unique to one plant. Therefore, a factor "market" is not common to all jobs.

A definite policy must be established as to whether the wage-rate structure is to be based primarily on internal standards or market rates. If the company is dependent upon a competitive labor market, some provision must be made for allowing rates to reflect going market conditions, or troubles of many types are bound to ensue.

Chronologically, the first problem to be met is what to do with the key jobs which were used to establish the wage curve. The key jobs will be located on a chart of point values vs. wage rates. The wage curve will then be drawn through them in such a way that the weighted quantity of those below the curve will be equal to the weighted quantity of those above the curve. The curve will also have to be drawn so that there is no net decrease in potential or actual pay roll if union acceptance is to be hoped for. It can be seen therefore that few, if any, of the key jobs—those with determinable market rates—will be on the curve. If internal standards are to prevail, these jobs must be either raised or lowered so that they do fall on the curve. Under present conditions of inflationary wage pressures, if the plant is unionized, all wage rates that are below the curve will undoubtedly have to be raised if the union is to accept the principle of job evaluation at all. This can, however, have an unfortunate effect upon the workers involved on the job. In some instances, it may be possible for the company to eliminate that work and contract it out to other firms paying the market rates and actually reduce the costs. This is most likely to occur in the service and maintenance functions. If it is not possible to eliminate these operations, the company will be put in an unfavorable cost position in relation to its competitors.

If, on the other hand, wage rates of key jobs above the curve are lowered to the curve, this will result in trouble in employing people to fill vacancies for those jobs or work stoppages and slowdowns.

The greatest trouble occurs where market rates of jobs change after a job-evaluation system has been in operation for some time. In order to avoid personnel troubles, wage rates must vary with important variations in market conditions. There are five general ways in which this may be done.

1. Reevaluate the job adding values where none exist in order to get the desired point value.
2. Apply an incentive bonus to an hourly job or relax standards on present incentive jobs.
3. Change the slope of the wage curve in order to decrease or increase differentials.
4. Keep knowledge of the existence of a job-evaluation system from the workers.
5. Admit by policy that market rates are more fundamental than internal standards.

The practice of reevaluating jobs to increase their point values in order to correspond to market rates is in common use. Although the problems it creates are, in the long run, more dangerous than the original problem, it is, in many cases, the only solution. This procedure, known in popular terms as "screwing the rates," will have the immediate effect of raising the job rate to correspond with the market rate. One representative of labor, however, admitted that usually they have a difficult time finding those last few points to raise the job another classification. The long-run effects of this type of action have a tendency to undermine the whole system. Each job that has been tampered with in this fashion is sometime going to be questioned by someone in the plant. Some worker is going to wonder why this job which is easier than his in all respects gets paid more money. That question is very difficult to answer. If enough of these jobs are present in a plant and enough of them questioned and found to be at fault, worker confidence may be so undermined as to require scrapping of the whole system and starting over again. That is a long and expensive process, and the entire procedure will not tend to improve relations between labor and management.

The second method, that of applying incentive rates to hourly jobs in order to increase wages, has fundamentally the same disadvantages of "screwing the rates" except that here it is not necessary to tamper with the actual point values. This protects the job evaluation from the brunt of the criticism from the workers. An example of this is the trouble one company had with a barrel-washing operation. The workers finally staged a wildcat strike in order to obtain their demands. Management satisfied them by applying an incentive rate which enabled them to increase their daily earnings by more than their original demands. The primary reason for the low rate was the weighting of the factor "working conditions" which was satisfactory for other jobs in the plant but did not allow sufficient points for this job. Because the job is dirty and unpleasant nobody wants to take it even at an increase of pay, and as yet no trouble has ensued from this action. This is not always the case. Frequently, during periods of a tight labor market it is desirable to increase facilities and hire many new employees, as, for example, during a war. In the same company, it was necessary to establish a new department performing simple, light repetitive work, suitable for women. In order to hire the necessary personnel and where a strong and well-integrated horizontal union is in operation. In such a case, job evaluation can have no effect in determining wage rates.

It is desirable from the standpoint of the company and the union that market rates be followed as closely as possible consistent with a stable wage structure. Under almost no conditions is it desirable to have a wage structure that is sensitive to short-run (less than 1 year) variations in wage rates. Inequities would be introduced to last for a long period if rates were raised on jobs that showed only temporary rises in market price, if the policy of not lowering rates for present incumbents were followed. If this policy were not followed (which in a strongly unionized plant is not likely to occur) the wage structure would be so unstable as to have an extremely detrimental effect on worker morale. A more satisfactory solution is to watch key jobs for significant changes which will have more than transient effect on the wages of the area.

JOBS "ABOVE THE CURVE"

Most of the literature on job evaluation mentions the handling of rates that are above the curve. However, very little concerns some very serious problems that arise from the principles. It is a generally accepted principle that all rates below the curve will be raised to the curve as of the date the plan is instituted. Frequently these raises are made retroactive to some prior date which has been agreed upon as the effective date of the job-evaluation plan.

The principles for handling rates above the curve, or "red-circle" rates, are as follows:

1. Wage rates of present incumbents shall not be lowered.
2. The rates of these jobs may be lowered by the following methods:
   - *a*. All workers subsequently hired for these jobs will be hired at the curve rate.
   - *b*. Workers on these jobs may be transferred to other jobs which carry the wage rate they now receive.
   - *c*. Normal turnover will slowly replace all present incumbents on these jobs.
   - *d*. Job content may be changed on these jobs thus substantially creating new jobs and eliminating the old ones.
   - *e*. Workers on these jobs may not take part in general wage increases until the inequities are ironed out.

One of the biggest problems is the definition of "present incumbent." One company, which had to go to arbitration to establish a wage curve, made an agreement with its union that the effective date of the job evaluation was the date that the petition for arbitration was approved. It was agreed that retroactive pay should be based from this date, and also present incumbents were defined as people hired before that date. Because the negotiation and arbitration extended over a period of about six months, many people were hired during that period for jobs that were later decided to be above the curve. On one job about fifteen per cent of the workers had been hired after the effective date and could not be counted as present incumbents. The situation was explained to these workers by a representative of management before their rates were cut, and it was accepted with good grace by all involved.

In another case present incumbents have been defined as all persons hired during the present contract year. This was done to put off the problem of hiring new workers at the curve rate to work with men who are getting the old higher rate. There are generally two unfortunate results to this type of situation. The old worker feels that the new man is "scabbing" on him, is out to cut his throat and take his job away from him. The new worker can't understand why he is doing the same work as the man next to him and doing it just as well, but getting only a little more than half his pay. No matter how well the reasons for this are explained there will usually be dissatisfaction on the part of one or both of the parties. The extent to which this dissatisfaction is generally made apparent will determine how successfully this situation can be handled. This company is anxious not to create this problem, at least during the present contract year. At present, with the continuing pressure for higher wages, it is not unlikely that this policy will be continued for the next contract year.

Another problem arises in defining present incumbent where promotion sequence is involved. One of the generally accepted advantages of job evaluation is that it defines more exactly the sequence of promotion and provides job incentives. If, for example, a group of jobs in promotional sequence are all found to be above the curve, how can a satisfactory definition of present incumbent be made? If only those persons working on the job at the time are to be present incumbents, why then the man on the next lower job will find that, if he makes his promotion, he will have to take a reduction in pay or at best no increase in pay at all. Under those conditions, he probably would not accept the promotion and would be extremely disgruntled about the whole affair. Under these conditions, the most satisfactory solution is to include all persons working at any one of the sequence of jobs as present incumbents for all of them. With this sort of policy, great care must be taken to define precisely the series of jobs which can be included in the promotional sequence. If this concept is accepted, it is evident that promotion must be made entirely within the framework of these jobs. This is probably a desirable thing to do in any case. This group of jobs will be in the class of "red-circle" rates for a much longer period than is generally accepted as being satisfactory, but in spite of this, this solution is the only satisfactory one in many cases.

The first method of lowering the rates of red-circle jobs, that of hiring all subsequent workers at the curve rate, is, of course, dependent upon the definition given for present incumbents. The problems involved have been discussed above and are sometimes of major importance. The union of one company has suggested that the only suitable time to bring wages down to the curve is during a general increase or decrease in the over-all wage level. However, in most cases, this principle is accepted if the union is honest in its belief that these rates should be brought down to the curve.

In order to hire workers at the lower rate, vacancies must be provided in these jobs. One method of providing vacancies is to transfer workers to other jobs which carry the same rate as that which they are now getting. In cases where the skills involved are of a general nature and the work is not radically different, this may take care of a high percentage of these people. If the job is one which requires a unique skill which is not required in other parts of the plant, this policy may offer no solution. If the work on the new job is very different in its nature or the environment less attractive, workers may be opposed to the transfer. At any rate, workers will generally be opposed to enforced transfers if they are fairly content on their old jobs. All those workers who for one reason or another cannot be transferred to other jobs will eventually be replaced through normal turnover. Where turnover is slow, this may be a long process, but it is eventually as sure as death itself.

In some cases it may be possible, by a change in process, to eliminate the job entirely or to change it so that a reevaluation is necessary. If the union admits that jobs which have been changed should receive the new rate as determined by evaluation, this procedure will also give management an added incentive to modernize and improve existing methods and processes. In some cases, however, this is impossible without completely changing all existing manufacturing procedures. This is especially true in the chemical industry where changing processes is sometimes actually impossible at the time, or investment in equipment and setup for present methods prohibits any changes.

The fifth method, that of excluding workers whose rates are too high from general wage increases, can be quite satisfactory if it is used with discretion. Management should adopt the attitude that their wage curve represents a long-run goal and should not insist on excluding these workers entirely from increases for too long a period. The workers whose rates are above the curve will usually accept without question the initial raises which were given to bring the low jobs into line. However, there may be trouble with subsequent raises if they are not given some share in them. One company suffered a 6 months' strike because of this very principle and was finally forced to grant the general increase across the board equally to all employees. It is quite possible that the strike would not have occurred if the company had been content to grant a portion of this increase to red-circle rates even though there would have been a less substantial decrease in intraplant inequities.

It has been argued that it is extremely difficult to bring jobs into line during a period of rising wages, the upward pressures being too high to allow segments of this wage structure to be held back. One union felt this so strongly that it was included as an issue in a case before the War Labor Board, although there was no possibility of a general increase at the time. They contended that the only way that wages could be brought down to the grade maximum was through death or separation from the company. The company felt that these jobs should not share in general wage increases. The issue was referred to the parties for negotiation as no wage increases were imminent. This is indicative of the fact that strong opposition to this procedure may be met.

A final method of getting around the problem of rates above the curve, but which is not to be recommended, is that of building the job description and point values around the existing rates. If this is done, the same results will occur as when rates are tampered with to correspond to market conditions. One company,[*] which did build its job evaluation around the existing rates, found the union was soon demanding reevaluation of all jobs or a complete scrapping of the whole system. When this happens, even if the plan is salvaged, it will be suspected by the union as a whole and will be, for that reason, less valuable. This procedure will, in the long run, create more problems than the red-circle rates.

There are two reasons why it is undesirable to retain these high rates. The first is that the company is forced to pay a higher total pay roll than would otherwise be acceptable to labor. The second is that these high rates will, as long as they exist, be a source of confusion and dissatisfaction to the workers. It was the experience of one company,[†] which had to retain these rates over an excessive period, that the union requested an entirely new job-evaluation plan. They claimed this was necessary because many jobs were higher than the maximums by from 2 to 31 per cent, which created inequities which they could not explain to the union body. If these high rates exist for too long a time, their original meaning will be lost sight of, and the union leaders will have difficulty in convincing the union body that there is a reason for them. Their continual existence will disturb the functioning of the job-evaluation system.

The only way this problem can ever be completely avoided is by granting a general increase at the time the system is established. This serves to lift all jobs up to the same relative level as the too-high jobs. This method could not be accepted by management, however, unless such a general increase was imminent anyway.

TECHNOLOGICAL CHANGES

Decreasing the rates on jobs that have been simplified by some change in methods has been objected to on the grounds that workers should be paid on the basis of productivity. This contention is diametrically opposed to the principle of paying on the basis of the skills required and the arduousness of the work to be done. The concept of pay based on productivity will break down logically in the extreme cases. Certainly, the operator of a highly automatic machine, who is required to have no special skill beyond pushing a button, should not be paid more than a highly skilled tool- and diemaker even though the daily output of the button pusher may far exceed in value the output of the machinist. If this policy were followed out, it would lead to the development of many highly paid sinecures. This is certainly not a goal to be desired. Jobs that have been simplified, even though their productivity may have increased, should have their pay rate decreased. The savings should be distributed to the workers as a whole in the form of general increases or to the general public in the form of reduced prices. The changed job should be paid on the basis of job evaluation.

If it can be agreed by union and management, the most satisfactory policy is to lower the rate on the job as soon as it has been changed and the new evaluation has been made. This is frequently difficult to manage if the job is changed only slightly and there is no change of personnel doing the work. If this is the case, it is frequently necessary to call the job a red-circle job and handle it by some method as outlined previously. In some instances, however, it will be possible to lower the rate immediately and for those people who have been working on the job all along. This can be established only by agreement between union and management. Another company has had considerable success with the policy of adding new duties to the job when it has been simplified in order to increase its point rating to the original value. If this is not practicable, the company increases the worker's merit rating on the basis of the residual skills the man has but is not using. In a small company, where the problem of replacing absentees is quite troublesome, these residual skills represent a form of insurance to the company which they feel they are warranted in paying for. In plants where a merit rating is in use, this solution has practical value and is theoretically sound.

[†] Brown and Sharpe Mfg. Co., Providence, Rhode Island, and The International Association of Machinists, Brown and Sharpe Lodges 1088 and 1442, Case No. 13-447-D, Nov. 27, 1944.

If job evaluation is to have current significance, it is necessary that no changes be made in job content without notifying the parties responsible for reevaluation. This can best be accomplished by the use of three policies or practices:

1. Close cooperation of department foremen and methods department with the job-evaluation committee
2. Rapid channeling of wage grievances to the evaluation administrator
3. Periodic audit or check of the descriptions of all jobs

Understanding of the significance of job evaluation and the role it plays in the company's wage structure is a necessity for all foremen. They must be trained to watch processes closely in order that job content may not be changed without their knowledge. Whenever a new job must be introduced or a present job changed, the job-evaluation administrator must be notified immediately. It is usually the best policy to establish a temporary rate until the job content has been permanently established. Retroactive payments will have to be made when the temporary rate is set too low. If job evaluation is administered entirely by management, it is probably best to have the job-evaluation administrator set the temporary rate as he is most familiar with the other jobs in the plant. If this is impractical, it would be satisfactory to have temporary rates set by the industrial engineering department if they are separate departments. In companies that have efficient methods engineering and where processes are tightly controlled from a standpoint of quality control or incentive rates, there should be little difficulty in quickly spotting any changes in jobs. Where this is true, it is advantageous to have job evaluation very closely tied to methods engineering if not actually in the same department. When job evaluation is handled by the personnel department, especially in a large organization, it is liable to become too far divorced from the actual manufacturing operations which it is evaluating.

The handling of wage grievances should be greatly simplified by the establishment of a job-evaluation plan. Wage grievances should be channeled directly to the job-evaluation committee, whether or not it operates under the personnel department. They should be treated differently from other types of grievances. It has been possible in some plants to establish a time, to occur at regular intervals, when grievances, or requests for reevaluation, may be submitted to the job-evaluation committee. This policy will have the effect of decreasing total grievances as it will automatically give the worker a "cooling-off" period. If labor-management relationships are not in a strained state, where the union is hunting for grievances, this should be agreeable to the union. When relationships are smooth, individual wage-rate grievances are as much a headache to the union committee as to management because, if one man gets more, it means that another is getting relatively less. The alternative solution is to accept wage grievances at any time. This has the advantage of not allowing inequities to exist after they are discovered. However, if the times that grievances are accepted occur frequently, this advantage is of doubtful significance. The form of the grievance slip is important. If an agreement is made by each worker that the reevaluation will be accepted even if it is found that the rate is already too high

there will be added insurance that the grievances will be legitimate. If job evaluation has the backing of the union, this principle will probably be accepted.

Application for Job Reevaluation

We, the undersigned employees now working on the job, wish to have the job evaluation reconsidered on

____
(Name of job)

for the following reasons ______________________________

____

____

____

____

____

In requesting this reconsideration we understand that there is an equal possibility of a reduction as well as an increase in evaluation and we agree to abide by the findings of the Job-evaluation Committee even though the reduced evaluation places the job in a lower wage-rate group

Signed ______________________________

Grievances will be of two general types:

1. The job was incorrectly evaluated originally
2. The job has been changed in such a way that the point value should be increased

In either case, care must be taken in the reevaluation to see that it is done accurately and objectively and that it is not influenced by pressures from the group presenting the grievance. It is in situations of this type that joint union-management job-evaluation committees display their inherent weaknesses. Grievances that are claimed to be based on changes in job content may actually be based on external conditions such as market rate, and under these circumstances, it is easy to read new values into a job which are not actually there. The support of really complete job descriptions makes it easier to avoid error in such circumstances.

To ensure the complete contemporaneousness of job evaluation, some sort of periodic review or audit of job descriptions is necessary. This may be done piecemeal throughout the year or all at one time but should be accomplished for each job at least once each year. This procedure will catch minor changes before they become serious and require drastic changes in the rates for any one job. This procedure is especially necessary where control of standards is fairly loose and changes are less likely to be caught by foremen or the methods department.

UNION PARTICIPATION

The basis for employee participation in job-evaluation plans is well expressed by Eugene Benge who said, "Success depends not only on selling the program to employees, but also upon the extent that employees believe in it. That belief is greatly enhanced by the opportunity to participate."[2]

The extent to which employees should participate is not a matter that can be decided categorically. The degree of participation should be decided upon the basis of the attitude of the workers and their general level of education and intelligence. A policy that may be quite successful in one case may fail completely in another. In one case where management had to deal with 14 different trade unions, a plan was set up independent of the workers, purely for management's information. If some sort of employee aid and participation is not enlisted, this will be the degree of effectiveness of most plans.

The degree of union participation may vary from the above type to a plan in which job evaluation is a joint function and responsibility of union and management. The most important weakness of this sort of plan is that job evaluations will be, to a large degree, negotiated, and there will be a greater tendency to attempt to fit the evaluation to the present rate. For example, in one company with this type of plan, no rates were found to be above the curve when the plan was established. It does not seem to be within the realm of possibility that this could happen with a fair and objective evaluation of all jobs. The evaluations were evidently built around the existing rates. The dangers of this action have been discussed under Jobs above the Curve. It is probable that the actual job evaluations are changed to reflect group pressures and market conditions as no red-circle rates of any kind are in existence. The second disadvantage is that union members of the evaluation committee may be removed by the union body. This leads to instability on the committee and has a tendency to force the union members of the committee to influence their decisions by what they feel to be the desires of the majority of the workers. This is true no matter how objective they may try to be. The presence of these rates is a continued threat to the very existence of the job-evaluation program.

If these disadvantages make a joint union-management plan unsatisfactory, to what extent should union participation be allowed, and what should be the role of collective bargaining in determining wage rates? In the long run, unions will not allow job evaluation to remove individual wage rates from the realm of collective bargaining. On the other hand, a typical management attitude is exemplified by W. H. Frater, Director of the Work and Wages Analysis Section of General Motors Corporation, who states that negotiation of individual wage rates will prostitute any job-evaluation program and nullify it in so far as the establishment of a rational wage structure is concerned.[3] This attitude assumes that job evaluation can measure and rank jobs with absolute accuracy and that labor must accept a rate for all time once it has been established. The labor movement will not admit that the plant's wage structure can be a unilateral decision by management and will reserve the right to change its mind concerning ranking of jobs and wage differentials.

In reality, there should be no fundamental conflict between collective bargaining and job evaluation. The actual point evaluations should not be subject to negotiation; the dangers of this have been pointed out. The job-evaluation program should provide common ground for the discussion of individual wage rates. Even without the existence of a job-evaluation system, rates are negotiated on the basis of what the worker must do and what he must know in order to do it. Job evaluation presents these facts completely and rationally and should make it much easier for union and management to come to an agreement on the pay for individual jobs. Job evaluation provides a framework for negotiating the rates of unique, new, and changed jobs in the company. Job evaluation should not attempt to establish, by management fiat, the rates of all jobs in the plant. In setting up a job-evaluation program, management and the union should agree that the actual evaluation of jobs is the prerogative of management, subject to normal grievance procedure.

In spite of the fact that the evaluation should be done by management, a certain amount of employee participation should be incorporated in the establishment of the program. The procedure of job evaluation and what it means to the individual worker should be explained, using terms and examples that will be understood by the average employee. Lengthy dissertations on point-valuating procedures and factor weighting will probably not be understood by the average employee and may serve to make him antagonistic. It is necessary only that he be instructed in what the plan is designed to accomplish and its general method of operation. The practice of questioning the worker on the job as to what his work actually involves will not only yield information but will increase his interest in the program. All efforts should be directed toward convincing the employee that the plan is being fairly and objectively administered and that it is to his benefit that a wage structure be established on some rational basis.

CHECKING RESULTS

In any phase of business activity, it is important to have some way of checking the results of expenditures of effort and money. In the field of industrial relations, this is a difficult thing to do. It is next to impossible to determine the effect of job evaluation on the yearly profit-and-loss statement. The only way that the results of job evaluation may be tested is by examining its effect on labor-management relations and its acceptance by the rank and file of workers. Comparing labor turnover and wage-rate grievances before and after job evaluation will usually provide a general idea as to its effects.

There are many characteristics of labor turnover which could invalidate any data which were gathered from these figures. First, it is usually impossible to find out why people quit a job. They may just never show up or they may actually lie when asked why they are quitting. Second, there are too many reasons that they might quit which have no relationship to job evaluation, and lacking knowledge of their reason for quitting, it is unsound to make any assumptions as to the effectiveness of job evaluation based on these figures. The soundness of a single rate may be determined with more accuracy than the whole structure, but even here the results are doubtful.

An examination of the amount and types of grievances is a better indication of the effect of the rates established, but even here there are many other factors that affect grievances other than wage rates. If union-management relations are better, shop stewards will discourage grievances. This change in attitude may be caused by a general wage increase or some other factor not even remotely related to job evaluation.

As these procedures are merely methods of determining worker reaction, probably the best method of determining this is by asking the workers themselves. If this seems unsuitable, it is possible to get the reactions of foremen and other supervisory people who are in a position to know the degree of worker acceptance. The union committee will probably be anxious to air worker reactions if they are not favorable. It should always be remembered that the only criterion of success of a job-evaluation system is whether the resulting rates are acceptable to labor.

CONCLUSIONS

Job evaluation, if properly used, can be an extremely useful tool of management. However, if jobs are hastily and inaccurately evaluated and described or the system haphazardly administered, it can become an expensive headache. The most basic pitfall to avoid is the belief that any job-evaluation plan known today can with absolute accuracy measure the relative worth of any group of jobs. Job evaluation can measure only those factors which are common to all jobs in some degree and which can be described and measured in concrete terms. Even those factors which are generally included are frequently next to impossible to evaluate rationally. The problem of measuring responsibility is one which has never been satisfactorily solved. At a job-evaluation meeting in one plant, a foreman gave his idea of responsibility: "Two men drive trucks of identical make, year, and model down the same road the same number of miles each day. One has a dump body and is loaded with sand; the other has a bus body, is used as a school bus, and is loaded with children." The difficulty of measuring the responsibility in this case and applying it to a wage differential is obvious. The foreman's final comment was that the man hauling the sand probably would be paid more anyway. There is still something to be desired in obtaining a really objective and adequate measurement of the relative worth of jobs. Therefore, it can be seen from the inherent inadequacies of any such plan, job evaluation should not be the ultimate authority but a guide in setting wage rates.

The following general policies will usually give the most satisfactory results:

1. The plan itself should be as simple and flexible as is consistent with reasonable accuracy. Wage-rate ranges for a scale of point values should be established rather than a single-rate system which gives a different rate for any small variation in point values. The accuracy of any system does not warrant using the latter method.

2. Because of the importance of going market rates, they should be recognized as more fundamental than internal standards, and suitable agreements should be drawn up to handle market variations. For this reason, job evaluation will be most valuable in setting rates for unique, new, or changed jobs.

3. Job descriptions and evaluations must be kept up to date. Labor must allow simplified jobs to be reevaluated and the rates eventually lowered if the plan is to

succeed. Close cooperation of industrial engineers, foremen, and the job-evaluation administrator, in addition to at least annual audits, is necessary to maintain current data.

4. Job evaluation should not exclude the possibility of negotiating wage rates but should provide information so that collective bargaining may be carried on more intelligently. Point values themselves should not be negotiated as this will result in compromised values with the resulting loss of objective point ratings. Management should establish rates and then, if they are found unacceptable to the workers, should bargain collectively over them.

5. The effective use of job evaluation requires a cooperative attitude on the part of labor. The plan must be sold and its method of application agreed upon before it is put into effect if it is to be of greatest service.

FOUNDATIONS

BY F. W. STUBBS, JR.

Professor of Civil Engineering, Purdue University

This section calls attention to some of the important problems arising in the design and construction of any structure, *viz.*, the foundations. At the outset, it may be well to suggest that, because of the importance of the foundation to any structure, an engineer competent in this field be selected to design and supervise the construction of all foundation jobs. Experience with the problems is essential. (This statement applies elsewhere.)

The essential problem in the design of foundations for buildings, bridges, towers, stacks, etc., is so to proportion the foundation that the settlement will be within the permissible limits. Actually the effect of the structure on the foundation material is considered. The problem of runways and taxiways of airports, highways, parking lots, and storage areas is similar, and in addition, the effect of the foundation material or subgrade on the wearing surface of such projects must be considered. The wearing surface must be so designed that applied loads do not cause failure of the subgrade. Also, the subgrade must be so selected that it will not cause failure of the wearing surface through frost action or other causes.

Structures may be divided into two parts, the superstructure and the substructure. That portion of a building above ground is considered the "superstructure," and that portion below the ground is called the "substructure." Likewise the trusses and deck of a bridge are called the "superstructure," and the supporting piers and abutments are generally referred to as the "substructure." The steel frame of a transmission tower is the superstructure, and the concrete footings are the substructure.

The substructure is commonly made of concrete, plain or reinforced, steel, or timber. That part of the substructure which transmits the load to the soil or rock is the foundation and in some cases may be called the "footing." The material on which the foundation is placed is called the "foundation material." Those portions of the substructure of a building above the footings are known as the "foundation walls." The substructure above the foundation of a bridge is the pier, abutment, or bent, although in some cases the various parts merge into one, and no distinction can be made, as in a pile bent. In highway, airport, and similar construction, the term "subgrade" refers to the foundation material on which the wearing surface or pavement is placed. In some types of construction the wearing surface merges into the subgrade, and there is no definite line of demarcation.

SOIL AND ROCK

The terms "soil" and "rock" may have different meanings depending upon the profession or field in which they are used. Geologists refer to the solid portion of the earth's crust as rock, using the more restricted terms of bedrock for the consolidated material and mantle-rock for the unconsolidated portion. The engineer refers to the unconsolidated portion as soil or earth and to the consolidated portion as bedrock. In agriculture, soil is used to designate that thin layer of unconsolidated material which supports plant life, and subsoil is used to designate the underlying material.

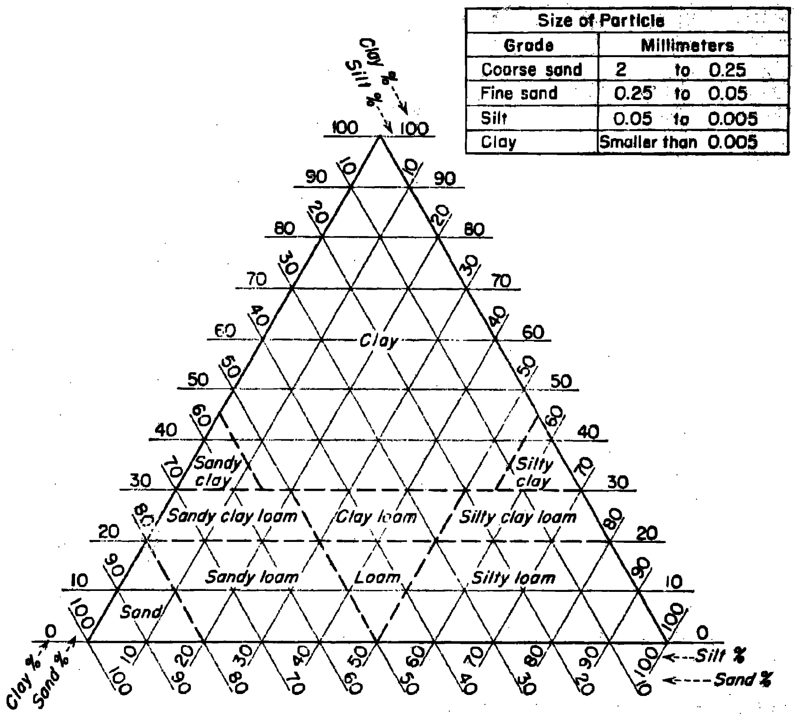
Table 3-1

Gravel . .	Over 2.00 mm
Sand . .	2.00 mm 0.05 mm
Silt	0.05 mm 0.005 mm
Clay	Smaller than 0.005 mm
Colloids . .	Smaller than 0.001 mm

Soil Classification. Soils may be classified according to the grain size of the granular mineral material as indicated Table 3-1. There is not complete agreement as to the limits of the size of the various constituents.

The separation into grain size by sieving is relatively simple down to 0.074 mm, which corresponds to a 200-mesh standard sieve. Below that size the gradation must be made by determining the rate of settlement in water, which is in part a function of the grain size. Some difficulties exist in the test procedures, producing results that are not entirely accurate.

Water is an important constituent of soil and may occur as free water or be absorbed. Water enters the soil by gravity flow from rain water and melting snow or by capillarity from an underlying source. Some inorganic chemical compounds occur in soils and have some importance because certain ones tend to flocculate fine-grained soils, while other compounds tends to deflocculate these soils. The mineral composition of fine-grained soils may be as important as the grain size.



Size of Particle	
Grade	Millimeters
Coarse sand	2 to 0.25
Fine sand	0.25 to 0.05
Silt	0.05 to 0.005
Clay	Smaller than 0.005

Fig. 3-1. Textural classification of subgrade soils. (After chart prepared by Public Roads Administration.[8])

Natural deposits of soils may consist of any combination of the several constituents. Here again, there is not complete agreement as to name, and owing to the diversity of combinations soils may be called blue clay, yellow clay, stiff blue clay, sandy loam, sandy clay, etc. These terms may mean one thing to one investigator and another to a second. The soil classification by "texture" is given in Fig. 3-1. It will be noted that the term "clay" here applies to a soil that may consist of varying percentages of sand, silt, and clay, as previously defined by particle size. The percentage ranges are sand, 0 to 50; silt, 0 to 50; and clay, 30 to 100.

Properties of Soils. *Particle Size and Shape.* The shape and size of soil particles influence or produce certain properties. Sand grains are somewhat spherical in shape, while clay grains are elongated or flat. The size and shape influence the arrangement of the particles in the soil mass and the resultant properties. Sand is less compressible than clay, and gravitational water flows through sand more readily than through clay.

Permeability. Permeability is the rate at which gravitational water flows through a soil and depends upon the size and continuity of the pores, the hydraulic gradient, and other factors

Shearing Strength. The supporting power of a soil is its ability to resist penetration or lateral flow. The shearing strength is made up of two elements: the friction between the soil particles—internal friction—and the attraction of the soil particles, or cohesion. Cohesion in turn consists of two elements: true cohesion—the molecular attraction of particle to particle—and apparent cohesion—the molecular attraction of water. Internal friction is greatest in sand and least in clay, while cohesion is greatest in clay and least in sand.

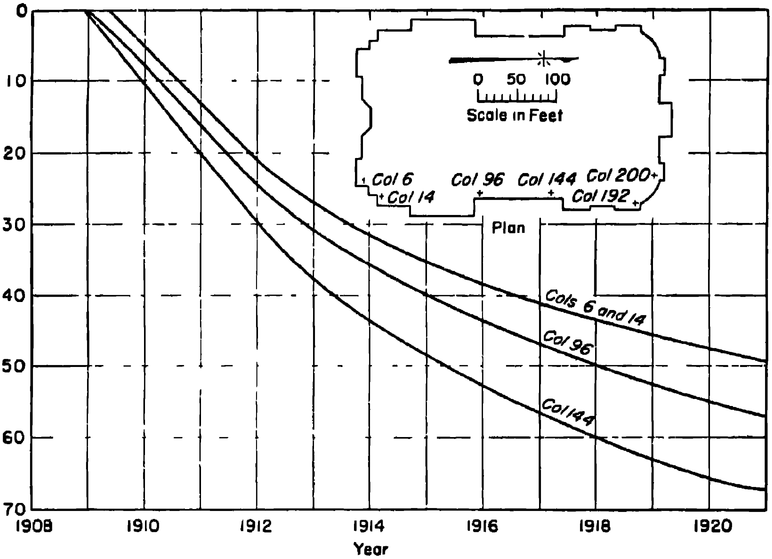


FIG. 3-2. Settlement curves of various columns of National Theater, City of Mexico, Mexico. (*Earths and Foundations, Proc ASCE, May,* 1933)

Capillarity Capillarity is that property of a soil which enables it to draw water from some source and transmit it in all directions against the force of gravity. Surface tension is the force that pulls the water against gravity and occurs when both air and water are present in the soil and the pores are of appropriate size The height to which water will rise depends upon the affinity of the particular soil for water and the diameter of the pores. For equal affinities the height is inversely proportional to the pore diameter. The rate of rise as well as the height is important. The rate of rise is inversely proportional to the diameter of the pores.

As the capillarity water evaporates, the surface tension causes a compressive force in the soil, and the soil will shrink When the surface tension is destroyed by "flooding," the soil expands. The large cracks that develop when "mud" flats dry out are examples of shrinkage.

Density. Density of a soil represents the extent to which the soil has been consolidated. It is a function of the relation of the volume of voids and the volume of soil particles in a given volume of soil. The specific gravities of soil particles vary over a relatively small range, and as there may be as much as 75 or 80 lb per cu ft difference in the weight of soils, these differences in weight are due to the variation in voids. The ratio of the volume of voids to the volume of soil is called the "percentage of voids," and the ratio of the volume of voids to the volume of soil particles is called the "voids ratio." Voids are sometimes called "pores."

The voids in sand are of relatively large size and therefore offer little resistance to the flow of water. The voids or pores in clay are relatively small and offer high resistance to the flow of water, although the total volume of voids may be more in clay than in sand.

Compressibility. Compressibility of a soil is a measure of the reduction in volume as load is applied. Generally the unit pressures are so small that the deformation of the individual soil particles is negligible, and therefore the settlement is due to the reduction of the volume of voids or lateral flow. As the volume of voids is reduced, water or air (or other gases) will be expelled from the voids.

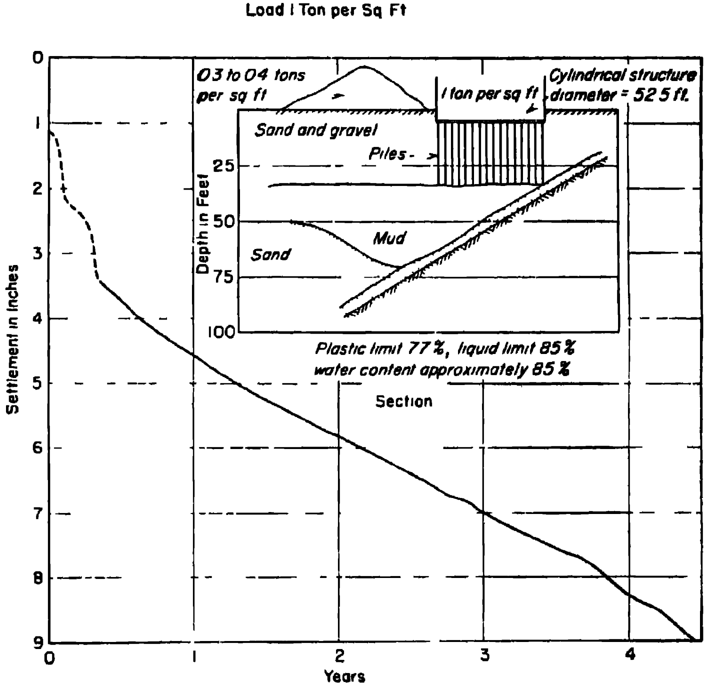

FIG. 3-3. Settlement of oil tank on wooden piles due to consolidation of mud layer. (*Earths and Foundations, Proc. ASCE, May,* 1933.)

The settlement of sands is relatively small unless there is a rearrangement of the soil particles due to a sudden shock. The settlement of clays, on the other hand, may be considerable and may take place over an extended period of time because of the high resistance to the flow of water or gas offered by the clay (see Figs. 3-2, 3-3, and 3-4).

Elasticity. Elasticity is that property of a soil which causes it to rebound after an applied load is removed. Sands are not elastic, while clays under low load are.

Plasticity. Plasticity is that property of a soil which enables it to undergo a marked change in shape without change in volume. Sands are not plastic.

Soil Tests. The foundations of buildings or similar structures, when founded on unconsolidated soils, are placed at some depth and on soils that are relatively undisturbed, whereas the subgrade for a highway, airport, or storage area is considerably disturbed by the very nature of the construction methods. The shear and consolidation tests on the soil of the first case are therefore generally made on "undisturbed" samples. The various tests on subgrade soils are generally made on disturbed samples.

The more common tests on subgrade soils are liquid limit, plastic limit, shrinkage limit, centrifuge-moisture equivalent, field-moisture equivalent, and density. Part or all of these are covered by ASTM standards.

The liquid limit of a soil is the minimum amount of moisture that will cause the soil to flow under a small force. The plastic limit is the smallest moisture content at which the soil can be rolled into a ⅛-in. diameter thread without breaking. The difference between the liquid limit and the plastic limit is the plasticity index. The plasticity index is a measure of the cohesion of the soil.

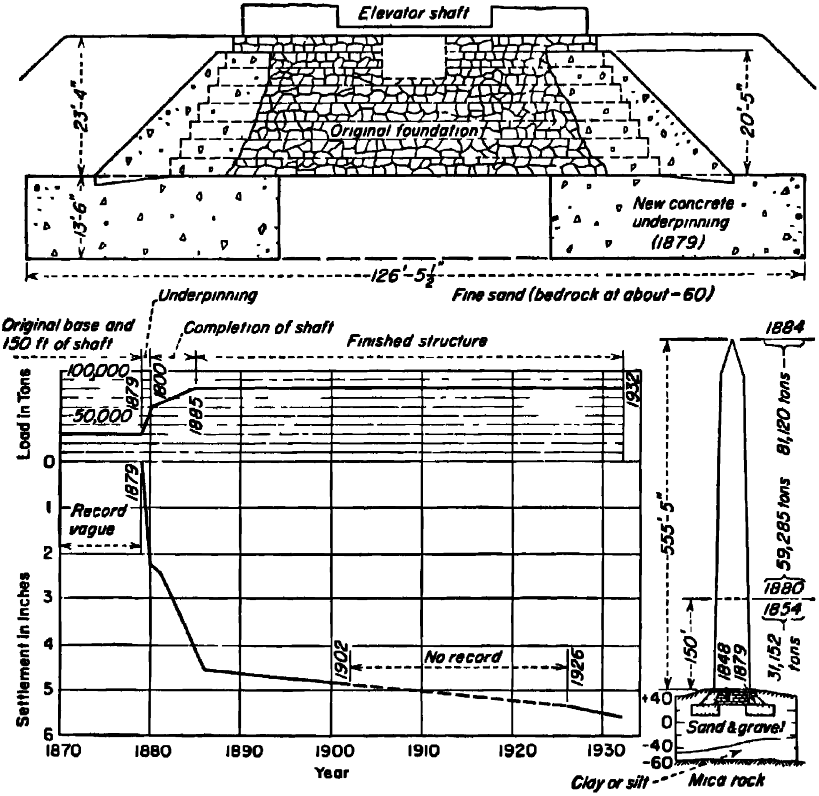

FIG. 3-4. Settlement record of Washington Monument. (*Earths and Foundations, Proc. ASCE, May*, 1933.)

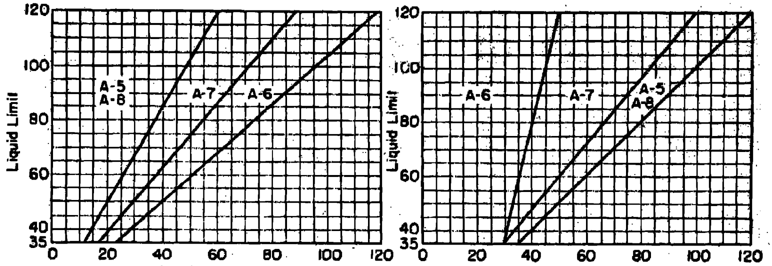
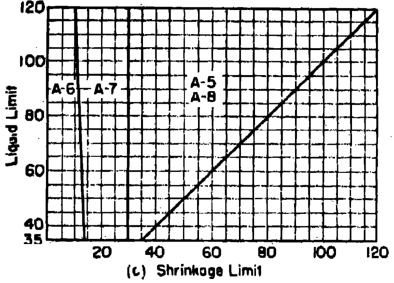
The shrinkage limit is the moisture content at which further evaporation does not cause additional shrinkage. This is the point at which the capillarity force equals the resistance of the soil particles to further consolidation.

The centrifuge-moisture equivalent is the moisture content of a soil that was previously saturated and subjected to a specified centrifugal force for a specified period of time. The centrifuge-moisture equivalent is indicative of the capillarity and permeability of the soil.

The field-moisture equivalent is the minimum moisture content at which a drop of water placed on a sample will not be immediately absorbed. The field-moisture equivalent is the starting point for determining volume change when the moisture content is reduced to the shrinkage limit. A volume change of 15 to 20 per cent between these moisture contents appears to be the dividing line between stable and unstable subgrade soils.

The Public Roads Administration has established eight classifications of soils. A summary of the characteristics and suitability for use of these soils under various conditions is given in Table 3-2 and Fig. 3-5.[1]





GROUP	A-1	A-2	A-3	A-4	A-5	A-6	A-7	A-8
Coarse material	0-65	+	+	+	+		+	
Soil mortar total sand	70-85	55 min.	+	55 max.				
Coarse sand	45-60	+	+	+	+		+	
Silt	10-20	+	+	+	+		+	
Clay	5-10	+	+	+	+		+	
Percentage passing No. 200 sieve	+	+	0-10	+	+		+	
Liquid limit	14-35	35 max.	N.P.	20-40	35 min			
Plasticity index	4-9	N.P.-15	N.P.	0-15	See chart (a)			
Field moisture equivalent	+	+	+	30 max.	See chart (b)			
Centrifuge moisture equivalent	15 max.	25 max.	12 max.	+	+			
Shrinkage limit	14-20	+	+	20-30	See chart (c)			

Note – Only the A-1 materials with values of liquid limit not greater than 25 and values of plasticity index not greater than 6 are suitable for use in base courses for thin flexible surfaces.

+ Not essential N.P. Nonplastic

FIG. 3-5. Range of soil characteristics. (*Courtesy of Public Roads Administration, Federal Works Agency.*)

FOUNDATION TYPES

The type of foundation selected for a particular structure depends upon the loads to be transferred to the foundation bed, upon the material on which the structure is founded, and upon the method of placing the foundation, which in turn depends upon the material. The purpose of the foundation is, of course, to distribute the load of the structure so that the settlement will not cause excessive maintenance or impair the usefulness of the structure.

The foundation of a light building may be simply a foundation wall founded upon rock or hardpan. This would be possible where a suitable foundation bed is near the surface or near the line of basement excavation.

When soil of lower bearing capacity is encountered, it may be necessary to increase the bearing area by the addition of a footing, as indicated in Fig. 3-6*b*, in order to reduce the pressure so that undue settlement will not take place. On simple structures the footings are usually made of plain concrete, and in such cases the projection b' (Fig. 3-6*b*) should not be greater than the depth of the footing and preferably less, say a ratio of b' to d of 2 to 3. When the projection b' is greater than the depth, transverse reinforcement is required, and the footing should be designed as a cantilever beam. The footing must be so proportioned that the shearing stress is within the limits set for beams without web reinforcement (Fig. 3-6*d*).

Table 3-2. Summary of Soil Characteristics and Classification

Group	A-1	A-2		A-3	A-4	A-5	A-6	A-7	A-8
		Friable	Plastic						
General stability properties	Highly stable at all times	Stable when dry, may ravel	Good stable material	Ideal support when confined	Satisfactory when dry, loses of stability when wet or by frost action	Difficult to compact, stability doubtful	Good stability when properly compacted	Good stability when properly compacted	Incapable of support
Physical constants:									
Internal friction	High	High	High	High	Variable	Variable	Low	Low	Low
Cohesion	High	Low	High	None	Variable	Low	High	High	Low
Shrinkage	Not detrimental	Not significant	Detrimental when poorly graded	Not significant	Variable	Variable	Detrimental	Detrimental	Detrimental
Expansion	None	None	Some	Slight	Variable	High	High	Detrimental	Detrimental
Capillarity	None	None	None	Slight	Detrimental	High	High	High	Detrimental
Elasticity	None	None	Some	None	Variable	Detrimental	None	High	Detrimental
Textural classification. General grading	Uniformly graded coarse-fine, excellent binder	Poor grading, poor binder	Poor grading, inferior binder	Coarse material only, no binder	Fine sand, cohesionless silt, and friable clay	Micaceous and diatomaceous	Deflocculated cohesive clays	Drainable flocculated clays	Peat and muck
Approximate limits:

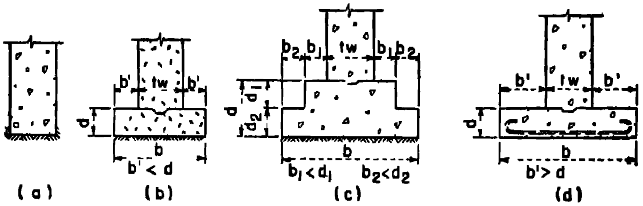
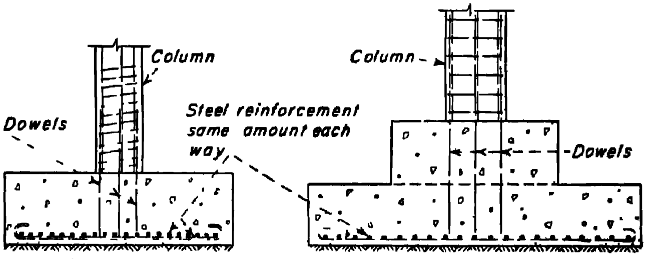
Where a considerable projection is required and it appears undesirable to use reinforcement, some saving in the quantity of concrete may be made by stepping the footing. In such a case, each projection must be proportioned as above. While there is some saving in the quantity of concrete in the stepped footing, the increased cost of forms may amount to more than the saving in the cost of the concrete (Fig. 3-6c).



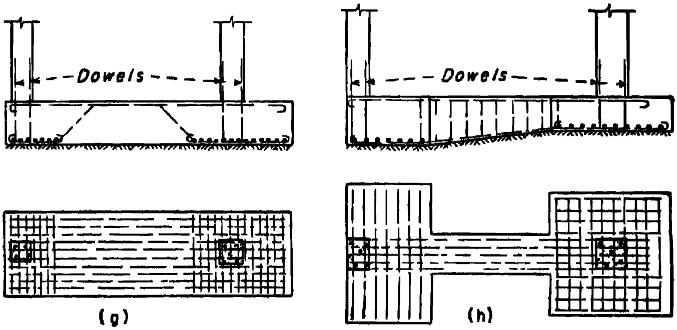
Cross-sections of foundation wall footings



(e) plain

(f) stepped

Simple spread footings (usually square in plan)



Combined footing

Cantilever footing

Fig. 3-6. Typical footings.

Spread footings may be used to distribute moderate column load to the foundation bed. They may appear as separate footings under individual columns, combined to distribute the load of two columns, or as a raft where several columns are supported on a continuous slab (see Figs. 3-6e, f, g, and h).

While the footings shown in Figs 3-6e and g are sketched as made of reinforced concrete, they be made of timber or steel and are then generally referred to as "grillages." Grillages may also be used to distribute the load from steel columns to concrete piers.

Piles are used to distribute the load to greater depths of soils of relatively low bearing values or to transfer the load through such soil to a more desirable material at lower depths. Piles may also be used to consolidate the material into which they are driven. The load is transferred from the pile to the foundation material by shearing forces along the pile, friction, or by bearing at the end of the pile, or by both friction and bearing. When the load is transferred primarily by friction, the pile is called a "friction pile," and when the load is transferred primarily in bearing, the pile is called a "bearing pile."

Timber piles may be used where the driving is relatively easy, and untreated piles should be cut off below the permanent ground-water level. Timber piles are susceptible to marine borers. Several species of wood provide satisfactory piles, especially Douglas fir, cedar, oak, and southern pine. Timber piles should not be overdriven.

Concrete piles may be cast in place or precast. Precast piles should be designed to withstand stresses caused by handling and driving as well as other applied loads. Cast-in-place concrete piles are generally made by driving a metal casing, with or without a mandrel, and filling the shell with concrete. In some cases the shell may be withdrawn as the concrete is poured. Also, hollow steel cylinders may be driven to the desired depth and the material within the shell removed by the use of compressed air and the cylinder filled with concrete. This type is called a "pipe pile." The diameter may vary from 6 or 8 in. to 36 in. or more. The larger sizes are sometimes referred to as "piers." Various methods have been developed for driving the cylinders.

Where long piles are required and the ground water is at a considerable depth, a combination timber and concrete pile may be used. The timber portion is driven to ground level by ordinary means, and then a follower is used to force the timber to the desired depth. The follower is withdrawn and the hole filled with concrete. A casing around the follower may or may not be required. A positive connection between the timber and the concrete is necessary.

Steel H-piles may be used where heavy loads are involved and where difficult driving may be encountered, such as through gravel or shale. H-piles do not displace as much material as timber or concrete piles.

METHOD OF PLACING FOUNDATIONS

While the method of placing foundations is listed here under a separate heading, it cannot be entirely separated from the type of foundation or from the particular conditions at a given site. The type of soil and the presence or absence of water are controlling factors both as to type and methods of placing and also influence the depth to which the foundations must be carried. The requirements for the support of adjacent structures must be considered.

Column footings for a light mill building without a basement may be placed in relatively shallow pits and generally present no serious problem. Buildings with one or more basements may create difficult problems. In relatively dry ground the pit may be excavated with sloping sides or by the use of sheathing If water is present, it may be controlled by pumping from sumps or by the installation of a system of well points whereby the water table is lowered over the entire area of excavation. If buildings or streets adjoin the new structure, bracing will frequently be required to prevent the caving of the ground with resultant damage to existing structures.

The columns of heavy buildings that are to be erected on a site where there is a considerable depth of stiff clay may be carried on concrete piers or caissons extending to rock or other suitable foundation material. In such cases the piers are usually constructed by the open-well or poling-board method (sometimes called the Chicago method). The diameter of the pier depends upon the column load. A section 4, 5, or 6 ft deep is excavated, and vertical sheathing fitted in the form of a cylinder is placed and held by channels bent to appropriate radius. The next lower section is then excavated and the lagging placed. The procedure is repeated until the excavation is of proper depth, *i.e.*, until suitable foundation material is reached. The open cylinder is then filled with concrete. Moderate amounts of water can be handled by pumping. Care should be exercised not to disturb existing structures by excessive pumping. In some cases it may be desirable to cap the cylinders and complete the excavation under air pressure.

Cofferdam. A cofferdam is an enclosure around an area in which the foundation is to be placed. The enclosure may be made of any material, but it is frequently made of steel-sheet piling or timber. It may be constructed with a single wall or with a double wall. Usually the cofferdam does not become a part of the foundation.

The cofferdam may be pumped out and the excavation carried on in the dry or the excavation may be made by dredging through the water. Likewise, the concrete may be placed in the dry, or a seal may be placed by pouring the concrete through the water with a tremie and then dewatering the cofferdam. The remaining concrete is then placed in the dry. The latter method is usually employed on bridge piers and similar structures.

Open Caisson. The open caisson is more generally used for the construction of bridge piers than for the foundations for buildings It might be a suitable method of construction for the foundation for a heavy stack under appropriate conditions.

An open caisson consists of a boxlike structure made of several vertical cells and generally provided with a false bottom in each cell. The caisson is placed in position and enough of the false bottoms removed to permit the caisson to sink. Excavation is carried out through the cells by means of an orange-peel or clamshell bucket, and by dredging in the various cells the caisson can be maintained in an upright position. As the excavation progresses, the caisson sinks, and additional height is added by pouring concrete in the walls or some of the closed cells. The alternate operations of excavation and concrete pouring continue until the bottom of the caisson reaches the desired depth. A diver then usually examines the foundation material and cleans and prepares it for final concreting. The bottom of the caisson is sealed by tremie concrete, and after that concrete has attained sufficient strength the various cells are unwatered and the remaining concrete placed in the dry.

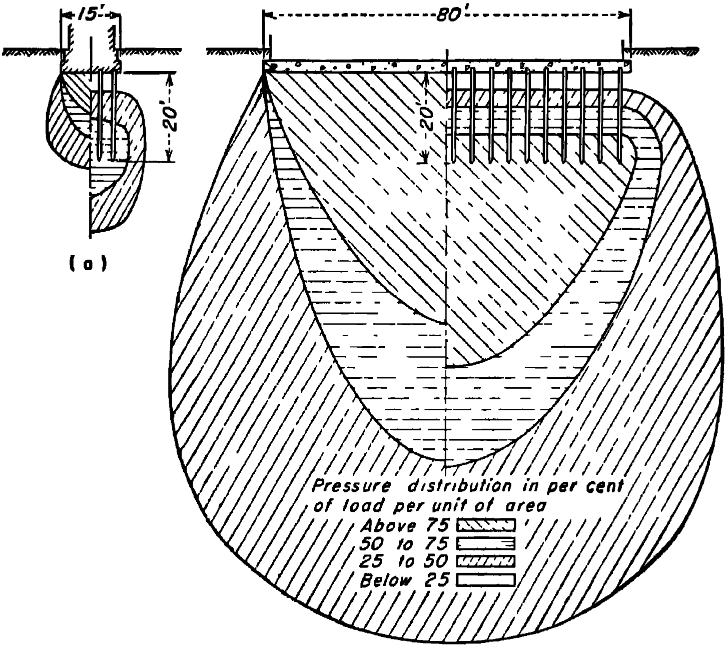
Pneumatic Caisson. A pneumatic caisson is essentially a boxlike structure, open at the bottom and closed at the top, in which compressed air is used to balance the water pressure on the outside. The excavation and placing of the concrete is done in the dry. Workmen are admitted to and excavated material is removed from the working chamber through air locks. As excavation progresses and the caisson sinks, additional height is added to the top. When the final grade is reached, the foundation bed is cleaned, and a concrete seal is poured while the necessary air pressure is maintained. After the concrete seal has attained sufficient strength, the air is released and the remaining concrete poured under atmospheric pressure.

FOUNDATION PRESSURES

The load from a foundation will be distributed in some manner to the foundation material, and pressures of varying intensities will develop in the material somewhat as indicated in the left half of Fig. 3-7a. The pressure lines form what is called the "bulb of pressure." The extent of the pressure bulbs depends upon the width of the loaded area. The pressure lines represent some fractional part of the unit pressure $p = P/A$, where P is the applied load and A is the area of the foundation. Lines of equal pressure are called "isobars." Studies by Terzaghi[2] indicate that for an ideal material (a perfectly elastic, isotropic, semi-infinite solid) about 80 per cent of the settlement of a foundation can be accounted for by the distortion of the material within the $0.2p$ pressure line. The depth of the $0.2p$ pressure line below the bottom of the foundation is about 1.5 times the width of the foundation. The load from piles develops similar pressure bulbs.

The pressure bulbs of closely spaced footings overlap and form a large bulb for the foundation as a whole. Likewise, the pressure bulbs of the individual piles in a group overlap and form a bulb for the group. The load capacity of a group of footings or of a group of piles is not directly proportional to the number of footings or the number of piles. The total is less. The settlement of a foundation covering a large area may be as much with piles as without piles. In other words, in some cases there may be no advantage in using piles. This situation is illustrated in Fig. 3-7.[3]

Settlement. The principal part of the settlement of a structure is due to two elements—the lateral and possible upward movement of the soil and the compression of the soil under the foundation. For footings near the surface the lateral movement of the soil may produce heaving around the foundation. The depth of the footing below the surface is a factor in lateral movement. Foundations placed on firm sand or gravel underlain with a strata of peat or other soft material may settle a considerable amount owing to the lateral flow of the soft material, and the heaving due to lateral movement may occur at some distance from the foundation.



(a)

(b)

FIG. 3-7. Pressure distribution under a foundation. (*Terzaghi, Charles, The Science of Foundations—Its Present and Future, Trans. ASCE, Vol. 93, 1929.*)

Distribution of Pressure. The distribution of pressure under an isolated footing placed at some depth below the surface on clay varies from a maximum at the edge of the footing to a minimum at the center. For a similar footing on sand the pressure varies from a minimum at the edge to a maximum at the center. The greater the depth, the more nearly are the edge and center pressures alike. Uniform pressures are usually assumed for design purposes. For isolated footing the assumption appears to be on the safe side, but for combined or mat foundations the assumption may be on the unsafe side.

Bearing Pressures. Elaborate investigations of the soil properties at a given site can be justified only in the case of a large, expensive structure. The cost of complete investigation for a minor job is prohibitive. Accordingly, the design of the foundation is usually based upon some allowable soil pressure which is the result of experience on similar sites. Building codes give a set of bearing pressures permitted on various soils. There is not complete agreement among the listed values.

Examination of the surface is generally not sufficient to determine the character of the soil at various depths, and unless data from adjoining structures are available, borings should be made to evaluate the kind of material that exists to a depth of about $1\frac{1}{2}$ times the width of the foundation The soil near the surface may be compact sand or gravel, which would indicate a satisfactory material If, however, a strata of soft material exists below the firm material, considerable settlement may be expected unless the appropriate bearing pressures are used Some of the more recently revised building codes recognize this situation

Table 3-3. Suggested Permissible Bearing Values

Type of soil	*Kips/sq ft*
Soft clay	2
Fine wet confined sand	4
Sand and clay mixed	4
Dry coarse sand	6–8
Hard clay	6–8
Gravel	10–12
Hardpan	16–20
Rock	30–40

Pressure on Planes at Various Depths The computation of the intensity of pressure on planes at varying depths below the foundation is most conveniently done by the use of influence charts which have been developed by N M Newmark[4]

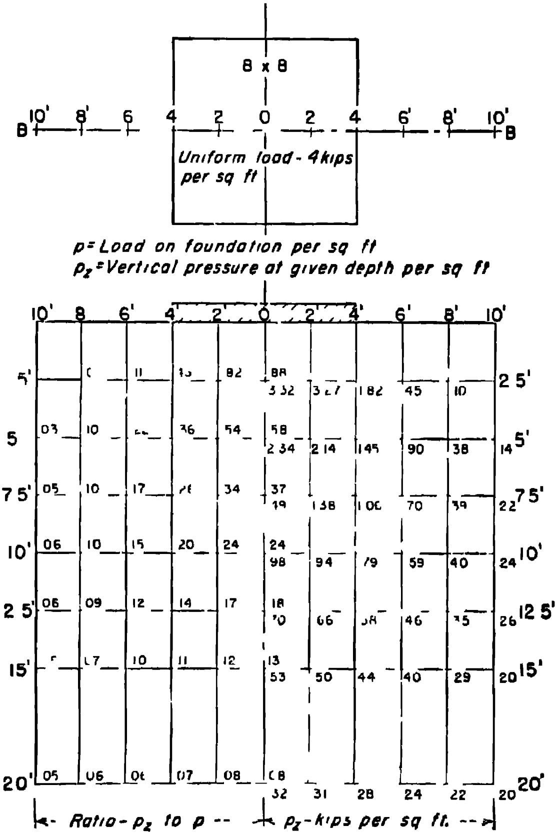


Fig 3-8 Vertical pressures on horizontal planes along center line of 8- by 8-ft footing. Uniform load, 4 kips per sq ft

Figure 3-8 gives the intensity of vertical pressure on various horizontal planes under a single spread footing 8 ft square The values on the left half of the chart are the ratios p_z/p of the intensity of vertical pressure at a given point to the intensity of loading. The values on the right half of the chart are the vertical pressures in kips per square foot at various points due to a load of 4 kips per sq ft. Figure 3-9 gives similar values for a foundation 40 ft square loaded uniformly with 4 kips per sq ft. Note the ratio of p_z to p in both Figs. 3-8 and 3-9 at a depth of about 1½ times the width. Note also that for the 8- by 8-ft footing the values are given for a depth of 12.5 ft and for the 40- by 40-ft foundation the depth is 60 ft. Comparison at a depth about equal to the width of the loaded area may also be made.

FIG. 3-9. Vertical pressures on horizontal planes along center line of 40- by 40-ft footing. Uniform load, 4 kips per sq ft.

SPREAD FOOTINGS

The design of wall and column spread footing is usually based upon the recommendations given by A. N. Talbot.[5] These recommendations have been frequently incorporated into various codes. The current Building Regulations for Reinforced Concrete (ACI 318-41)[6] makes allowance for bending moments approximately 15 to 20 per cent greater than those computed under the recommendations of Talbot.

The following design computations for plain wall footing, reinforced wall footing, and spread footing for a single column are based on the recommendations of the 1941 Building Regulations for Reinforced Concrete of the American Concrete Institute. The combined footing is designed under the recommendations of the 1940 Report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete.

Wall Footings. Specifications: 1941 ACI Building Regulations.

$f_c' = 2{,}000$ psi $\qquad j = 1 - 0.143 = 0.857$

$f_s = 18{,}000$ psi $\qquad p = \dfrac{0.429 \times 900}{2 \times 18{,}000} = 0.0107$

$n = 15$

$k = 900 \div 2{,}100 = 0.429 \qquad R = \dfrac{900 \times 0.429 \times 0.857}{2} = 165$

18-in. concrete wall and applied load = 25,000 lb per ft of wall
Allowable soil pressure = 5,000 psf

Plain Concrete Footing

Tension in concrete $\gtrless 0.03 f_c' = 60$ psi

25,000 ÷ 5,000 = 5 ft Use 5 ft 6 in.
−1 ft 6 in.
4 ft 0 in. ÷ 2 = 2 ft 0 in. projection each side

$M = (25{,}000 \div 5{,}000) \times 2 \times 1 = 9{,}100$ ft-lb

$d^2 = \dfrac{9{,}100 \times 12 \times 6}{12 \times 60} = 910$

$d = 30.2$ in. Use 30 in. Wt = 375 psf

25,000 ÷ 5,000 = 4,550
+ 375
4,925 psf OK

Diagonal tension OK $d >$ projection

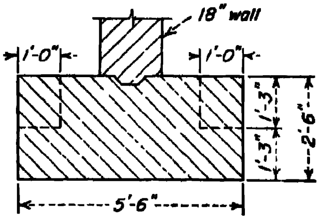

FIG. 3-10.

NOTE: Some saving in concrete may be made by stepping footing as indicated by dotted lines. Added cost of formwork may be greater than saving in cost of concrete.

Reinforced Footing. Same wall, load, and bearing pressure as above.

25,000 ÷ 5,000 = 5 ft 0 in. Use 5 ft 3 in.
− 1 ft 6 in.
3 ft 9 in. ÷ 2 = 1 ft $10\frac{1}{2}$ in.

25,000 ÷ 5.25 = 4,760 psf

$M = 4{,}760 \times 1.87 \times 0.93 = 8{,}300$ ft-lb

$V = 8{,}900$ lb

$d = \sqrt{\dfrac{8{,}300 \times 12}{165 \times 12}} = 7.1$ in.

Try 7 in.
+ 3 in. cover
10 in. over-all

$A_s = 7 \times 12 \times 0.0107 = 0.91$ sq in. per ft

FIG. 3-11.

$\Sigma 0 = \dfrac{8{,}900}{\frac{7}{8} \times 7 \times 112} = 13$ in. per ft Too much

Increase d to 12 in. 15 in. over-all

$\Sigma 0 = 13.0 \times 7/12 = 7.7$ in. per ft

$$A_s = \frac{8,300 \times 12}{0.86 \times 12 \times 18,000} = 0.54 \text{ sq in. per ft}$$

Use ½-in. diam, 3-in. centers $A_s = 1$ sq in. per ft $\Sigma 0 = 8.0$ in. per ft

$V = 4,760(1.87 - 1.00) = 4,150$

$$v_c = \frac{4,150}{7/8 \times 12 \times 12} = 33 \text{ psi}$$ Diagonal tension OK

v, allowable $= 60$ psi

$$\begin{array}{r} 4,760 \\ +\ \underline{190} \\ 4,950 \end{array}$$ psf OK

Spread Footing. Specifications: 1941 ACI Building Regulations

Column load = 325 kips

Column = 18 in. × 18 in.

Allowable pressure = 6 ksf

$f_c' = 2,000$ psi

$f_s = 18,000$ psi

$R = 165$

$u = 112$ psi, deformed and hooked

$A = 325 \div 6 = 54.2$ sq ft $7.5 \times 7.5 = 56.3$ sq ft $325 \div 56.3 = 5.78$ ksf

$M = 7.5 \times 3.0 \times 1.5 \times 5.78 \times 0.85 = 166$ ft-k

$V_{\text{bond}} = 7.5 \times 3.0 \times 5.78 \times 0.85 = 110$ kips

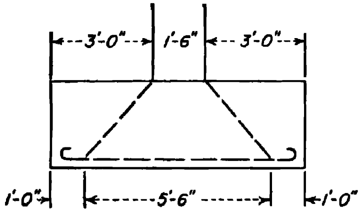

Fig. 3-12. Spread footing section for diagonal tension.

$$d = \sqrt{\frac{166,000 \times 12}{90 \times 165}} = 11.6 \text{ in.}$$

Say 12 in.

$$A_s = \frac{166 \times 12}{0.86 \times 12 \times 18} = 10.7 \text{ sq in.}$$

$$\Sigma 0 = \frac{110,000}{0.86 \times 12 \times 112} = 94 \text{ in.}$$

Too much

Make $d = 24$ in. Over-all depth = 28 in.

$$A_s = \frac{10.7 \times 12}{24} = 5.3 \text{ sq in.}$$

$$\Sigma 0 = \frac{94 \times 12}{24} = 47 \text{ in.}$$

Use 20 ¾-in.-diam bars $A_s = 8.8$ sq in. $\Sigma 0 = 47.2$ in. OK

$$V = \frac{7.5 + 5.5}{2} \times 1.0 \times 5,780 = 37,600 \text{ lb}$$

$$v = \frac{37,600}{66 \times 24 \times 0.86} = 27 \text{ psi}$$

OK. Allowable = 60 psi

$5,780 + 350 = 6,130$ psf Little high, OK

Length of dowels—column steel ⅞ in. diam:

$$l = \frac{16,000 \times 7/8}{4 \times 112} = 31 \text{ in.}$$

Use 26 in. × 26 in. × 6 in. pedestal

$$\text{In column } l = \frac{16,000 \times 7/8}{4 \times 150} = 24 \text{ in.}$$

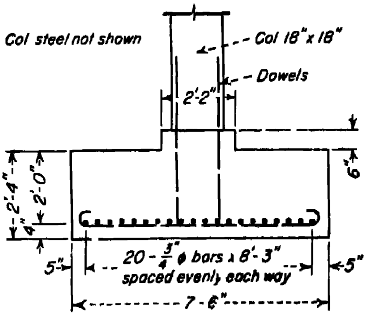

Fig. 3-13. Spread footing.

Transfer of compressive stress in concrete at base of column:

Column steel = 12 – ⅞ in. diam $\quad A_s = 7.2$ sq in.

$$f_c = \frac{325{,}000 - 7.2 \times 16{,}000}{324} = 645 \text{ psi}$$

Allowable on pedestal:

(*a*) Full area loaded = 0.25 × 2,000 = 500 psi

(*b*) ⅓ or less loaded = 0.375 × 2,000 = 750 psi

$$\text{Permissible ratio of loaded area to total area} = 1 - \left[\frac{(645 - 500)(1 - 0.33)}{250}\right] = 0.61$$

Minimum area of pedestal = 324 ÷ 0.61 = 530 sq in.

Area provided = 26 in. × 26 in. = 672 sq in. $\quad$ OK

Combined Footing. Specifications: 1940 Joint Committee Report.

$f_c' = 2{,}000$ psi $\quad R = 165$

$f_s = 18{,}000$ psi $\quad p = 0.0107$

$n = 15$ $\quad u = 112$ psi

$k = 0.43$ $\quad v = 60$ psi

$j = 0.86$ $\quad$ Use end anchorage.

Exterior column No. 11 $\quad$ 16 in. × 16 in. $\quad$ load, 176 kips

Interior column No. 21 $\quad$ 18 in. × 18 in. $\quad$ load, 272 kips

Maximum distance from property line to center line of exterior column No. 11 is 1 ft 1 in

Columns are 14 ft 0 in. on centers

Allowable soil pressure = 5 ksf

$$\text{Column No. 11 to center of gravity of footing} = \frac{272 \times 14}{448} = 8.5 \text{ ft}$$

Length of footing = (8.5 + 1.1) × 2 = 19.2 ft $\quad$ Use 19 ft 0 in.

Estimated weight of footing = 50 kips

Area required = (176 + 272 + 50) ÷ 5 = 99.6 sq ft

19 ft × 5 ft 3 in = 99.7 sq ft

Longitudinal Beam

$$d_M = \sqrt{\frac{484{,}600 \times 12}{165 \times 63}} = 24 \text{ in.}$$

$$v_c\text{, 2 ft to left of column 21} = \frac{112{,}700}{0.86 \times 24 \times 63}$$

= 87 psi $\quad$ Too high without web reinforcement

Make d = 30 in. $\quad$ Over-all depth = 31 in.

$$v_c\text{, 2 ft 6 in. to left of column 21} = \frac{100{,}900}{0.86 \times 30 \times 63}$$

= 62 psi $\quad$ OK. 60 psi allowable

$$A_s = \frac{484.6 \times 12}{0.86 \times 30 \times 18} = 12.5 \text{ sq in.}$$

$$\Sigma 0 = \frac{159{,}900}{0.86 \times 30 \times 75 \times 1.5} = 55 \text{ in.}$$

Use 17 1-in.-diam bars, negative steel in top between columns

A_s = 13.4 sq in. $\quad \Sigma 0$ = 53.4 in. $\quad$ Anchor bars

Interior end, right of column 21:

$$A_s = \frac{130 \times 12}{0.86 \times 30 \times 18} = 3.35 \text{ sq in.}$$

$$\Sigma 0 = \frac{76{,}700}{0.86 \times 30 \times 75 \times 1.5} = 26.5 \text{ in.}$$

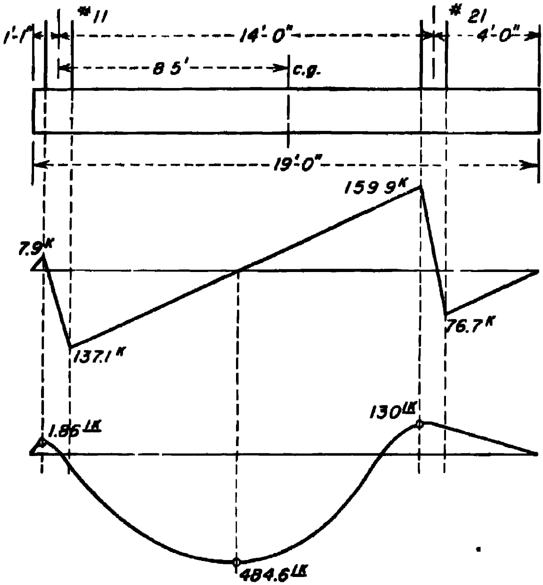

FIG. 3-14. Combined footing shears and moments.

Use 14 $\frac{5}{8}$-in.-diam bars in bottom
$A_s = 4.34$ sq in. $\Sigma 0 = 27.4$ in. OK

Exterior end, left of column 11:

$$f_c = \frac{1860 \times 12 \times 6}{63 \times 30 \times 30} = 2.4 \text{ psi} \qquad \text{No steel needed}$$

Transverse Beams

At exterior column 11: Assume effective width of 24 in. for compression

$$M = \frac{176 \times 1.96 \times 1.96}{5.25 \times 2} = 64.3 \text{ ft-k}$$

$$V = \frac{176 \times 1.96}{5.25} = 65.6 \text{ kips}$$

$$d = \sqrt{\frac{64{,}300 \times 12}{165 \times 24}} = 14 \text{ in.} \qquad \text{OK.} \qquad 30 \text{ in. available}$$

$$A_s = \frac{64.3 \times 12}{0.86 \times 30 \times 18} = 1.67 \text{ sq in.}$$

$$\Sigma 0 = \frac{65{,}600}{0.86 \times 30 \times 75 \times 1.5} = 22.6 \text{ in.}$$

Use 12 $\frac{5}{8}$-in.-diam bars $A_s = 3.41$ sq in. $\Sigma 0 = 23.5$ in.
Diagonal tension OK

At interior column 21: Assume effective width of 36 in. for compression

$$M = \frac{272 \times 1.88 \times 1.88}{5.25 \times 2} = 91.5 \text{ ft-k}$$

$$V = \frac{272 \times 1.88}{5.25} = 97.3 \text{ kips}$$

$$d = \sqrt{\frac{91{,}500 \times 12}{165 \times 36}} = 14 \text{ in.} \qquad \text{OK.} \quad 30 \text{ in. available}$$

$$A_s = \frac{91.5 \times 12}{0.86 \times 30 \times 18} = 2.37 \text{ sq in.}$$

$$\Sigma 0 = \frac{97{,}300}{0.86 \times 30 \times 75 \times 1.5} = 33 \text{ in.}$$

Use 17 $\frac{5}{8}$-in.-diam bars $A_s = 5.27$ sq in. $\Sigma 0 = 33.3$ in.
Weight of footing = 19 × 5.25 × 425 = 42,000 lb OK. 50,000 assumed

Transfer of stress at base of columns

Column 11:

$$\text{Area of pedestal} = \left(\frac{675}{500}\right)^2 \times 256 = 626 \text{ sq in.} \qquad \text{Use } 26 \text{ in.} \times 26 \text{ in.} = 676 \text{ sq in.}$$

$$\text{Length of dowels into column} = \frac{16{,}000}{4 \times 150} \times \frac{7}{8} = 23 \text{ in.}$$

$$\text{Length of dowels into footing} = \frac{16{,}000}{4 \times 100} \times \frac{7}{8} = 35 \text{ in.}$$

Use pedestal 26 in. × 26 in. × 5 in.

Column 21:

$$\text{Area of pedestal} = \left(\frac{675}{500}\right)^2 \times 324 = 794 \text{ sq in} \qquad \text{Use } 28 \text{ in.} \times 28 \text{ in.} = 786 \text{ sq in.}$$

$$\text{Length of dowels into column} = \frac{16{,}000}{4 \times 150} \times 1 = 27 \text{ in.}$$

$$\text{Length of dowels into footing} = \frac{16{,}000}{4 \times 100} \times 1 = 40 \text{ in.}$$

Use pedestal 28 in. × 28 in. × 10 in.

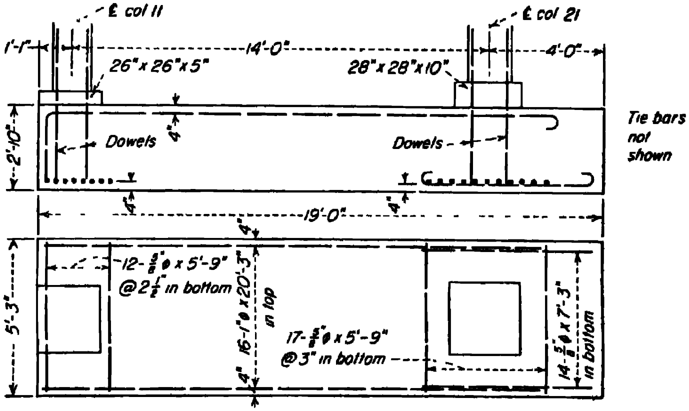

Fig. 3-15. Combined footing.

PILE-DRIVING FORMULAS

Formulas have been developed for computing the safe load on a pile based upon the observed penetration under stipulated conditions, the properties of the driving hammer, and the properties of the soil into which the pile is driven. There are many uncertain elements, and different formulas give different weights to these elements. Comparison of the ultimate load capacity of piles as computed by various formulas and the actual static loads at failure show erratic results.[7] At best, the formulas can be used only as a guide to the judgment of an experienced foundation engineer. It should be emphasized again that the load capacity of a group of piles is not the test load on a single pile multiplied by the number of piles in the group.

BASES AND SURFACES FOR STORAGE AREAS AND FLIGHT RUNWAYS

Table 3-4. Estimated Minimum Thickness of Concrete Runway Pavements[8]

Static wheel load, lb	Minimum slab thickness	
	Excellent subgrade support, in.	Inferior subgrade support, in.*
10,000	6	7
25,000	8	9
40,000	10	11
80,000	12	14

* Excellent support is considered to be furnished by soils of the A-1, A-2, or A-3 groups or by a foundation course of these materials from 12 to 18 in. thick placed on soils of the A-4, A-5, A-6, or A-7 groups. Inferior support [illegible]dered to be furnished by soils of the A-4, A-5, A-6, and A-7 groups without base courses under the pavement.

FLEXIBLE BASES AND SURFACES

Table 3-5. Total Combined Thickness of Subbase, Base Course, and Surface Course, In.[8]

Wheelloads, lb	10,000	25,000	40,000	80,000
Class of soil	Thickness, in.			
A-1	0-6	3-6	3-9	4 12
A-2 (friable)	0 6	3-6	3 9	4 12
A-2 (plastic)	2 8	4 10	6 12	8 15
A-3	4-6	5 8	6 9	8 12
A-4	9 18	15 25	18 30	24 36
A-5	9 24	15 30	18 36	24-48
A-6	12-24	18 30	24-36	30 54
A-7	12-24	18-30	24-36	30-54

REINFORCED CONCRETE

BY C. E. O'ROURKE

Late Professor of Structural Engineering, Cornell University

MANUFACTURE AND PROPERTIES OF CONCRETE

Definition. Concrete is a mixture of cement, fine aggregate, coarse aggregate, and water. The water reacts chemically with the cement, causing the water-cement paste to harden and thus bind the aggregate particles together. Concrete mixtures are defined by the relation between the amount of cement, the amount of fine aggregate, and the amount of coarse aggregate, *i.e.*, a 1:2:4 concrete contains 1 part cement, 2 parts fine aggregate, and 4 parts coarse aggregate. These proportions may be specified by weight or by volume, the latter being the more common.

Portland Cement. Portland cement is the principal binding agent or active ingredient in concrete. It is made by pulverizing the clinker obtained in burning an intimate and properly proportioned mixture of argillaceous and calcareous materials with no additions subsequent to calcination except water and calcined or uncalcined gypsum. Portland cement is classed as a hydraulic cement since it will harden under water. In order to be considered satisfactory for concrete work, portland cement should pass such standard specifications as those of the ASTM (see *ASTM Standards*, 1933).

Natural Cement. Natural cement is a hydraulic cement obtained by grinding to a fine powder the clinker resulting from the calcination of an argillaceous limestone (cement rock) at a temperature below fusion. Natural cement costs about the same as portland; it is not so strong as portland, it sets slower, and it is not so uniform in quality. Some natural cements are more resistant to variations of temperature and moisture conditions than portland. The practice of combining a high-grade natural cement with portland, in proportions from 1:6 to 1:3, for use in making concrete for structures with severe exposures is slowly coming into favor.

Special Cements. White portland cement is made of selected materials, low in iron oxide content, burned with iron-free fuel. Its physical properties are practically the same as those of normal portland cements. It is used principally in ornamental structures in which the white color is desired in the architectural treatment.

High-early-strength Portland Cements High-early-strength portland cements are made from mixtures with high lime content and are ground very fine (about ninety-seven per cent passing through a 200-mesh sieve as compared with about eighty-five per cent for normal portland cements). The time of setting is about the same as for normal portland cements, but they harden and gain strength much more rapidly. Concrete made with high-early-strength portland cement will attain in 72 hr a strength equal to that attained in 28 days by a similar concrete made with normal portland cement.

Fine Aggregate. Fine aggregate usually consists of sand, although stone screenings, or other inert materials with similar characteristics, having clean, hard, strong, durable, uncoated grains free from injurious amounts of dust, lumps, soft or flaky particles, shale, alkali, organic matter, loam, or other deleterious substances, may be used. At least 85 per cent of the fine aggregate should pass

Table 3-6

	Percentage by weight
Passing through a 3/8-in. sieve..	100
Passing through a No. 4 sieve .	85 100
Passing through a No 16 sieve.	45 80
Passing through a No 50 sieve.	2-30
Passing through a No 100 sieve	0-5
Removed by decantation... ...	Not more than 3

through a No. 4 sieve (4 meshes per linear inch) and not more than 5 per cent should pass through a No. 100 sieve. Between these two limits the fine aggregate should be well graded. The gradation recommended by the ASTM is as shown in Table 3-6.

Coarse Aggregate. Coarse aggregate should consist of well-graded crushed stone, washed gravel, or other approved materials of similar characteristics, having clean, hard, strong, durable, uncoated particles free from injurious amounts of soft, thin, or laminated pieces, alkali, and organic or other deleterious matter. Coarse aggregate includes all particles larger than ¼ in.; the maximum size allowable depends upon the class of work for which the resulting concrete is to be used. In small reinforced-concrete work, *i.e.*, slabs, beams, and thin walls, a maximum of ¾ in. is usually specified. For larger reinforced-concrete units, a maximum of from 1½ to 2 in. may be used. For mass concrete, derrick stones, or "plums," varying in size up to large boulders which must be handled by a derrick, are satisfactory and desirable.

Coarse aggregate should be well graded from fine to coarse. A common recommendation is that at least 95 per cent should pass the screen designating the largest size; not less than 40 or more than 75 per cent should pass a screen of half the largest size; not more than 10 per cent should pass a No. 4 sieve or more than 5 per cent a No. 8 sieve.

Artificial Aggregates. The artificial aggregates include well-burned boilerhouse cinders, air-cooled blast-furnace slag, and burned clay. Cinders produce a permeable, nailable, low-strength, and lightweight concrete (90 to 110 lb per cu ft, as compared with 140 to 150 lb for stone or gravel concrete). In the best practice the cinders are screened into two or three size groups—fine, medium, and coarse—and the groups are mixed in proper proportions to form a well-graded aggregate. Sometimes natural sand is used as the fine aggregate with coarse cinders as the coarse aggregate, but the resulting concrete is somewhat heavier than an all-cinder concrete, and the nailability is impaired.

Slag from blast furnaces is a hard though porous material of high compressive strength, which offers a very rough surface for the adhesion of the cement. Slag concrete is satisfactory in many cases for massive construction, but generally, on account of its porosity, it should not be used in thin sections exposed to the action of water. The weight will vary materially, depending upon the grading of the slag and the method of manufacture, from about 70 to 100 lb per cu ft.

Burned-clay aggregates produce concretes of practically any desired strength, averaging about one hundred pounds per cubic foot in weight. Burned-clay aggregates, fine and coarse, are sold under various trade names, such as Haydite, Gravelite, etc. The aggregates themselves weigh from 40 to 65 lb per cu ft.

Water. Water used for concrete should be clean and free from oil, acid, alkali, organic matter, or other deleterious substances. Sea water is not so desirable as fresh water, although, where it has been used in plain concrete structures subject to the weathering action of sea water, no greater disintegration has resulted. Sea water should not be used in reinforced-concrete work because of the corrosive effect of salt water on the steel reinforcement.

Proportioning. It is a generally accepted fact that the strength of mortar or concrete depends entirely upon the water-cement ratio, provided (1) that suitable cement and aggregates are used, (2) that the amounts of the aggregates are such as to produce a workable mix, and (3) that proper curing conditions are maintained during the hardening period. Three problems are involved, therefore, in the design of a concrete mixture: (1) the selection of suitable materials, (2) the selection of the proper water-cement ratio, and (3) the determination of the proper quantities of fine and coarse aggregates. A fourth factor, the method of curing, must be considered after the mixture has been placed properly in its final position.

Proportioning is done either by weight or by volume. Proportioning by weight is more accurate owing to the fact that dampness in fine aggregate, and to a lesser extent in coarse aggregate, has a material effect on the volume of the aggregate. Proportioning by weight is expensive on a small job, however, owing to the cost of the necessary weighing hoppers. If proper allowance is made for "bulking," proportioning by volume can be done with a reasonable degree of accuracy. In the following discussion, except where otherwise stated, proportions are given by volume. In any case, one bag of cement weighing 94 lb is considered to be 1 cu ft. Concrete strengths are invariably specified in terms of the unit ultimate compression strength at the age of 28 days of 8- by 16-in. cylinders, prepared, cured, and tested in accordance with ASTM Standard C39-44. In actual construction, concrete strengths will vary from 1,500 psi for mass concrete where great strength is not required to 4,000 psi for the more important structural units, with the most common values ranging from 2,000 to 3,000 psi. Mixtures will vary from as lean as 1:3:6 for mass construction, such as large abutments and gravity retaining walls, to a rich 1:1½:3 or 1:1:2 for comparatively thin and heavily reinforced structural elements where greater workability, durability, and strength are required. In general, the required strength being known (as assumed in the structural design), the proper water-cement ratio (see below) must be determined, and the proportions of fine and coarse aggregate must be selected so as to produce a plastic mass having the desired workability.

Tests should be made during the progress of actual construction work to check the strength of the concrete which is being used in that work. Quite frequently it is impractical to wait for the results of a 28-day test. In such cases samples may be tested at the age of 7 days, and the probable 28-day strength may be computed from the formula

$$f_{28} = f_7 + 30\sqrt{f_7}$$

in which f_{28} = probable 28-day strength, and f_7 = actual 7-day strength.

Water-Cement Ratio. The selection of the proper water-cement ratio for any desired strength under average job conditions may safely be made from the specification for strength of the American Concrete Institute (1928), which is illustrated graphically in Fig. 3-16. The amount of surface moisture contained in the aggregates must be determined and considered as a part of the mixing water.

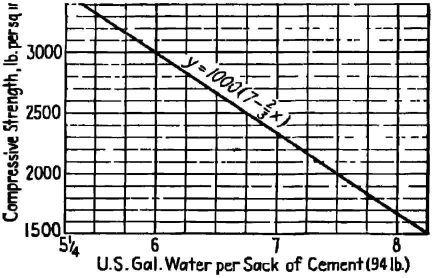

Fig. 3-16.

Quite frequently the strength requirement alone cannot be used as the determining factor in selecting the water-cement ratio. With present-day cements and fair curing conditions, a 2,000-lb concrete, which might economically satisfy ordinary design requirements, may be obtained with a very lean mixture, but the resulting concrete will be neither watertight nor capable of withstanding variations in weather conditions. Maximum water-cement ratios for concretes in various types of constructions and with various conditions of exposure are recommended by F. R. McMillan in "Basic Principles of Concrete Making." These vary from 5½ gal of water per bag of cement for thin sections with extreme climatic exposures to 7½ gal of water per bag of cement for normal structural elements protected from the weather.

Workability. A workable concrete is one that can be worked into all corners of the forms and around the reinforcement without excessive puddling, without segregation of the ingredients, and without the collection of free water on the surface. Workability is influenced by the nature and amount of the fine and coarse aggregates, the water content, and the amount of cement in the mix. A method of measuring the workability, or more properly, the consistency, is the slump test (*ASTM Tentative*

Standard D 138-32T), which is made as follows: A conical shell of 16-gauge galvanized metal with a base 8 in. in diameter, a top 4 in. in diameter and a height of 12 in. is filled to overflowing with concrete rodded into the shell in three separate layers, each receiving 25 strokes of a $\frac{5}{8}$-in. bullet-ended rod 24 in. in length. The excess is carefully struck off, and the mold is at once slowly lifted vertically. The amount of drop of the top of the mass below the original 12-in. height, measured in inches, is known as the "slump." Experience has shown that, to be workable in various types of construction, concrete must have minimum slumps as indicated in Table 3-7.

Table 3-7. Recommended Slumps for Proper Workability

Type of concrete	*Slump, in.*
Mass concrete	3–5
Reinforced concrete:	
Thin sections and columns	6–7
Heavy sections	3–5
Confined horizontal sections	6–9
Pavement concrete	1–4
Mortar for floor finish	2

With a given water-cement ratio, the larger the desired slump, the less is the amount of aggregate that can be included in the mix. Hence, for a given quantity of cement the yield is reduced by an increase in slump. To obtain the maximum economy consistent with placing requirements, the concrete should therefore be made as dry as possible, within the limits of successful construction. Mechanical vibrators, especially in thin-walled sections, will permit the use of slumps somewhat less than those recommended in Table 3-7, and in large constructions the additional cost of vibrating as compared with hand puddling will be more than offset by the saving in materials, and honeycombing will be reduced to a minimum.

Mixing. Practically all concrete is machine-mixed. The materials for each batch are carefully measured or weighed and placed in the rotating drum of the mixer. Most specifications require that the mixing of each batch shall continue for at least 1 min after all the materials, including the water, are in the mixture.

Hand mixing is expensive and difficult, and the resulting concrete is usually not so good as that which is mixed by machine. Hand mixing should be permitted only when a small quantity of concrete is required. Hand mixing is accomplished by placing the proper quantities of cement, fine aggregate, and coarse aggregate on a watertight platform and thoroughly mixing these before the water is added. When the dry mixture shows a uniform texture, the correct amount of water is added and the entire mass is again turned and mixed to a uniform consistency.

Placing. Concrete is conveyed to the forms from the mixer by means of wheelbarrows or two-wheeled buggies or by inclined chutes or pipes. Chutes should ordinarily have a slope not flatter than 1:3 or steeper than 1:2, depending upon the wetness of the mix. The slope of the chute and the consistency of the mix should be so adjusted to each other that the concrete will travel fast enough to keep the chute clean but not so fast as to cause segregation of the materials.

Concrete should not be dumped in one place and allowed to flow horizontally, but should be deposited in approximately uniform layers. Forms should be tight so that cement will not be carried away by the escaping water. In hot, dry weather, wooden forms should be wetted thoroughly on the contact faces to prevent them from absorbing water from the mortar faces in contact with the forms; such absorption causes these faces to be pulled away with the forms upon stripping. Where fresh concrete is to be placed on old concrete or on rock, the old surface should be wetted thoroughly before the new concrete is placed, but it should be free from standing water.

The filling of the forms should be continuous where possible. Where such continuous deposition is impossible, the surface of the old concrete should be cleaned, roughened, and wetted before placing is resumed. Where forms have considerable height, some means should be provided for depositing the concrete without dropping it through too great a distance. Spading or puddling of the concrete is necessary to cause it to spread laterally after it has been deposited in the forms. This puddling should be done in such a manner as to force the coarse aggregate against the forms. In a properly designed mix, sufficient mortar will follow and encase the coarse aggregate to ensure a good finish, but if all the coarse aggregate is forced into the interior, away from the forms, the surface is less durable.

Vibrators are sometimes used to aid in the flow of the concrete in the forms.

They are operated either by compressed air or by electricity. They are used both internally and against the outside of the forms. Since they allow the use of a very sluggish mixture, with its consequent lower water-cement ratio, higher strength concretes may be expected.

Placing under Water. When concrete is placed under water, it is essential that the water be still and not flowing and that the concrete be dumped as a batch in its final position so as to avoid the segregation that would take place if it were allowed to fall freely through several feet of water. For underwater placement, drop-bottom buckets or, preferably, the tremie method may be used. A tremie consists of a vertical pipe, with the lower end resting in the freshly deposited concrete, and with a hopper at the upper end which is above the water. The tremie is kept at least partially filled with fresh concrete during the entire placing operation. From time to time the tremie is lifted slightly to allow part of the concrete in the pipe to flow out the bottom. A stiff but thoroughly plastic mix should be used.

Cold-weather Precautions. If concrete is to be placed during cold weather, particularly in near-freezing temperatures, the materials should be heated before being placed in the mixer, and provision should be made for keeping the concrete warm after it has been placed in the forms. Heating of aggregates on large jobs can be accomplished by placing perforated pipes under the storage piles and forcing steam through the pipes. On small jobs, wood fires built in sheet-iron pipes buried in the storage piles will usually prove satisfactory. The heating should be sufficient to ensure that the temperature of the concrete will be at least 50°F when it reaches the forms.

Curing. Concrete hardens because of chemical reactions which take place between the cement and water. These reactions continue indefinitely, so long as the temperatures are favorable and moisture is present to complete the hydration. The strength and quality of concrete, therefore, are dependent upon its age and the conditions under which it cures.

The strength of concrete, under favorable curing conditions, increases with age This increase is very rapid in the early ages but continues more slowly for an indefinite period The increase in strength from 7 to 28 days is about equal to the increase from 6 months to 2 years. If concrete is cured under dry atmospheric conditions, some of the water in the concrete will evaporate before the chemical reactions have continued for a sufficiently long time to obtain a reasonable proportion of the maximum strength attainable. In general, good practice requires that all concrete should be protected against premature drying out for at least 1 week and for a longer time if the temperature is near the freezing point. This may be done by sprinkling the concrete with water at intervals or by covering it with wet burlap, canvas, or straw.

Tests show clearly that concrete gains strength very slowly, if at all, at near-freezing temperatures and that the strength of similar mixes at any given age increases with an increase in the curing temperature. These facts emphasize (1) the desirability of placing concrete in warm weather if possible, (2) the importance of heating the aggregates and water in cold weather, and (3) the necessity of keeping the concrete warm after it has been placed in the forms when the surrounding air temperature is close to the freezing point. Low temperatures may so delay the hardening that the water in the concrete will evaporate before even a reasonable strength is obtained. When the water has evaporated, no further increase in strength is possible. If, however, evaporation of the water can be prevented and the concrete can be kept from freezing, the concrete will ultimately gain strength when the temperature rises sufficiently to permit the hardening process to continue at its normal rate.

Proper curing, in addition to increasing the strength, has a marked effect on other qualities of concrete, particularly watertightness and resistance to wear. Building up the internal structure of the concrete through more complete hydration of the cement is one of the most effective and economical means of making it impervious to water, a characteristic especially important in walls, tanks, and other elements subject to hydrostatic pressure or severe weather conditions. Continuous damp curing, particularly in the early stages of hardening, helps to produce a hard, dense surface and to prevent checking and dusting, especially important in floors, pavements, and other surfaces subject to abrasive wear.

Modulus of Elasticity. Concrete is not a perfectly elastic material, there being a slight decrease in the ratio of stress to strain (deformation) as the stress increases. Concrete also shows a permanent set under the smallest loads, but within working limits there is a fairly constant relation between stress and strain, which may be considered the modulus of elasticity of the concrete. This varies with the strength and the age of the concrete. In reinforced-concrete design the principal use of the modulus of elasticity is in determining the relative amount of stress carried by the steel and the concrete, assuming that there is perfect bond between the two materials. The value of the ratio n between the modulus of elasticity of the steel and that of the concrete, as ordinarily used in design for both tension and compression, is given by the relation

$$n = 30{,}000/f_c'$$

in which f_c' is the ultimate compressive strength of the concrete at 28 days in pounds per square inch.

Contraction and Expansion. Concretes expand as the temperature is raised and contract as the temperature is lowered. The coefficient of expansion per degree of temperature change increases somewhat with the richness of the mix, but the range of values is small. A value of 0.000006 is usually used in design.

Concretes expand in volume if kept wet or immersed in water and contract if exposed to air. This property is not confined to freshly placed concrete but is characteristic of concretes of many years' service. A concrete that dries out in air may be expected to contract from 0.02 to 0.05 per cent and when immersed in water may expand at least one-half of this amount.

This tendency to change in volume with different moisture conditions and changes in temperature does, of course, set up stresses of both tension and compression in a restrained reinforced-concrete structure. The tensile stresses often exceed the amount that the concrete can sustain, and cracks result. Shrinkage or temperature reinforcement is placed near the surfaces of concrete walls to minimize the formation of such cracks

Bond. The adhesion of new concrete to work previously placed is an important consideration in certain classes of construction. The old concrete should be thoroughly wetted, cleaned, and roughened and coated with cement grout before the new concrete is placed. If the old concrete is not thoroughly wetted, it will draw the moisture from the new concrete, often leaving insufficient moisture in the new concrete for a normal consistency. The result is weak concrete near the joint as well as an inefficient joint. Tests indicate that mere wetting of the old surface results in a joint efficiency of about forty per cent; wetting and roughening about fifty per cent; wetting, roughening, and coating with cement grout about eighty per cent. Several commercial compounds are available which, when mixed with water and brushed on the old surface, result in joints which are just as strong as the concrete in the mass.

Resistance to Fire. Concrete not only is incombustible but also is a poor conductor of heat. Hence it is a splendid fire-resisting and fireproofing material. The low coefficient of expansion of concrete lessens its tendency to crack when heated, and the low conductivity prevents the transference of the heat of the fire to the interior of the mass and to the reinforcing steel.

Weight. The weight of concrete varies with the proportions of the mix, the consistency, and the character of the aggregates. Weights per cubic foot of various types of concrete as usually used are as follows: gravel or crushed-stone concrete, 145 lb if unreinforced, 150 lb, if reinforced; cinder concrete, 110 lb; burned-clay concrete, 100 lb. Patented methods of aerating concrete are in use to some extent. Finely divided chemicals, which generate gases, are added to ordinary concrete, causing it to fluff up so that upon hardening it is full of air spaces. Weights as low as 50 lb per cu ft may be obtained by aerating.

Effect of Admixtures. Materials other than cement and aggregate are sometimes added to concrete (1) to increase the workability, (2) to reduce the freezing temperature of the mixture, (3) to accelerate the hardening, or (4) to make the concrete more watertight.

Small quantities of hydrated lime (up to 15 per cent by weight of the cement) improve the workability, particularly for the leaner mixes. If the lime is added without decreasing the amount of cement or increasing the amount of water, the strength is increased somewhat, but if some of the cement is replaced by the lime, a reduction in strength can be expected.

Sodium chloride (common salt) and calcium chloride lower the temperature at which the water will freeze. The addition of sodium chloride lowers the freezing point about 1°F for each 1 per cent of salt added to the mixing water; up to 12 per cent it is beneficial to the strength of concretes cured at freezing temperatures, but it is detrimental to the strength of concretes cured at normal temperatures. The set is retarded in all cases, and in reinforced concrete the salt is likely to cause corrosion of the steel. Calcium chloride up to 4 per cent is beneficial to the strength of concretes cured at any temperature, and the setting is accelerated. Percentages are expressed in terms of the weight of sodium or calcium chloride as compared with the weight of the mixing water.

The accelerating admixtures that are most generally used are calcium chloride and calcium oxychloride. They do not react alike with all portland cements. The quantity of calcium chloride should not exceed from 2 to 4 per cent by weight of the cement, and the quantity of calcium oxychloride should not exceed from 7 to 10 per cent. The admixture should be dissolved in the mixing water before it is placed in the mixer.

Various waterproofing compounds in powdered or liquid form are sometimes used to make a more impervious concrete. They are either added to the mixing water, mixed with the cement on the job, or added to the cement during its manufacture. Their function is to fill the voids or pores of the concrete with a more or less soapy, insoluble filler. The results obtained are varied, and practically all the compounds in use detract from the strength of the concrete. In general, it is better to depend for watertightness upon correct methods of construction, with the use of sound aggregates of low porosity, a limited amount of mixing water, thorough mixing, proper placing, and favorable curing conditions.

Surface Treatments. Surface treatments are used on concrete floors in industrial buildings to prevent "dusting" and to protect the concrete against corrosion by some oils and acids. Even where comparatively small abrasive forces are present, as in offices and corridors, an untreated concrete surface will dust owing to the grinding effect of the abrasive forces. Thoroughly hardened concrete is unaffected by mineral oils such as ordinary petroleum or pure engine oils. Various animal and vegetable oils may have a slight disintegrating effect. Some acids, such as acetic, carbolic, carbonic, lactic, phosphoric, and tannic, have a slight disintegrating effect, while others, such as hydrochloric, hydrofluoric, muriatic, nitric, sulphuric, and sulphurous, have a marked disintegrating effect. Some salts and alkalies, particularly nitrate and sulphate solutions, have a marked disintegrating effect on concrete cured in the ordinary manner.

Dusting may be minimized by painting the surface with any of the commercial cement paints which are available. To prevent lime burns in the paint film, concrete surfaces less than 6 months old should be treated before painting with a solution of 3 lb of zinc chloride per gallon of water. The surface should be wetted thoroughly with the solution, allowed to dry for at least 24 hr, and then rinsed thoroughly with cold water before painting. Dusting may also be reduced by hardening the surface with two or more applications, applied as above, of a solution of magnesium fluosilicate or zinc fluosilicate. The first application should contain 1 lb of the crystals per gallon of water and the subsequent applications 2 lb per gal.

Treatments required for protection against acids, oils, and alkalies vary with the degree of disintegrating effect. In some cases the magnesium fluosilicate treatment may be sufficient. Better protection is obtained by applying two or three coats of boiled linseed oil, preferably hot, after the magnesium fluosilicate treatment. Sodium silicate (water glass) of about 42.5° Baumé gravity, diluted in proportions of about 1 gal with 4 gal of water and applied in two or more applications, is satisfactory for mild effects. To resist very strong acids it may be necessary to cement vitrified brick or tile units, glass, lead, or sheets of resin, rubber, or synthetic rubber to the concrete with special adhesives.

REINFORCED-CONCRETE BEAMS AND SLABS

Types of Reinforcement. Square and round bars of structural- or intermediate-grade steel, varying in size from ¼ to 1¼ in., are used for reinforcing beams, slabs, walls, and columns. Wire fabric and expanded metal in various forms are used to a considerable extent in slabs, walls, and other thin sections. Bars are almost invariably made with projections or indentations or both on the surfaces to increase the adhesion between them and the concrete. These bars are called "deformed bars,"

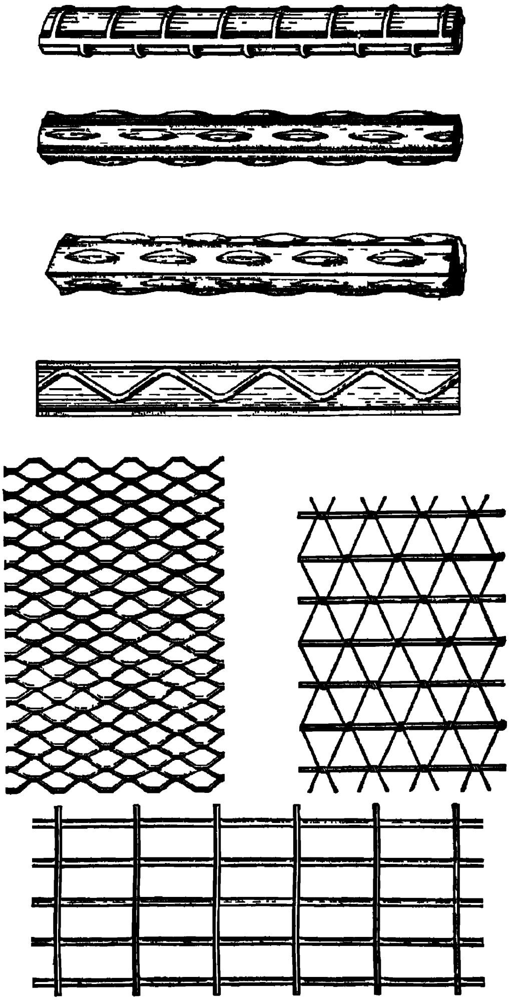

Fig. 3-17. Standard bar and mesh reinforcements.

several types of which are shown in Fig. 3-17. Standard bar sizes are given in Table 3-8. Some of the types of mesh reinforcement are shown in Fig. 3-17.

Table 3-8. Standard Reinforcing Bars

Round bars					Square bars				
Size, in.	Area, sq in.	Perimeter, in.	Weight, lb/lin ft	Size extra, cts/100 lb	Size, in.	Area, sq in.	Perimeter, in	Weight, lb/lin ft	Size extra, cts/100 lb
¼	0 0491	0 785	0 17	100	½	0 2500	2 00	0 85	20
⅜	0 1104	1 178	0 38	40	1	1 0000	4 00	3 40	0
½	0 1963	1 571	0 67	20	1⅛	1 2656	4 50	4 30	0
⅝	0 3068	1 964	1 04	10	1¼	1 5625	5 00	5 31	0
¾	0 4418	2 356	1 50	0					
⅞	0 6013	2 749	2 04						
1	0 7854	3 142	2 67						

Placing the Reinforcement. Most specifications require that the minimum clear distance between parallel bars shall be 1½ times the diameter for round bars and 2 times the side dimension for square bars, but in no case shall the clear spacing between bars be less than 1 in. or less than 1⅓ times the maximum size of the coarse aggregate. The reinforcement of footings and other principal structural members in which the concrete is deposited against the ground shall have not less than 3 in. of concrete between it and the ground contact surface. At surfaces of concrete exposed to the weather, the reinforcement shall be protected by not less than 2 in of concrete. In structures in which the fire hazard is limited, reinforcement at surfaces not exposed directly to ground or weather shall be protected by not less than ¾ in. of concrete for slabs and walls, 1½ in. for beams and girders, and 2 in. for columns. In structures with an abnormal fire hazard, the minimum covering for slab reinforcement shall be 1 in., for beam and girder reinforcement 2 in., and for column reinforcement 3 in.

Standard Design Notation. For convenience of reference, the standard notation, as used in the following equations for the design of reinforced-concrete beams and slabs, is given below:

A_s = effective cross-sectional area of steel in tension, sq in.
A_s' = effective cross-sectional area of steel in compression, sq in.
A_v = total area of web reinforcement in any one plane, sq in.
b = width of rectangular beam, or width of flange of T beam, in.
b' = width of stem of T beam, in.
d = depth from compression surface of beam or slab to center of longitudinal tension reinforcement, in.
d' = depth from compression surface of beam or slab to center of compression reinforcement, in.
E_c = modulus of elasticity of concrete in compression, psi
E_s = modulus of elasticity of steel in tension = 30 million psi
f_c = compressive unit stress in extreme fiber of concrete, psi
f_s = tensile unit stress in longitudinal reinforcement, psi
f_s' = compressive unit stress in longitudinal reinforcement, psi
f_v = tensile unit stress in web reinforcement, psi
j = ratio of lever arm of resisting couple to effective depth d
jd = arm of resisting couple, or distance from center of gravity of tension forces to center of gravity of compression forces, in.
k = ratio of distance from compression surface to neutral plane to effective depth d
kd = distance from compression surface to neutral plane, in.

l = span length of beam or slab
M = bending moment
M_c = resisting moment as governed by the compression forces, in.-lb
M_s = resisting moment as governed by the tension forces, in.-lb
n = ratio of modulus of elasticity of steel to that of concrete = E_s/E_c
Σ_0 = sum of perimeters of bars in one group at a given section, in.
p = ratio of effective area of tension reinforcement to effective area of concrete in beams = A_s/bd
p' = ratio of effective area of compression reinforcement to effective area of concrete in beams = A_s'/bd
r = ratio of unit stress in tension reinforcement to the simultaneous compressive unit stress in extreme fiber of concrete in beams = f_s/f_c
s = spacing of web reinforcement members, measured at the plane of the lower reinforcement and in the direction of the longitudinal axis of the beam, in.
t = thickness of flange of T beam, in.
u = bond stress per unit of area of surface of bar, psi
v = unit shearing stress, psi
v_c = unit shearing stress that can be resisted by concrete alone, psi
V = total shear, lb

Allowable Unit Stresses. The unit stresses recommended by the "Joint Committee"* of the engineering societies are stated in terms of the ultimate unit compressive strength f_c' of the concrete at the age of 28 days, as determined by tests of 6- by 12-in. or 8- by 16-in. cylinders. Concretes used in ordinary constructions have ultimate compressive strengths varying, with the type of member involved, from 1,500 to 4,000 psi, the most common values ranging from 2,000 to 3,000 psi. The required strength of the concrete is obtained by the proper proportioning of the cement, aggregate, and water.

A. Direct Compression	
Bearing on plain concrete piers and pedestals	$0.25f_c'$
B. Compression in Extreme Fiber	
Extreme fiber stress in flexure	$0.45f_c'$
C. Shear	
1. Beams with no web reinforcement	
a. Longitudinal bars anchored	$0.03f_c'$
b. Longitudinal bars not anchored	$0.02f_c'$
2. Beams with web reinforcement	
a. Longitudinal bars anchored	$0.12f_c'$
b. Longitudinal bars not anchored	$0.06f_c'$
D. Bond	
1. Between concrete and plain bars	$0.04f_c'$
2. Between concrete and deformed bars	$0.05f_c'$
E. Reinforcement	
Tensile or compressive unit stress not to exceed	
1. Structural-steel-grade bars	18,000 psi
2. Intermediate- and hard-grade bars	20,000 psi
F. Modulus of Elasticity	
Values of $n = E_s/E_c$	
For $f_c' = 2{,}000$	$n = 15$
For $f_c' = 2{,}500$	$n = 12$
For $f_c' = 3{,}000$	$n = 10$
For f_c' = any value	$n = 30{,}000/f_c'$

Rectangular Beams with Tension Reinforcement. The equations for designing or reviewing reinforced-concrete beams are derived in a manner similar to that used for any homogeneous beam, except that the difference between the elastic properties of steel and concrete and the method of stress distribution require certain obvious modifications in the derivations. The tensile strength of the concrete is disregarded because of its low value, and hence all the tension force is concentrated in the steel; the amount of this tension is equal to the area of the steel in square inches (A_s) multiplied by the unit stress in the steel in pounds per square inch (f_s), as shown in Fig. 3-18, which represents the elevation of a portion of a simply supported rectangular beam and a cross section of the beam. It is assumed that the unit compression force is a maximum at the extreme fiber and decreases uniformly to zero at the neutral axis. The total compression is therefore equal to the area of the shaded triangle in Fig. 3-18 times the width of the beam. This total compression is assumed to be concentrated at the center of gravity of the triangle, which is one-third of the distance *kd* from the upper (or compression) surface. The internal moment in the beam, as determined by the compression forces, is therefore equal to the total compression times the distance *jd* between the centers of gravity of the compression and tension forces. Hence

---

* The Joint Committee on Standard Specifications for Concrete and Reinforced Concrete. Its Report on Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete is known as "Joint Code" or "Joint Committee Report."

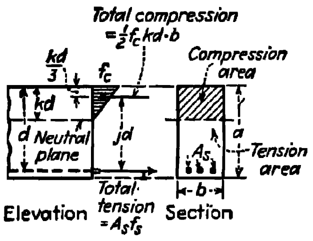

FIG. 3-18.

$$M_c = (\tfrac{1}{2}f_ckd\cdot b)jd = \tfrac{1}{2}f_ckjbd^2$$

Similarly, the internal moment, as determined by the tension forces, is

$$M_s = A_sf_sjd$$

Formulas for the value of *k*, which locates the neutral axis, and for *j*, which determines the lever arm of the resisting couple, and the formula giving the relation between the unit stress in the steel and the unit stress in the concrete, are derived from the usual assumptions made in the theory of flexure, complicated by the fact that the moduli of elasticity of the steel and the concrete are not the same ($E_s = nE_c$). A complete derivation of all these equations is given in any recognized text on reinforced-concrete design. The necessary equations follow (see page 122 for notations):

$$M_c = \tfrac{1}{2}f_ckjbd^2 \qquad (1)$$

$$M_s \quad A_sf_sjd = pf_sjbd^2 \qquad (2)$$

$$f_c = f_sk/[n(1-k)] \qquad (3)$$

$$\sqrt{2pn + (pn)^2} - pn \quad \text{(review only)} \qquad (4)$$

$$k = n/(n+r) \quad \text{(design only)} \qquad (5)$$

$$j = 1 - k/3 \qquad (6)$$

Method of Design. Compute the bending moment caused by the external loads. Assume the weight of the beam and add the bending moment due to this assumed weight to that caused by the external loads to get the total bending moment in the beam. This must be revised later if the actual weight of the beam does not agree with the assumed weight. Determine *k* [Eq. (5)], *j* [Eq. (6)], cross section of beam [Eq. (1)], area of steel [Eq. (2)]. Unless it is governed by architectural or other limitations, make *b* from one-half to three-fourths of *d*, and keep *b* in multiples of 2 in.

Method of Review. Determine *k* [Eq. (4)], *j* [Eq. (6)], M_c or f_c [Eq. (1)], M_s or f_s [Eq. (2)]. If the safe load is required, use the smaller of the values M_c or M_s, deduct the moment due to the weight of the beam, and compute the live load which will produce the remaining moment.

Design of a Rectangular Beam with Tension Reinforcement. Determine the required cross section and area of steel for a simply supported rectangular beam with a span of 18 ft 0 in., which is to carry a uniform live load of 1,000 lb per lin ft. A 2,500-lb concrete and reinforcing bars of structural-grade steel are to be used.

Assume weight of beam 220 lb per lin ft. Total load = 1,220 lb per ft.

$$M = (\tfrac{1}{8} \times 1{,}220 \times 18^2) \times 12 = 593{,}000 \text{ in.-lb}$$

From Eq. (5), $k = 0.430$, and from Eq. (6), $j = 0.857$. Then from Eq. (1),

$$593{,}000 = \tfrac{1}{2} \times 1{,}000 \times 0.430 \times 0.857 \times bd^2$$

$$bd^2 \text{ (required)} \quad 2{,}860 \text{ in.}^3$$

Select $b = 10$ and $d = 17$ in. The total cross section of the beam (see Fig. 3-19) $= 10 \times 20$ in., and the weight $= (10 \times 20/144) \times 150 = 210$ lb per lin ft, approximately as assumed. From Eq. (2),

$$593{,}000 = A_s \times 18{,}000 \times 0.857 \times 17$$
$$A_s \text{ (required)} = 2.26 \text{ sq in.}$$

Three 1-in. round bars will be used, as shown in Fig. 3-19. The purpose of the stirrups, shown in Fig. 3-19, and the method of determining their size and spacing are explained on page 128.

Review of a Rectangular Beam with Tension Reinforcement. A rectangular reinforced-concrete beam has a total cross section of 8 by 14 in. and a length of 20 ft 0 in. It is reinforced with four $\frac{1}{2}$-in. square bars in one row, the center of which is $1\frac{1}{2}$ in above the lower surface of the beam. Assuming a 2,000-lb concrete and structural-grade steel, what is the greatest concentrated load that can be placed on the beam at mid-span?

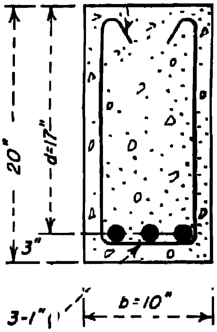

FIG. 3-19.

$$p = \frac{4 \times 0.25}{8 \times 12.5} = 0.0100$$

From Eqs. (4) and (6), $k = 0.418$, and $j = 0.861$.

$$M_c = \tfrac{1}{2} \times 900 \times 0.418 \times 0.861 \times 8 \times (12.5)^2 = 204{,}000 \text{ in.-lb}$$

$$M_s = 1.00 \times 18{,}000 \times 0.861 \times 12.5 = 194{,}000 \text{ in.-lb}$$

Hence, this beam is slightly weaker in tension than it is in compression, and the maximum bending moment cannot exceed 194,000 in.-lb. Owing to its own weight (117 lb per lin ft) the bending moment is $\frac{1}{8} \times 117 \times (20)^2 \times 12 = 70{,}200$ in.-lb. The maximum moment available for the concentrated load is then

$$194{,}000 - 70{,}200 = 123{,}800 \text{ in.-lb}$$

The maximum bending moment caused by the concentrated load is

$$\tfrac{1}{4}Pl = \tfrac{1}{4}P \times 20 \times 12 = 60P \text{ in.-lb}$$

hence $60P = 123{,}800$, and P (maximum allowable) $= 2{,}060$ lb.

Slabs Supported on Two Sides. A slab supported on only two sides is essentially a rectangular beam of comparatively large ratio of width to depth. Such a slab is analyzed by cutting out a 12-in. strip at right angles to the supporting beams and applying the same formulas as given for rectangular beams on page 124. Slabs are usually designed for uniformly distributed loads only, and the load per square foot on the slab becomes the load per linear foot on the imaginary 12-in. strip. Since all the load on the slab must be transmitted to the two supporting beams, it follows that all the reinforcing steel should be placed at right angles to these beams, with the exception of any bars that may be placed in the other direction to take care of shrinkage and temperature stresses. A slab that is so supported thus consists (in theory) of a series of rectangular beams 12 in. wide, placed side by side. The steel ratio p is equal to the area of one bar divided by the product of the effective depth d and the distance between bars, center to center. The areas furnished per foot of slab width by various sizes of bars and spacings are given in Table 3-9.

Slabs may be of one span only, resting freely on the supports, in which event they are designed for a moment of $\frac{1}{8}wl^2$. They may, however, be continuous over several supports, in which case moment coefficients for continuous or partly continuous beams may be used. Usually, for slabs of only two spans, a moment of $\frac{1}{8}wl^2$ is used, while for slabs of several spans, a moment of $\frac{1}{12}wl^2$ is used for the interior spans and $\frac{1}{10}wl^2$ for the end spans. Continuous slabs must have some steel near the upper surface over the supports to provide for the tension near this surface caused by the negative moment. This negative-moment steel is usually furnished by bending up some of the positive-moment steel at about the quarter points of the span and continuing this steel near the top surface to the corresponding points in the adjacent spans.

Table 3-9. Areas of Bars in Slabs, Sq In. per Ft

Spacing, in.	Size of round bar, in.							Size of square bar, in.

Design of One-way Slab. Design a fully continuous reinforced-concrete slab, supported on two sides only, to sustain a live load of 120 psf. Each span of the slab is 11 ft 0 in. Use allowable unit stresses of 800 and 18,000 for the concrete and steel, respectively, with $n = 15$.

Assume weight of slab as 62 psf (5-in. thickness). For a 12-in. strip at right angles to the supports,

$$M = \tfrac{1}{12} \times (120 + 62) \times (11)^2 \times 12 = 22{,}000 \text{ in.-lb}$$

From Eqs. (5) and (6), $k = 0\ 400$ and $j = 0\ 867$

$$22{,}000 = \tfrac{1}{2} \times 800 \times 0\ 400 \times 0\ 867 \times 12 \times d^2$$
$$d \text{ (required)} = 3.6 \text{ or } 4 \text{ in}$$

The total thickness, with 1-in. insulation, is 5 in., and the slab weight is 62 psf, as assumed.

$$72{,}000 = A_s \times 18{,}000 \times 0\ 867 \times 4$$
$$A_s \text{ (required)} = 0\ 353 \text{ sq in.}$$

Use ½-in. round bars on 6½-in. centers.

Slabs Supported on Four Sides. When a slab is square or nearly so and there are beams at the four edges of the panel, the slab should be reinforced in two directions so as to transmit the total load to all four beams. If the panel is square and if the construction is such that the same degree of restraint exists at each edge, one-half of the total load will be transmitted to each pair of beams. If the panel is longer in one direction than in the other, more than one-half of the load will be transmitted in the shorter direction, and the remainder will be transmitted in the longer direction.

A satisfactory assumption for distribution for ordinary panels is that recommended in the *Joint Building Code* (1928), where the part w_1 of the total load w, which is transferred in the short direction (see Fig. 3-20), is

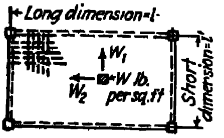

FIG. 3-20.

$$w_1 = \left(\frac{l}{l'} - \frac{1}{2}\right) w \tag{7}$$

in which l = the longer dimension and l' the shorter dimension, both in feet. Then, if w_2 is the part of the total load that is transferred in the longer direction,

$$w_2 = w - w_1 \tag{8}$$

Two strips, each with a width of 12 in., must be designed (or investigated), one strip parallel to the short dimension of the slab and one parallel to the long dimension. The values of d for each strip differ by one bar diameter. The shorter bars are usually placed beneath the longer bars, with the two layers in direct contact.

Design of Two-way Slab. A typical interior (fully continuous) floor panel is to be 9 ft 0 in. × 10 ft 0 in. in plan. The slab is to be reinforced in two directions and is to carry a uniform live load of 300 psf. Assume $f_c = 1{,}000$, $f_s = 18{,}000$, and $n = 12$. Design the slab.

Assume weigh of slab as 50 psf (4-in. slab); then $w = 300 + 50 = 350$ lb/ft. *For a 12-in. strip in the short direction,*

$$w_1 = ({}^{10}\!/_{9} - {}^{1}\!/_{2})350 = 215 \text{ lb/ft}$$
$$M = {}^{1}\!/_{12} \times 215 \times (9)^2 \times 12 = 17{,}500 \text{ in.-lb}$$

From Eqs. (5) and (6), $k = 0.400$ and $j = 0.867$.

$$17{,}500 = {}^{1}\!/_{2} \times 1{,}000 \times 0.40 \times 0.867 \times 12 \times d^2$$
$$d \text{ (required)} = 2.9 \text{ in.}$$

Use $d = 3$ in.; with 1-in. insulation, total thickness = 4 in., as assumed.

For a 12-in. strip in the long direction, $w_2 = 350 - 215 = 135$ lb/ft.

$$M = {}^{1}\!/_{12} \times 135 \times (10)^2 \times 12 = 13{,}500 \text{ in.-lb}$$
$$13{,}500 = {}^{1}\!/_{2} \times 1{,}000 \times 0.400 \times 0.867 \times 12 \times d^2$$
$$d \text{ (required)} = 2.55 \text{ in.}$$

With a 4-in. slab, the d furnished for the long bars (assumed as ½ in. in diameter) is only $4 - 1 - {}^{1}\!/_{2} = 2.50$ in. While sufficiently close for practical purposes, theoretically the slab should be made thicker to furnish at least 2.55 in. of effective depth for the long (upper) bars. A 4¼-in. slab will be used. Then, for the short bars, $d = 3.25$ in., and for the long bars, $d = 2.75$ in.

Short Bars:

$$17{,}500 = A_s \times 18{,}000 \times 0.867 \times 3.25$$
$$A_s = 0.345 \text{ sq in.}$$

From Table 3-9, ½-in. round bars, 6½ in. center to center are satisfactory for the short direction.

Long Bars:

$$13{,}500 = A_s \times 18{,}000 \times 0.867 \times 2.75$$
$$A_s = 0.314 \text{ sq in}$$

From Table 3-9, ½-in. round bars, 7½ in. center to center are satisfactory for the long direction.

Shear and Bond. In addition to the design for bending stresses as previously discussed, reinforced-concrete beams must be designed to resist shear and bond stresses. The latter tend to cause the steel to pull away from the concrete when under stress and thus destroy the unity of the beam.

The maximum unit shear v (pounds per square inch) at any cross section is

$$v = V/bjd \qquad \text{(rectangular beams)} \qquad (9)$$
$$v = V/b'jd \qquad \text{(T beams)} \qquad (10)$$

In any beam, the absolute maximum unit shear occurs at the section where the total shear V is a maximum. Allowable unit stresses are given on page 123.

The maximum unit bond stress u (pounds per square inch of contact surface between the longitudinal reinforcement and the concrete) occurs at the section where the shear is a maximum and is equal to

$$u = V/\Sigma_0 jd \qquad (11)$$

in which Σ_0 = sum of the perimeters of all the tension bars at the section. In all computations for shear and bond, a value of $j = {}^{7}\!/_{8}$ may be used.

Example: A rectangular beam with an over-all cross section of 12 by 22 in. supports live loads as shown in Fig 3-21. The beam is reinforced with four $\frac{3}{4}$-in round bars in one row, the center of which is 2 in. above the lower surface of the beam A 2,000-lb concrete is assumed Determine the maximum unit shearing stresses in sections at the left and right supports and in sections just to the left and right of the concentrated load Determine also the maximum unit bond stress

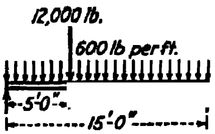

Fig. 3-21.

The dead weight of the beam is 275 lb per lin ft, hence the total uniform load is 875 lb per ft. At the left support,

$$V = (\tfrac{2}{3} \times 12{,}000) + (\tfrac{15}{2} \times 875) = 14{,}560 \text{ lb}$$

$$v = \frac{14{,}560}{12 \times \frac{7}{8} \times 20} = 70 \text{ psi}$$

At the right support,

$$V = (\tfrac{1}{3} \times 12{,}000) + (\tfrac{15}{2} \times 875) = 10{,}560 \text{ lb}$$

$$v = \frac{10{,}560}{12 \times \frac{7}{8} \times 20} = 50 \text{ psi}$$

Just to the left of the concentrated load,

$$V = 14{,}560 - (5 \times 875) = 10{,}180 \text{ lb}$$

$$v = \frac{10{,}180}{12 \times \frac{7}{8} \times 20} = 49 \text{ psi}$$

Just to the right of the concentrated load,

$$V = 14{,}560 - (5 \times 875) - 12{,}000 = -1{,}820 \text{ lb}$$

$$v = \frac{1{,}820}{12 \times \frac{7}{8} \times 20} = 9 \text{ psi}$$

The maximum unit bond stress occurs at the left support, since the shear is a maximum at this point

$$\frac{14{,}560}{4 \times 2.356 \times \frac{7}{8} \times 20} = 88 \text{ psi}$$

The above computations indicate that the beam is safe from shearing or bond failures provided adequate web reinforcement is used throughout those portions of the span where the unit shear is greater than $0.02 \times 2{,}000 = 40$ psi The design of the web reinforcement is given in the following paragraphs

Diagonal Tension and Web Reinforcement. Inclined tension stresses are produced by a combination of vertical and horizontal shearing forces and the flexural stresses in the tension fibers These stresses tend to cause diagonal cracks in regions of large shearing stresses, as shown in Fig 3-22 The magnitude of the diagonal-tension stress varies primarily with the amount of the shearing stress at the section By limiting the allowable unit shearing stress to a value which has been found by actual tests to be low enough to ensure against failure by diagonal tension, it may be considered that the danger of such failure has been eliminated.

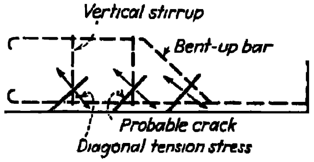

Fig. 3-22.

When the unit shearing stress at any section exceeds $0.02f_c'$ (or $0.03f_c'$ if the longitudinal bars are hooked at the ends), some form of web reinforcement must be used at that section in order to prevent the diagonal cracks from opening up Separate vertical stirrups may be used for web reinforcement, or some of the longitudinal bars may be bent up where they are no longer required for the tension fiber stresses so as to cross the planes of the probable cracks and thus prevent the formation of the cracks. Stirrup bars are usually bent in the form of the letter U and placed as shown in Fig. 3-19 The effective area A_v of the stirrup is then twice the area of the bar. For very wide beams, more legs than two might be used, in which case the area A_v would be equal to the number of vertical legs times the area of the bar.

The size and spacing of vertical stirrups (if required) are determined from Eq. (12). The spacing should not exceed about $\frac{1}{2}d$.

$$s = \frac{A_v f_v jd}{V - V_c} \tag{12}$$

In Eq. (12), V is the total shear at the section under consideration, and V_c is the amount of shear that can be taken by the concrete itself, i.e., $V_c = v_c bjd$ for rectangular beams, or $V_c = v_c b'jd$ for T beams, in which v_c is either $0.02f_c'$ or $0.03f_c'$.

EXAMPLE. Referring to the example on page 128, if the longitudinal bars are not hooked at the ends, the allowable unit shear that can be resisted by the concrete is $0.02 \times 2{,}000 = 40$ psi. Over what portions of the beam is web reinforcement required, and what arrangement of ¼-in. round U stirrups is necessary to provide for the diagonal-tension stresses?

A study of the unit-shear computations on page 128 shows that web reinforcement is required from the left support to the concentrated load and from the right support for a distance x to the section at which the unit shear is 40 lb per sq in. This distance is obtained from Eq. (9) as follows.

$$40 = \frac{10{,}560 - 875x}{12 \times \frac{7}{8} \times 20}$$

$$x = 2.47 \text{ ft}$$

The maximum spacing of stirrups at the left support, from Eq. (12), is

$$s = \frac{2 \times 0.0491 \times 16{,}000 \times \frac{7}{8} \times 20}{14{,}560 - (40 \times 12 \times \frac{7}{8} \times 20)} = 4.4 \text{ in.}$$

Just at the left of the concentrated load the total shear is 10,180 lb, and

$$s = \frac{2 \times 0.0491 \times 16{,}000 \times \frac{7}{8} \times 20}{10{,}180 - (40 \times 12 \times \frac{7}{8} \times 20)} = 15.5 \text{ in.}$$

Remembering that the spacing of vertical stirrups should not exceed $\frac{1}{2}d$, or 10 in. in this case, by simple proportion the following selection of spacings may be made for the region between the left support and the concentrated load, placing the first stirrup about two inches from the edge of the support: three at four in., two at six in., and four at ten in.

At the right support the total shear is 10,560 lb, and $s = 12.7$ in.; four stirrups will be used at this end, spaced 10 in. on centers.

T Beams. When a reinforced-concrete floor slab is constructed as a monolith with the supporting beam, part of the slab may be assumed to assist the upper part of the beam in resisting compressive stresses. These two acting together constitute what is known as a T beam (Fig. 3-23). The slab is called the "flange," and the portion of the beam below the slab is called the "web" or "stem." The exact width of slab that can be assumed effective in resisting compressive stresses depends upon the thickness of the slab, the span of the beam, and the spacing of beams. This effective width b is determined as follows.

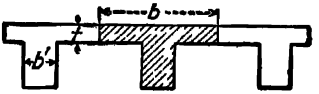

FIG. 3-23. T beam.

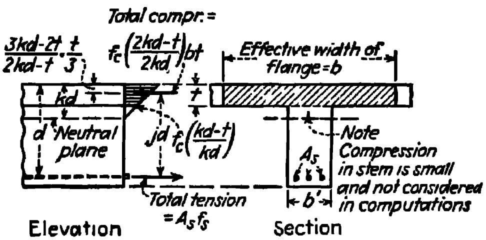
1. It shall not exceed one-fourth of the span length of the beam, except that, for beams with a flange on one side only, it shall not exceed one-tenth of the span.
2. Its overhanging width on either side of the stem shall not exceed eight times the thickness of the slab.
3. It shall not exceed the distance center to center of beams.

Owing to the relatively large width of flange, it is safe to say that the compressive strength of a T beam which is part of a floor system will seldom (if ever) govern the design. The effective cross section $b'd$ is determined from the shearing requirement, Eq. (10), with $v = 0.06f_c'$, web reinforcement being provided as necessary and in accordance with the methods outlined on page 128. In all computations involving shearing strength of T beams, the width of the stem b' is used, instead of the width of flange b, because of the fact that the unit shear involved is the unit shear along any horizontal plane between the tension steel and the neutral axis.

Formulas for the resisting moments, and for k and j, are derived in a manner similar to that used for similar functions of rectangular beams. The small amount of compression in the stem (between the neutral axis and the bottom of the slab) is disregarded, so that the total compression is considered to be a trapezoid with bases equal to f_c and $f_c[(kd - t)/kd]$, an altitude equal to t, and a length equal to the effective width of the flange b as shown in Fig. 3-24. Approximate resisting-moment formulas for use in design are obtained by assuming that $jd = d - \frac{1}{2}t$ and that the average compression stress in the trapezoid of depth t is $\frac{1}{2}f_c$. The essential equations for T-beam design and review are tabulated below:



Total compr. = $f_c\left(\frac{2kd-t}{2kd}\right)bt$
$\frac{3kd-2t}{2kd-t}\cdot\frac{t}{3}$
Effective width of flange = b
kd
t
d
Neutral plane
jd
$f_c\left(\frac{kd-t}{kd}\right)$
A_s
Note Compression in stem is small and not considered in computations
Total tension $=A_sf_s$
b'
Elevation
Section

FIG. 3-24.

$$b = \tfrac{1}{4}\text{ span} \quad \text{or} \quad 16t + b' \quad \text{(maximum)} \tag{13}$$

$$p = A_s/bd \tag{14}$$

$$M_s = A_s f_s jd \tag{15}$$

$$M_s = A_s f_s(d - \tfrac{1}{2}t) \quad \text{(approximate, for design only)} \tag{16}$$

$$M_c = f_c\left(1 - \frac{t}{2kd}\right) bt \cdot jd \tag{17}$$

$$M_c = \tfrac{1}{2}f_c bt(d - \tfrac{1}{2}t) \quad \text{(approximate, for design only)} \tag{18}$$

$$b'd = V/vj \tag{19}$$

$$f_c = \frac{f_s k}{n(1 - k)} \tag{20}$$

$$k = \frac{np + \frac{1}{2}(t/d)^2}{np + (t/d)} \tag{21}$$

$$j = \frac{6 - 6(t/d) + 2(t/d)^2 + (t/d)^3(1/2pn)}{6 - 3(t/d)} \tag{22}$$

Method of Design. Determine $b'd$ [Eq. (19)] and select proper values for each (b' is usually from $\frac{1}{3}$ to $\frac{1}{2}d$); A_s [Eq. (16)]. If a more exact design is required, review the beam (see following paragraph) to determine f_s and f_c. If f_c is too great, the beam must be deepened; if f_s is too small, less steel may be used and the review repeated. In rare cases only will the cross section be governed by the bending stress in the concrete.

Method of Review. Determine k [Eq. (21)], j [Eq. (22)], M_c or f_c [Eq. (17)], M_s or f_s [Eq. (15)]. In all computations $p = A_s/bd$ [Eq. (14)], in which b is the width of the flange [Eq. (13)]. After the resisting moment has been determined, the safe live load may be computed as explained on page 125.

Design of a T Beam. A series of parallel continuous floor beams is spaced 11 ft 0 in. on centers, supporting a monolithic 5-in. slab which sustains a live load of 100 psf. The span of the beams is 23 ft 0 in. Design one of the beams, assuming $f_s = 20{,}000$ and $f_c' = 2{,}000$.

Weight of slab = 62 psf. Load on beam from slab = 11(100 + 62) = 1,780 lb per ft. Assume weight of stem = 200 lb per ft; then the total load on the beam is 1,780 + 200 = 1,980 lb per ft.

$$M = \tfrac{1}{12} \times 1{,}980 \times (23)^2 \times 12 = 1{,}045{,}000 \text{ in.-lb}$$

$$V = 1{,}980 \times \tfrac{23}{2} = 22{,}700 \text{ lb}$$

$$b'd = \frac{22{,}700}{\tfrac{7}{8} \times 120} = 215 \text{ sq in.}$$

Select $b' = 10$ in., and $d = 22$ in. Allowing for two rows of bars, the total height of the beam must be $22 + 3 = 25$ in. (see Fig. 3-25). The cross section below the slab is 10×20 in., and the weight of the stem is 210 lb per ft, approximately as assumed.

$$A_s = \frac{1{,}045{,}000}{20{,}000 \times (22 - 2.5)} = 2.68 \text{ sq in.}$$

Six $\tfrac{3}{4}$-in. round bars (area 2.65 sq in.) will be used. The required size and spacing of web reinforcement bars are obtained as explained on pages 128 and 129.

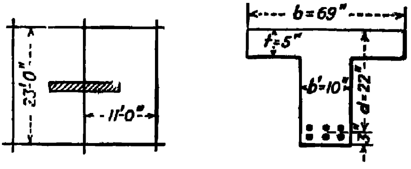


Fig. 3-25.

Beams Reinforced for Tension and Compression. *Design.* Quite frequently a beam is limited by certain structural conditions or architectural limitations to a size which is not adequate to furnish the required compression resistance. Additional compression resistance is furnished in such cases by placing reinforcing bars near the extreme compression surface of the beam, of sufficient area to provide for the moment in excess of the carrying capacity of the concrete Formulas for the design of a beam reinforced for tension and compression are derived by determining first the amount of moment (M_1) which the given concrete area can develop in compression [Eqs. (1), (5), and (6)] and computing the area of tension steel (A_{s1}) required to develop this moment [Eq. (23)]

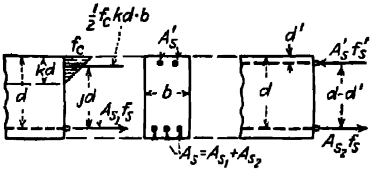

Fig. 3-26.

$$A_{s_1} = M_1/f_s jd \tag{23}$$

If the total moment (M) in the beam is greater than M_1, the amount (M_2) still to be taken care of by the compression steel (A_s') and additional steel (A_{s_2}) is $M - M_1$. The lever arm of this additional stress couple (Fig. 3-26) is $d - d'$. Hence

$$M_2 = A_{s_2} f_s(d - d')$$

from which

$$A_{s_2} = \frac{M_2}{f_s(d - d')} \tag{24}$$

The total tension steel area required to develop the moment M is, then,

$$A_s = A_{s_1} + A_{s_2} \tag{25}$$

The area of compression steel required is determined from the assumptions that, for equilibrium, the additional tension resistance must be equal to the added compression resistance, and that unit stresses vary as the distance from the neutral axis. Thus,

$$A_s' f_s' = A_{s_2} f_s$$

$$\frac{f_s}{f_s'} = \frac{d - kd}{kd - d'}$$

Hence

$$A_s' = A_{s_2} \times \frac{1 - k}{k - (d'/d)} \tag{26}$$

Example: A simply supported rectangular beam with a span of 20 ft 0 in. is limited in cross section to 8 by 18 in. The beam supports a live load of 580 lb per lin ft over its entire length. Using 2 in. of insulation and assuming $f_s = 18{,}000$, $f_c = 1{,}000$, and $n = 12$, determine the area of steel required for tension (A_s) and for compression (A_s').

The weight of the beam is 150 lb per ft; hence

$$M = \tfrac{1}{8}(580 + 150) \times (20)^2 \times 12 = 438{,}000 \text{ in.-lb}$$

From Eqs. (5) and (6), $k = 0.400$, and $j = 0.867$.

$$M_1 = \tfrac{1}{2} \times 1{,}000 \times 0.400 \times 0.867 \times 8 \times (16)^2 = 355{,}000 \text{ in.-lb}$$

$$M_2 = 438{,}000 - 355{,}000 = 83{,}000 \text{ in.-lb}$$

$$A_{s_1} = \frac{355{,}000}{18{,}000 \times 0.867 \times 16} = 1.42 \text{ sq in.}$$

$$A_{s_2} = \frac{83{,}000}{18{,}000(16 - 2)} = 0.33 \text{ sq in.}$$

$$A_s = 1.42 + 0.33 = 1.75 \text{ sq in.}$$

$$A_s' = 0.33 \times \frac{1 - 0.44}{0.400 - {}^2\!/_{16}} = 0.72 \text{ sq in.}$$

Four ¾-in. round bars in tension and two ¾-in. round bars in compression are selected; each set is placed in one row, the center of which is 2 in. from the bottom and top surfaces of the beam, respectively.

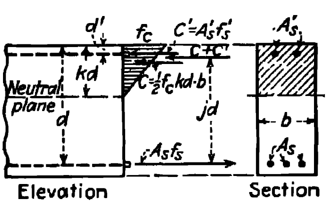

FIG. 3-27.

Review. The equations for k, j, and the resisting moments to be used in reviewing a doubly reinforced rectangular beam are derived in a manner similar to that used in deriving the corresponding equations for rectangular beams with tensile reinforcement only. The resulting equations are as follows (see Fig. 3-27):

$$p = A_s/bd \tag{27}$$

$$p' = A_s'/bd \tag{28}$$

$$M_s = A_s f_s jd \tag{29}$$

$$M_c = \frac{1}{2} f_c k \left(1 - \frac{k}{3}\right) bd^2 + f_s' p' bd(d - d') \tag{30}$$

$$f_c = \frac{f_s k}{n(1 - k)} \tag{31}$$

$$f_s' = \frac{f_s \left(k - \dfrac{d'}{d}\right)}{1 - k} \tag{32}$$

$$k = \sqrt{2n\left(p + p' \cdot \frac{d'}{d}\right) + n^2(p + p')^2} - n(p + p') \tag{33}$$

$$j = \frac{k^2 - \dfrac{1}{3}k^3 + 2p'n\left(k - \dfrac{d'}{d}\right)\left(1 - \dfrac{d'}{d}\right)}{k^2 + 2p'n\left(k - \dfrac{d'}{d}\right)} \tag{34}$$

If the unit stresses for a given loading are required, determine k [Eq. (33)], j [Eq. (34)], f_s [Eq. (29)], f_s' [Eq. (32)], f_c [Eq. (31)]. If the resisting moment of a given beam is required, determine k [Eq. (33)], j [Eq. (34)], M_s [Eq. (29)] and M_c [Eq. (30)]. The smaller of the two latter values is the resisting moment of the beam.

REINFORCED-CONCRETE COLUMNS

Types of Columns. The two general types of columns are (1) square or rectangular columns reinforced with longitudinal bars which are stayed laterally with ¼-or ⅜-in. ties spaced from 8 to 12 in. on centers (Fig. 3-28*a*); (2) round or octagonal columns with longitudinal bars wrapped with a continuous spiral wire ¼ to ⅝ in. in diameter, with a pitch (spacing) of from 1½ to 3 in. (Fig. 3-28*b*).

Columns with Longitudinal Reinforcement and Lateral Ties. Columns of this type which support concentric loads are designed by Eq. (35).

$$P = 0.18f_c'A_g + 0.8A_sf_s = 0.18f_c'A_g + 0.8pA_gf_s \qquad (35)$$

in which P = total load that the column can or must support
A_g = over-all cross-sectional area of the column
A_s = area of longitudinal steel
p = steel ratio = A_s/A_g
f_c' = ultimate strength of the concrete in compression
f_s = the working stress in the longitudinal reinforcement, at present specified as 16,000 psi for intermediate-grade steel

The longitudinal reinforcement should consist of at least four bars with a minimum diameter of $\frac{5}{8}$ in., and the value of the steel ratio $p = A_s/A_g$ should not be less than 0.01 or more than 0.04. The lateral ties should be at least $\frac{1}{4}$ in. in diameter, spaced not more than 48 tie diameters, or 16 bar diameters, apart, and so arranged as to support all the bars against lateral displacement when the concrete is placed in the form. In designing such a column, the value of p may be assumed (usually the minimum value of p will give the most economical, although the largest, column) and the required value of A_g can be obtained from the second form of Eq. (35). The size of the column can then be selected and the value of A_s obtained from the relation $A_s = pA_g$. The thickness of concrete outside the lateral ties should be at least $1\frac{1}{2}$ in.

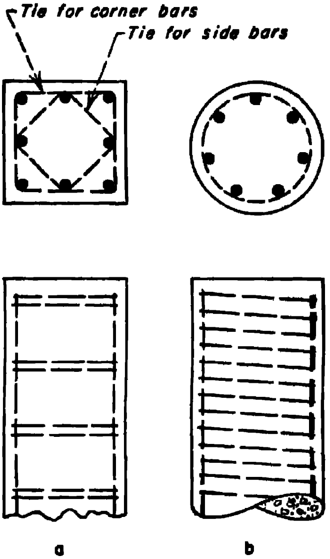

Fig. 3-28 Types of columns.

Example: Design a square column, using the minimum amount of reinforcement, to support an axial load of 240,000 lb, assuming f_c' = 3,000 psi and using intermediate-grade steel.

$$240{,}000 = 0.18 \times 3{,}000A_g + 0.8 \times 0.01A_g \times 16{,}000$$
$$A_g = 360 \text{ sq in.} \qquad \text{19-in. square column}$$
$$A_s = 0.01 \times 360 = 3.6 \text{ sq in.}$$
Use six $\frac{7}{8}$-in. round bars

Columns with Longitudinal Reinforcement and Spirals. Whenever a material is subjected to compression in one direction, there will be an expansion in the direction perpendicular to the compression axis. Spirals tend to resist this expansion and thus develop lateral compressive stresses which neutralize to some extent the effect of the axial stress. Such columns can, therefore, support greater loads than the same size of column without spirals. Equation (36) is used in the design of spirally reinforced columns which support concentric loads.

$$P = 0.225f_c'A_g + A_sf_s = 0.225f_c'A_g + pA_gf_s \qquad (36)$$

in which the terms have the same significance as in the preceding example. The design procedure is also the same.

At least six bars with a minimum diameter of $\frac{5}{8}$ in. should be used, and the value of p should be not less than 0.01 or more than 0.08. The size of spiral wire and the spacing or pitch of the spirals are obtained from the fact that the ratio p' of the volume of spiral reinforcement to the volume of the spiral core (out to out of spirals) should not be less than

$$p' = 0.45(R - 1)\frac{f_c'}{f_s'}$$

in which R = ratio of over-all area of column to core area, and f_s' = useful limit stress of spiral reinforcement, 40,000 psi for hot-rolled bars of intermediate-grade, 50,000 for hard-grade, and 60,000 for cold-drawn wire.

The center to center spacing of the spirals should not exceed one-sixth of the core diameter, and the clear distance between spirals should not be more than 3 in or less than $1\frac{3}{8}$ in The thickness of concrete outside the spirals should not be less than $1\frac{1}{2}$ in

Example Design a round column with spirals to support an axial load of 262 000 lb, assuming $f_c' = 3{,}000$ psi and using the minimum amount of intermediate-grade reinforcement

$$262\,000 = 0\ 225 \times 3\,000 \times A_g + 0\ 01 \times A_g \times 16\,000$$
$$A_g = 314 \text{ sq in} \qquad \text{Diameter of column} = 20 \text{ in}$$
$$A_s = 0\ 1 \times 314 = 3\ 14 \text{ sq in} \qquad \text{Use eight } \tfrac{3}{4} \text{ in round bars}$$

Hot-rolled intermediate-grade spirals $\frac{3}{8}$ in in diameter with a pitch of 2 in, are required to satisfy the above equation for p'

FLOOR SYSTEMS FOR CONCRETE BUILDINGS

Floor and Roof Loads. The minimum live loads for which the floors and the roof of any building must be designed are always specified in the building code that governs the site of the construction Typical minimum live-load values are given in Table 3-10 In all cases the dead weight of the floor and surfacing must be included in the total design load When plastered ceilings are specified, as is frequently the case where ribbed floor construction is used, an additional allowance of from 10 to 15 lb per sq ft is made for the lath and plaster In certain types of buildings particularly office buildings where all partitions are not definitely located on the plans, an extra allowance of from 10 to 20 lb per sq ft of floor area is frequently made for the weight of these partitions

Table 3-10. Average Minimum Live Loads for Buildings, Lb per Sq Ft

Apartments	50	Office buildings first floor	100
Assembly halls	100	Upper floors	75
Dwellings	50	Roofs slope under 20°	40
Hospitals	60	Schools	75
Hotels lobby floor	80	Stables garages	100
Upper floors	60	Stores and warehouses	200
Manufacturing buildings	150	Stairways	75 100

Types of Floor Systems. The different floor systems that are commonly used in reinforced-concrete buildings may be divided into five general classes as follows

1 Beam-and-girder floors
2 Beam-and-slab floors
3 Flat-slab floors
4 Ribbed floors, with clay-tile, gypsum-tile or steel-tile fillers
5 Steel-joist or precast-concrete-joist floors

Beam-and-girder Floors The beam-and girder floor consists of a series of parallel beams supported at their extremities by girders which in turn frame into concrete columns placed at more or less regular intervals over the entire floor area This framework is covered by a reinforced-concrete slab the load from which is transmitted first to the beams and thence to the girders and columns The beams are usually spaced so that they come at the mid-points, at the third points or at the quarter points of the girders As the slabs, beams, and girders are built monolithically, the beams and girders are designed as T beams, and advantage is taken of continuity

Beam-and-slab Floors Beam-and-slab floors are those in which a solid reinforced-concrete slab is supported on beams that transmit the loads directly to the columns The beams are framed into the columns, usually in both rectangular directions the slab is poured monolithically with the beams, with reinforcement parallel to each side of the floor panel Occasionally the beams in one direction are omitted, and the slab is supported on the beams between the columns in the other direction the main slab reinforcement is then all placed at right angles to the beams, and only shrinkage reinforcement is placed in the other direction Two-way slab construction is economical only for panels that are approximately square, with spans not exceeding 16 or 18 ft

One-way slab construction is suited to rectangular panels if the shorter span is not greater than 10 or 12 ft.

Flat-slab Floors. A flat-slab floor consists of a reinforced-concrete floor slab, built monolithically with the columns and supported directly by the columns without the aid of beams and girders. The slab may be of uniform thickness throughout the entire floor area; or part of it, symmetrical about the column, may be made somewhat thicker than the rest of the slab, the thickened portion of the slab thus formed constituting what is known as a dropped panel or "drop" (see Fig. 3-29). Dropped panels are usually square, the width being approximately equal to one-third (Joint Committee Report specifies 0.35) of the longer dimension of the panel. The thickness of the drop (below the slab) varies in practice from $0.25t_2$ to $0.50t_2$, in which t_2 is the thickness of the slab outside the drop.

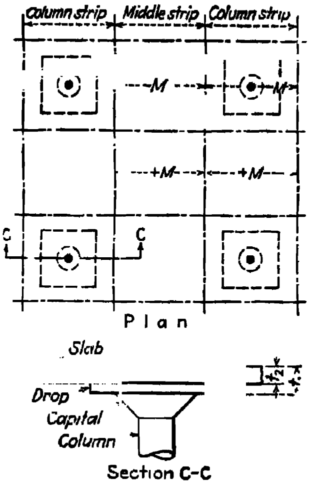

FIG. 3-29. Flat-slab floor.

The columns themselves in practically all cases flare out toward the top, forming a *capital* of a shape somewhat similar to an inverted truncated cone. The capital gives a wider support for the floor slab, reduces the shearing stresses in the slab, and tends to make a more rigid structure. In practice, the effective diameter c of the capital is usually equal to $0.225l$, in which l is the average span of the panel.

Flat-slab construction is the ideal type for industrial buildings in which the live load is 100 lb or more per sq ft and where the spans are 18 ft or greater. The panels should be as nearly square as possible. If rectangular panels are necessary, the longer span should not be greater than 1.33 times the shorter and preferably not greater than 1.1 times the shorter.

The two most common methods of reinforcing flat-slab floors are (1) the two-way system and (2) the four-way system. In the *two-way system* small bars are placed parallel to the lines of columns over the entire area of the floor at short intervals. The maximum spacing allowable varies in the different codes and specifications but is seldom greater than 1½ times the thickness of the slab, or 12 in. The *four-way system* consists of two main bands of steel running parallel to the lines of columns, each band centered about the column lines, and two diagonal bands of sufficient width to fill up the floor area left uncovered by the direct bands.

Ribbed Floors. For apartments, hotels, schools, hospitals, etc., where the live loads are relatively light and the spans relatively long, ribbed-concrete floor systems are usually the most economical. This type of construction consists of a series of small T beams spaced fairly closely, framing into beams or girders which in turn frame into the supporting columns. The T beams are formed by the use of fillers, which may be terra-cotta tiles, gypsum tiles, steel cores, or wood forms. When terra-cotta or gypsum tiles are used, the tile blocks are left in place, giving a flat ceiling which may be plastered underneath. Steel cores are either permanent (left in place) or removable; the latter type permits the reuse of the cores. If a flat ceiling is desired, metal lath is placed in contact with or hung below the bottom of the ribs or T beams when steel cores are used, and the lath is plastered.

The ribs are usually 4 or 5 in. wide, but for unusual loads they may be made an inch or two wider; ribs directly under partitions or concentrated loads are generally made from 1½ to 2 times the normal width, with a proportionate increase in reinforcing steel. As it is not easy to place stirrups in these narrow ribs or beams, the shear resistance of the rib will often govern the depth required. The cover slab forming the flange of the T is generally 2, 2½, or 3 in. in thickness. The floor construction is designated by the depth of the tile pieces plus the cover-slab thickness, *i.e.*, 6 + 2, 10 + 3, etc.

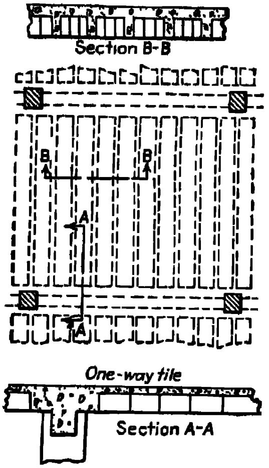

Fig. 3-30. One-way tile ribbed floor.

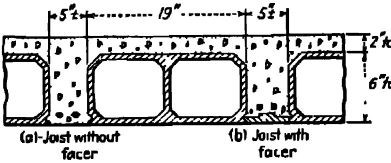
width equal to the distance center to center of the ribs.

Terra-cotta Tile Blocks. Terra-cotta tile blocks are usually 12 in. square and can be obtained in thicknesses varying from 4 to 12 in. The blocks are placed flatwise and end to end, in rows between, and at right angles to the girder forms, as shown in Fig. 3-30. They are supported either by a solid decking similar to that used for regular concrete slabs or on 2- by 8-in. planks called "soffit boards," which are centered under the space between the rows of tile. The decking or soffit boards are supported on light shoring from the floor below. The usual clear distance between rows is 4 in., so that the distance center to center of the rows is 16 in.

Gypsum-tile Fillers. Gypsum-tile fillers are made of dense, specially prepared gypsum, in two sizes, one 12 in. wide and 30 in. long, with thicknesses of 3, 4, or 5 in., and the other 19 in. wide and 18 in. long, with thicknesses of 6, 8, 10, or 12 in. The 19- by 18-in. fillers are cast with one integral end, which provides a seal for each row at the girders. The 12-in. tiles are usually placed 16 in. on centers (with 4-in. rib), while the 19-in. tiles (Fig. 3-31) are usually placed 24 in. on centers (with 5-in. rib). Rib widths can, however, be varied to suit any conditions. Open centering, consisting only of planks or soffit boards for the bottom forms of the ribs, is usually used.



(a)-Joist without facer (b) Joist with facer

Fig. 3-31. Ribbed floor with gypsum tile fillers.

When *special steel cores* are used, the formwork again consists of open centering, in which planks or soffit boards are placed only under the concrete ribs or joists. The steel cores are available usually in lengths of 30, 35, and 36 in. and in depths of 4, 6, 8, 10, 12, and 14 in. They are tapered in cross section, as shown in Fig 3-32; the most common width at the bottom is 20 in., although other widths between 10 and 31 in. are also obtainable. With permanent cores, if a plastered ceiling is desired, metal lath *f* (Fig. 3-32) is placed under the cores before they are put in position and anchored to the concrete ribs by suitable metal clips which project up into the ribs. The entire ceiling is plastered after the formwork is removed. With removable cores, the ceiling may be plastered by fastening metal lath to the concrete after the cores

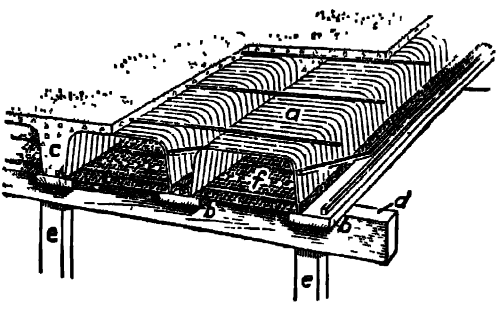


Fig. 3-32. Ribbed floor with steel cores.

are removed, or the ribs may be left exposed. The ribs are usually made 5 in. wide at the bottom, so that the distance center to center of ribs is ordinarily 25 in.

The girders which support the ribs are rectangular beams or T beams with a maximum flange thickness equal to the total floor thickness, as shown in Fig. 3-33. If the maximum flange thickness is to be used, the rows of tiles are stopped at the proper distance from the stem of the girder. If a flange thickness less than the maximum is desired, the end pieces of tile in each row are short sections which are dropped down on the forms so that the tops of the pieces are at the proper elevation to furnish the required slab thickness above them. End caps are used at each end of each row of tile to hold the girder concrete in position.

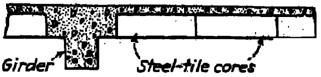

Fig. 3-33.

Steel-joist and Precast-concrete-joist Floors. A steel-joist floor consists of a series of closely spaced, parallel, shallow joists or trusses of the Pratt, Warren, or double-Warren type, supported at the ends on steel or concrete beams, or on masonry walls, and covered with a thin concrete slab. Two common types of steel joists are shown in Fig. 3-34. Ordinary steel joists are manufactured in depths of 8, 10, 12, 14, and 16 in. and are carried in stock in a range of depths and lengths to meet all usual conditions of load and span. The span limits vary from 4 to 32 ft. The joists are spaced from 12 to 30 in. on centers, depending on the load and span, and are covered with a 2- or 3-in. concrete slab poured on metal rib lath which rests on and is fastened to the upper surfaces of the joists. The joists are braced transversely by some form of rigid diagonal bridging placed between adjacent trusses, at intervals of from 5 to 7 ft. One type of bridging is shown in position in Fig. 3-35. The bridging members are light ¾-in. channels which are notched at the ends to rest against and be clipped to the chords of the trusses.

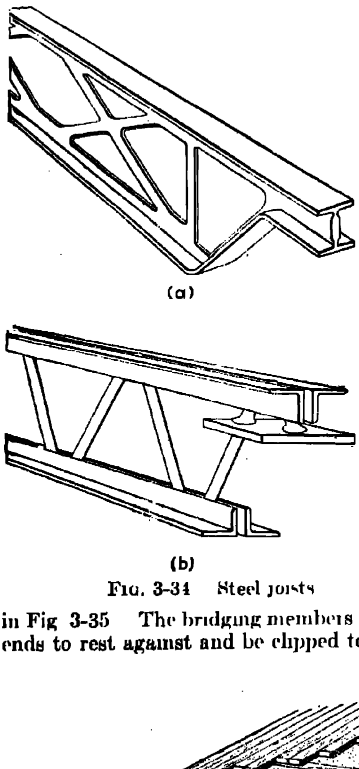

Fig. 3-34. Steel joists.

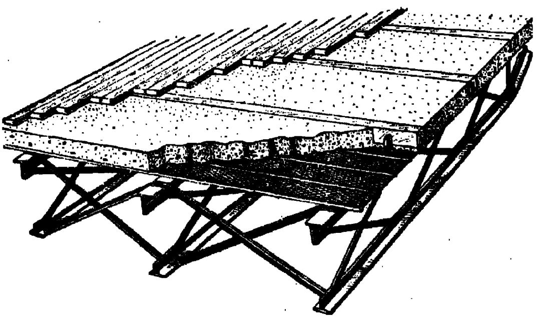

Fig. 3-35. Steel-joist construction.

Special long-span steel joists are also available, primarily for roofs or very light floors, with depths up to 32 in. for spans up to 64 ft. Roofs supported by these long-span joists have wood-plank, gypsum-plank, or precast-concrete-plank decks with built-up roofing or poured concrete decks. The spacing of the joists is limited by the safe span of the floor slab or roof deck. Long-span joists are bridged with cross bracing of not less than 1¼- by 1¼- by ⅛-in. angles, bolted together at the intersection and spaced not more than 10 ft apart.

Steel-joist floors are economical for light occupancies, but they are unsuitable for heavy or vibrating loads. They are easily installed, and the cost of construction is low because no forms are required for the concrete slab. Ceiling lath for plaster is attached directly to the lower chords of the trusses. Since the webs of the joists are open, all plumbing and service pipes may be concealed in the construction without interfering with the structural members. Joists are selected from the manufacturers' catalogues, which give the total load which may be supported safely by joists of various depths, spans, and spacings.

Precast-concrete joists may be used in much the same way as steel joists. Concrete joists are made of lightweight aggregates in depths varying from 6 to 14 in. and in lengths up to 36 ft. They are of I cross section, reinforced top and bottom. A 2- or 2½-in. slab is poured over the joists after they are set in position, as shown in Fig. 3-36. Concrete joists are selected from the manufacturers' catalogues.

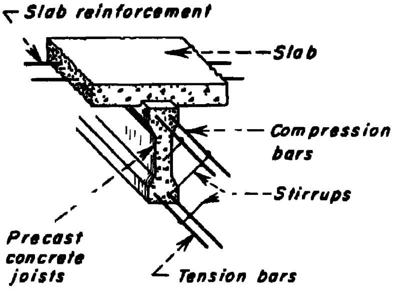

FIG. 3-36. Precast-concrete-joist construction.

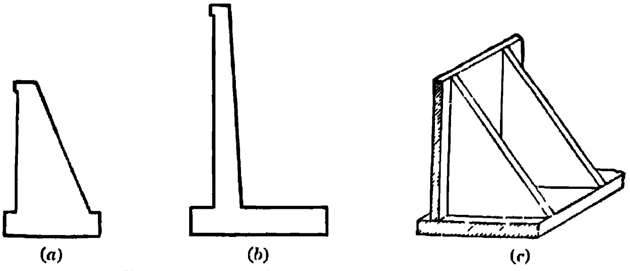
RETAINING WALLS

Types. Concrete retaining walls are of three classes: (1) gravity (Fig. 3-37*a*), (2) cantilever (Fig. 3-37*b*), and (3) counterfort (Fig 3-37*c*). The latter two are reinforced. The gravity type is commonly used for low walls, the cantilever type for walls of medium height, and the counterfort type for the higher walls No marked line of separation exists, in general, counterfort construction is not economical for walls less than 18 ft in height.



(*a*) (*b*) (*c*)

FIG. 3-37. (*a*) Gravity wall. (*b*) Cantilever wall. (*c*) Counterfort wall.

The width of the base of the wall will, in general, average about 0.45 of the total height of the equivalent earth column at the heel of the wall, measured from the base of the wall. Greater economy is obtained in the reinforced walls by placing the vertical arm at some distance back of the toe

Conditions of Loading. Four general cases are possible: (1) walls with no surcharge, the top surface of the fill being horizontal and level with the top of the wall; (2) walls with an inclined surcharge, the top surface of the fill extending upward and back from the top of the wall (the angle of inclination of the sloping surcharge is usually taken as the angle of repose of the material in the fill); (3) walls with a horizontal surcharge extending some distance above the top of the wall, and (4) loadings in which the actual surface of earth does not extend above the top of the wall but supports an external load such as a building, railroad tracks, etc. Such loads are converted into an equivalent height of earth above the top of the wall by dividing the weight of the additional load per square foot by the weight of the earth per cubic foot. The pressure against the wall is then computed for this equivalent height of earth surcharge, as in case 3.

Formulas for Earth Thrust. Rankine's development of the theory of earth pressure leads to the general equation,

$$P = C \times (wh_1^2/2)$$

where P is the total thrust per linear foot of wall upon the back of a retaining wall, w the weight of the earth per unit volume, h_1 the height of the earth column, and C a constant depending upon the angle of inclination of the back of the wall, the conditions of loading, and the physical properties of the earth fill. Equations for P are given in Fig. 3-38. In the equations, h is the height of the wall in feet, h' the height of surcharge in feet, and ϕ the angle of repose of the retained fill. The location of the line of action of P is also given in Fig. 3-38 for each of the cases shown. The value of ϕ is usually taken as 33°42′ (slope $1\frac{1}{2}$ to 1) for ordinary earth fills. The amount of pressure on any given horizontal strip 1 ft in height at a distance x ft below the surface of the earth is

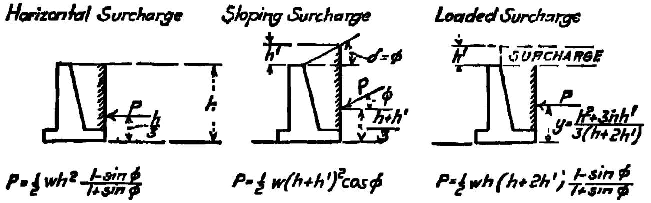


FIG. 3-38. Earth pressures on retaining walls.

$$P_1 = Cwx$$

Overturning and Crushing. In order to prevent overturning of the wall, the resisting moment of the weight of the wall and the earth above the base of the wall about the toe must be greater than the overturning moment of the earth pressure about the same point. A factor of safety of 2 is generally required, *i.e.*, in Fig. 3-39, $W_1x_1 + W_2x_2 + W_3x_3$ must be greater than $2Py$.

In order to prevent crushing of the soil at the toe of the wall, the soil pressure at that point should not be greater than the allowable pressure for the soil under the wall. Formulas for the toe and heel pressures are given in Fig. 3-40,

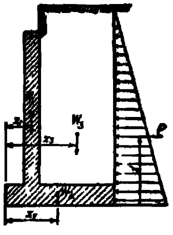

FIG. 3-39.

where E = resultant of the total earth pressure and the resisting weight (concrete and earth above base of wall) on a 1-ft strip of wall, lb

F = vertical component of E

l = length of base, ft

a = distance, ft, from toe to intersection of E with the base

Figure 3-40 illustrates the desirability of having the resultant pressure E intersect the base of the wall within the middle third in order that the base will bear on the soil for its full length.

Sliding. In order to prevent sliding, the frictional resistance of the base against the foundation material must be greater than the horizontal component of the earth pressure P. A safety factor of $1\frac{1}{2}$ is usually specified, *i.e.*, $f(\Sigma W)$ must be greater than $1\frac{1}{2}P_H$,

where f = coefficient of friction, concrete on earth

ΣW = total vertical load on base of wall = F in Fig. 3-40

P_H = horizontal component of earth pressure P

Values of f may be assumed as follows: on dry clay, 0.5; on wet clay, 0.33; on sand, 0.4; on gravel, 0.6. In case an adverse condition of sliding exists, the base may be widened, thus increasing the weight of the wall; narrow shallow trenches may be dug in the foundation, forming projections which will materially increase the resistance to sliding; or the base may be inclined upward toward the toe.

Design of Gravity Walls. Assume a cross section (see Fig. 3-37a), and investigate for sliding, overturning, and crushing of the soil as previously outlined, basing all computations on a 1-ft length of wall. If any of these factors is unsatisfactory, revise the cross section and repeat.

Design of Cantilever Walls. Assume a cross section (see Fig. 3-37b), and investigate for sliding, overturning, and crushing of the soil as for a gravity wall. The vertical slab is then designed as a cantilever (using a wall length of 1 ft) with a horizontal load equal to the horizontal component of the total earth pressure on the vertical slab. The horizontal slab is designed as a cantilever which supports an upward load equal to the reaction from the soil under the cantilever and a downward load equal to the weight of the slab and earth above it.

FIG. 3-40. Foundation pressures.

Design of Counterfort Walls. Assume a cross section (see Fig. 3-37c), and investigate for sliding, overturning, and crushing, basing all computations on a length of wall equal to the distance center to center of counterforts. A spacing of about ten feet for the counterforts for walls of medium height will usually prove economical. The thickness of counterforts varies from 12 to 18 in. The face wall is built with a vertical back; the front might be battered slightly for appearance. This wall is designed as a simple or partly continuous slab, supported by the counterforts with a horizontal load equal to the horizontal component of the earth pressure. The base slab is designed as a simple slab supported by the counterforts; sometimes as a partly or fully continuous slab. The steel is placed parallel to the wall and may be in the top or in the bottom of the slab, depending upon whether the resultant moment causes tension in the upper or lower portions of the slab. The resultant moment is the algebraic sum of the moments caused by the upward earth pressure and the downward load of the filling.

The counterforts are designed as wedge-shaped, vertical cantilever beams supporting a horizontal load equal to the total horizontal component of the earth pressure on the face wall between two counterforts. The effective depth of the counterfort is the perpendicular distance to the steel near the rear edge of the counterfort from the point of intersection of the counterfort, the front face of the vertical wall, and the upper face of the base slab. The counterforts must be tied to the vertical wall and to the base slab with horizontal and vertical bars, respectively. The main steel in the counterforts is placed along the back or sloping edge.

Details of Construction. The front face of a retaining wall is usually built with a batter of from ½ to 1 in. in 12 in. A coping, projecting a short distance beyond the wall, adds to the architectural appearance and, to a certain extent, protects the masonry in the body of the wall from dripping water. A top width of less than 10 in. is generally undesirable; heavy gravity walls should preferably have a top width not less than 18 to 24 in. The base of the foundation should be a sufficient distance below the surface of the ground to prevent damage by frost, a minimum of about 3½ ft being satisfactory in ordinary climates. Expansion joints should be provided at intervals along the wall, preferably not farther apart than 30 ft. In the reinforced walls where cracks would not only be unsightly but also detrimental to the integrity of the wall, additional steel should be placed at right angles to the main reinforcement to provide for temperature and shrinkage stresses An amount varying from 0.10 to 0.33 per cent of the cross section is usually specified. Proper drainage of the fill behind the wall may be effected by inserting 4-in. drain tiles through the wall near the bottom, at intervals of 10 to 15 ft, and piling crushed stone, gravel, or other coarse material around the holes. At least one drain should be provided for each pocket formed by counterforts.

MODERN MATERIALS OF CONSTRUCTION

BY RUSSELL D. ROGERS, B.S.

Senior Architectural and Civil Engineer, E. I. du Pont de Nemours & Co.

Numerous excellent texts are available on analytical design of structures, strength of materials, and methods of erection of simple and composite structures of wood, metal, and masonry. The plant engineer can find volumes of these data in any public library, but he will have considerable difficulty in locating a text that will assist him in his maintenance and repairs.

Usually the plant engineer inherits his job after the plant has been designed and erected, and it is his duty to keep the plant operating with a minimum of interference with operation and with a minimum of expense.

This section will therefore consist of information relative to proper selection of materials for construction and repair with a description of the advantages and disadvantages of these materials for certain uses. For useful coverage, the discussion must be limited to floors, walls, and roofing.

FLOORS

Probably 90 per cent of all recently constructed large industrial plants have concrete floors, and the remaining 10 per cent have wooden floors

The types of finishes for concrete floors, each of which is suitable for a specific use, are listed below and discussed in the paragraphs following.

1. Cement
2. Mastic
3. Wood block
4. Wood, laminated
5. Brick
6. Rubber
7. Plastic, resin type
8. Linoleum
9. Mastic tile
10. Mastic block
11. Cork
12. Magnesite

Cement Finish. A cement finish should not be used when the surface is continuously subjected to extremely high temperatures, *i.e.*, above 250°F. The effect of heat on the strength of concrete, as reported by Portland Cement Association's *Bulletin* ST32, is shown in Table 4-1.

Table 4-1

Temp., deg F	*Reduction in compressive strength, per cent*
200	18
500	40
800	52
1100	85
1400	96
1700	97

While the above statistics apply specifically to monolithic concrete, the effects are relative in so far as the cement finish is concerned. The finish will disintegrate owing to a combination of temperature change and impact from floor loads.

Where heat resistance is necessary, the use of a special cement such as Atlas Lumnite is recommended.

Cement finishes are susceptible to attack from

Coal-tar distillates—phenol, cresol, lysol, creosote, carbolinium

Acids—acetic, nitric, hydrochloric, hydrofluoric, lactic, carbonic, carbolic, humic, phosphoric, sulfuric, sulfurous, and tannic

Salts and alkalies—carbonates of ammonium, potassium, and sodium

Chlorides —calcium, potassium, sodium, strontium —especially when in presence of moisture, also chlorides of ammonia, copper, iron, magnesium, mercury, zinc

Hydroxides— Ammonia, potassium, sodium

Nitrates—Ammonia, potassium, sodium

Sulfates—Practically all

Vegetable oils—Almond, castor, cocoa nut, olive, peanut, poppy seed, rape seed, and walnut

Additional valuable information on this subject may be secured from Portland Cement Association's *Bulletin* ST4.

Preparation of a proper base is necessary to maintain a proper finish. The following precautions will assist in obtaining maximum service with minimum maintenance costs. A sound coarse and fine aggregate meeting ASTM Specification C33 should be used.

Mix. A laboratory-designed mix to obtain a 28-day compression strength of *at least* 2,500 psi should be prepared An arbitrary but safe mix would be 1 part portland cement; 2½ parts fine aggregate, well graded from ¼ in. down; and 3½ parts coarse aggregate, well graded from 1½ down to ¼ in. Not more than 6 gal of water should be used per bag of cement.

The base should be poured in alternate areas bounded by the column center lines, preferably not exceeding 1,000-sq ft areas. Tests and experience have indicated that the initial shrinkage of concrete is greater than any subsequent expansion due to either moisture or temperature changes. By pouring in alternate areas, this initial shrinkage will have taken place before the adjacent area is poured.

If a separate finish is used, it is the general opinion of experienced contractors and engineers that it is preferable in the average industrial plant to permit the finish to crack on a straight line directly over the construction joint rather than deliberately to construct a tooled groove. If a scored finish is desired and not objectionable to traffic and operations, it should always be placed on the center line of columns or at the corner of large foundations projecting above the floor.

Where the unit pressure on the floor is greater than that on the footings, especially in heavily loaded one-story structures, an expansion joint should be placed at all walls and around all column and machinery foundations to permit differential settlement The joint should be free to move vertically without resting on its edge, thus causing "dishing." A typical expansion joint is shown in Fig. 4-1.

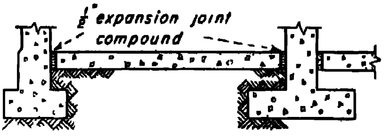

Fig 4-1. Typical expansion joint for floating floor.

The top surface should be screeded to the proper elevation and roughened if a separate topping is to be provided The topping should consist of a mix of 1 part portland cement, 1 part fine aggregate, and 1¾ parts coarse aggregate. The fine aggregate should range from No. 100 mesh to No. 4 sieve and the coarse aggregate from ⅛ to ½ in.

For severe service a metallic aggregate of from 50 to 150 lb per square, *i.e.*, 0.5 to 1.5 lb per sq ft, may be used. This type of topping and all heavy-duty toppings require experience and skill beyond the average for proper installation. Specialists such as the Kalman Floor Co. or Master Builders Co. should be consulted for assistance.

Patching. In spite of advertising to the contrary by manufacturers of patching compounds, no patch should be "featheredged." The sides should be chipped to secure a vertical surface and thoroughly soaked until they cannot absorb further moisture Then a grout of pure cement and water of the consistency of paint should be broomed into the area. While still damp, the patching material should be applied and thoroughly tamped into place. This material should consist of a mix as nearly like the original material as possible. The mix should be so dry that it will just retain its shape when squeezed in the hand. It should then be troweled to match the adjacent surface.

As an additional precaution against shrinkage, pulverized pure grey iron such as Master Builders Embeco may be added in the proportion of 25 lb of iron to each bag of cement. An excellent proprietary patching compound identified as Hydroment, manufactured by Upco Co., of Cleveland, Ohio, is also available for emergency use.

Where a wearing surface is to be added for trucking aisles, the method shown in Fig. 4-2 should be used.

Proprietary compounds are available to assist in securing a good bond between new and old concrete surfaces. Examples of such compounds are Bondsit, made by the A. C. Horn Co., Hydroment, by The Upco Co., or Bond-tite, by the American Fluresit Co. A prime coat of cement and iron with an oxidizing agent can also be secured from L. Sonneborn Sons, Master Builders, A. C. Horn, and others.

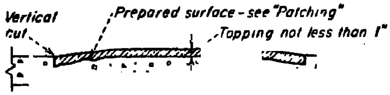

FIG. 4-2. Trucking-aisle patch to eliminate "featheredge."

Mastic Topping. Mastic topping consists of the best grade of asphalt, especially Trinidad Lake natural asphalt, silica filler, silica sand and pebbles, carbon, and other similar fillers.

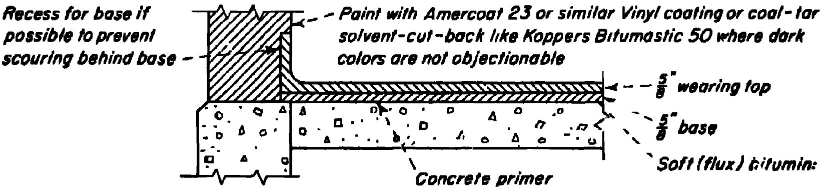
This topping is satisfactory where it is free from heavy or concentrated traffic, especially heavy wheel loads. It should not be used where constant temperatures exceed 100°F or in the presence of oils unless special oil-resistant mastic (similar to Ralph V. Rulon Co. mastic) is used.

If properly installed, mastic topping is excellent protection in extremely wet and wet-acid areas, is odorless, dustless, slipproof, and easily repaired. It is also satisfactory as a tank or pit lining.

If installed by a specialist in this line of work, no waterproof membrane is required for protection against acid leaks and their resultant attack on the concrete base. If membrane is used, the use of Fiberglas (Owens-Corning) cloth instead of cotton fabric is recommended. Graded carbon is added where resistance to hydrofluoric or hydrofluosilic acid is required.

A method proved satisfactory is to prime the concrete surface, apply approximately 1/8 in. of asphalt matrix consisting of a pure grade of low-melting-point asphalt similar to the Trinidad Lake matrix of the Ralph V. Rulon Co., Atlas Mineral Products Co. No. 31, or Johns-Manville No. 60 flux. Over this a 5/8-in layer of acid-resisting mastic is applied. The aggregates used should be free from limestone or materials that are easily attacked by acid. The material should be maintained at a temperature of between 350 and 450°F and combined to produce a plastic mixture. A second layer of 5/8 in. thickness should then be applied with all joints broken. Hot mastic should overlap the cold about four inches to make a soft edge. The top layer should be proportioned for its intended loading. It should be remembered that the softer and more elastic material is more acid-resisting but also unsatisfactory for either static or moving loads.

The finished surface should be given a sand- or silica-dust sprinkle while hot and rubbed to a smooth finish with wood floats.



Recess for base if possible to prevent scouring behind base
Paint with Amercoat 23 or similar Vinyl coating or coal-tar solvent-cut-back like Koppers Bitumastic 50 where dark colors are not objectionable
5/8" wearing top
5/8" base
Soft (flux) bitumin:
Concrete primer

FIG. 4-3. Acid-proof mastic floor.

Fillets and coves are as necessary as the floor and should be used throughout to prevent the accumulation of salts and dirt in sharp corners (see Fig. 4-3).

The maintenance on this type of floor is very low if it is installed by a reputable, experienced contractor. It can also be extremely high if so poorly constructed that frequent repairs are necessary to floor and damaged equipment. Premiums paid for expert application in this work will result in a long-time economy.

Wood Block. Wood block is available in treated and untreated end-grain blocks. The advantages of this type of floor finish are that it is comfortable for footwork; dustless; has a low noise factor; is odorless if necessary; cushions the fall of tools, castings, etc., in machine-shop service; insulates against ground coldness; is repellent to insect attack; sparkproof; skidproof; has a low maintenance cost; does not sliver; is easy to repair; and has excellent resistance to mechanical abuse. It is also medium-priced for its service.

Its disadvantages are that it is dark-colored except in redwood and untreated block and cannot withstand frequent wetting without a drying period, although the treated type is immune to wet rot. Also careful workmanship is required to secure true and level surfaces, or the surface should be sanded and refilled.

Typical Available Types. 1. Kreolite (Jennison-Wright Co., Toledo, Ohio), single end-grain yellow-pine lug blocks, 2 to 3 in. in thickness, 3 to 4 in. in width, 4½ to 8 in. in length. This block is treated and provided with lugs to secure proper spacing. It is installed on a concrete base with a coat of primer, ⅛ in. bitumen. The joints are filled with pitch. The surface may be buffed or varnished after a top coating of coal-tar-pitch emulsion. It is also available in flexible strips with metal splines, 2 to 8 ft long to secure a true and level surface. Dark or light blocks are available. It may be waxed.

2. Worthwood (Worth Lumber Co., Seattle, Washington), end-grain Douglas fir, with the wood splined in lengths of 2 to 8 ft, 1⅜ by 3½ in. minimum, 1⅞ by 4½ in. maximum face, thickness of 2 or 2½ in., width of 3½ to 4½ in. It has a grooved base, shaved edges, and sanded face to secure uniform thickness. There are two grades, select and clear. The strips are set in mastic over a concrete primer. Subfloors on ground or basement should have a three-ply waterproof membrane under the blocks.

3. The Koppers Co., Century Wood Preserving Division, has a wood block which is the same as the Jennison-Wright without lugs. It can be secured with V-cut faces to assist the placing of bitumen.

4. Palco Redwood (Pacific Lumber Co., Chicago, Illinois) consists of 3⅝- by 5⅝-in. redwood vertical-grain blocks, 2, 2½, 3, and 4 in. in thickness. There are also fancy finished floors for parquetry, herringbone, etc., in patterns 2 in. thick. The weight of 2 in is 4.3 lb. It has a compressive strength of 1,000 psi. It is set on a concrete subbase with special mastic.

Precautions. In truckways and wherever possible, the loose blocks should be set with their length at right angles to the line of traffic. The joints should be staggered, and expansion joints should be provided around the room and adjacent to columns and other vertical obstructions. Machinery should not be bolted to blocks. A three-ply membrane should be used over subfloor when at or below grade.

Pipes extending through floors should be encased in sleeves firmly set in subfloor. Concrete curbs should be provided at all openings, stairs, elevators, edges of platforms, etc., to act as stopping points for blocks. Ramps should be provided with curbs at both top and bottom.

Wood Floors- -Industrial-laminated Type. The advantages of laminated floors are that they are resilient; easily maintained; easily obtainable; flexible for moving machinery; economical; long lived owing to freedom from termites and dry rot or dampness; will stand medium to heavy loads with good foundation; and expert skill is not required for installation.

The disadvantages are that multiple joints catch dirt; they are hard to keep clean if the wood is not properly dried or oil and dust or grit are present in operation; and they are not suited to extremely wet operation continuously.

Advantageous use of this type of construction naturally cannot be obtained without proper construction. A type of construction proved satisfactory and which should be used as a basic type for any necessary variation is the Tar-Rok construction as recommended by the Barrett Division of the Allied Chemical & Dye Corp., illustrated in Figs. 4-4 and 4-5.

The construction of subfloors over earth is shown in Figs. 4-4 and 4-5. The foundation course consists of 4 in. of dry crushed stone or screened gravel thoroughly mixed with No. 5 Barrett tar. The proper amount to use is

6 gal per cu yd of 1- to 2½-in. crushed stone
9 gal per cu yd of ¼- to 2½-in. crushed stone

7 gal per cu yd of coarse screened gravel
10 gal per cu yd of fine screened gravel

The tar should be heated to not more than 200°F. After it is uniformly spread, the foundation courses should be rolled and compacted with at least a 300-lb roller (per foot of length). Over this foundation course the final dampproof course should be installed.

The dampproof course is made by thoroughly mixing in a suitable mechanical mixer Barrett tar No. 7 with clean, dry sand which has been preheated. Thirty gallons of tar are required per cubic yard of sand. The temperature of the tar should not exceed 225°F. If a thick, white smoke, indicating overheating, rises from the mix, 5 gal of tar should be added for each cubic yard of sand. The dampproof course should be spread evenly to a depth of 1¼ to 1½ in. (so it will compact to 1 in.) over the concrete, leveled with a straightedge, and followed closely with the plank, which is set and hammered level in the soft mix and firmly toenailed in position.

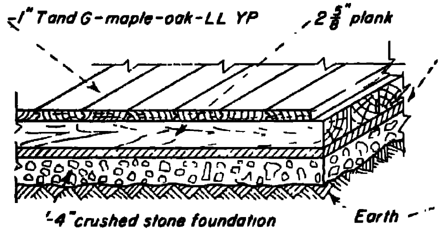


FIG. 4-4.

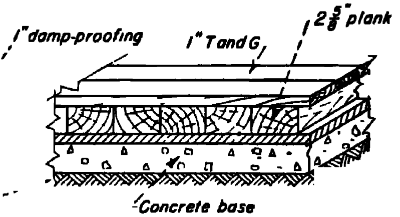

FIG. 4-5. Industrial-laminated-type wood floor.

For intermittent wet use, or for local areas subjected to wet processes, it is most advisable to use lumber that is treated with 1 lb of chromated zinc chloride salts per cubic foot of wood or at least 8 lb of pressure-treated creosote in accordance with the American Wood Preserving Association specification.

Brick. Brick floors are so seldom used for other than acidproof areas that their installation will not be described; and all details and discussions will be confined to acidproof floors.

Brick floors are immune to attack of acids or alkalies; are capable of withstanding high temperatures and extremely heavy static or moving loads; can be made attractive and sanitary; are easily incorporated with construction of equipment foundations, curbs, sumps, trenches, etc.; are easily patched; and have low maintenance cost if properly constructed.

The disadvantage of brick floors is their high first cost. The bricks used should be a dense deaired acidproof shale, having an absorption of approximately 1 per cent or less, equal in quality to Claycraft, Hanley, Belden, Atlas, Knight, Duro, Summitville, General Refractories, etc. The most commonly used sizes are (nominal sizes) 1⅛ by 4 by 8 in.; 1⅜ by 4 by 8 in.; 2¼ by 4 by 8 in.; 1½ by 6 by 12 in.; 3¾ by 4½ by 8 in.; 2½ by 4½ by 9½ in ; 2½ by 4 by 8½ in. Special shapes, such as bullnose, internal and external corners, cove bases, jamb tiles, etc , are generally available, especially for the 1⅜- by 4- by 8-in. size, which is an excellent general-utility size for all but extremely heavy moving loads. Abrasive-surfaced or nonskid-type bricks should be used in wet areas.

Acidproof Mortars. There are many reliable sources of supply for a variety of mortars, each of which is designed for a specific purpose. It is evident that this discussion can indicate only a very small portion of the technical details and precautions essential for proper installation.

If a considerable amount of this type of construction is necessary, more economy will be realized if the engineer will present his entire problem to one of the many reliable manufacturers and profit by their extensive field and laboratory tests on similar problems.

An abbreviated list of products and their manufacturers is provided for guidance. It is not intended to be all-inclusive, as each manufacturer has available special modifications of these cements for specific uses.

The type of material used, width of joint, moisture, temperature, mixing, and placing are all extremely important for proper workmanship. If work of this type is contracted, it should be kept in mind that the lowest bidder may not necessarily be the most economical, unless he has had considerable experience in this type of work.

There are three major types of hard-setting cements available, sulphur, resin, and silicate. The proper joint thickness and method of mixing are given in Table 4-2.

Table 4-2

Sulfur type	Resin type	Sodium silicate type
1. Tegul Vitrobond, Tegul Tileset	8. Korez	20. Penchlor
2. Carbo Vitrobond	9. Carbo Korez	21. Vitrex
3. Basolit	10. Alkor	22. Sauereisen No. 31
4. Carbon Basolit	11. Durisite	23. Glaseal
5. Plasul Basolit	12. Alk-Li-Pruf	24. Duro
6. Sauereisen No. 48	13. Pennsalt PRF	25. Quigley Black
7. Weldtite	14. Pennsalt HF and HFK	26. Knight No. 2
	15. Causplit	
	16. Permanite	
	17. Asplit	
	18. Nukem-ALKA	
	19. Nukem-Carbon Resinous	

Approximate average characteristics

	Sulfur type	Resin type	Sodium silicate type
Weight, standard types, lb/cu ft	137	120	120
Carbon types, lb/cu ft	137	90	
Tensile strength, psi	650–900	650–1 500	375
Compressive strength, psi	6,200–8 000	10 000–12,000	2,800
Absorption, per cent	1–2	1–2	10–15
Setting time @ 70°F	5 min	1 to 6 hr	25 min to 1 hr
Elasticity, in deflection, bar 24 × 1 × ½ in thick	0.20–0.25	1.3	0.17
Bond strength psi	500	600	185
Max service temp, deg F	200°F	350°F	1600–2000°F
Coef of expansion	8.3×10^{-6}*	6.5–14×10^{-6}	6.2×10^{-6}
Ready for service	5 min	16–24 hr	2–4 days
Joint thickness	¼–½ in max	1/16 to ⅛ in.	(20) ¼–⅛ in. (21) ¼–⅜ in. (22) 1/16–5/16 in. (23) ⅛–⅛ in.
Application	Melting and pouring at 280°–300°F	Mix liquid and powder to form plastic mix per mfr's directions, apply with trowel	Mix and apply with trowel

* Tegul Tileset = 5×10^{-6}.

NOTE. The values given are averages for the group. Actual values for the specific material should be secured from the manufacturer before installation of work. The width of joints must obviously be increased to at least ¼ in. for repointing.

It is important to note that sulphur cements should not be used where operating temperatures exceed 200°F, resin cements at 350°F, and silicate cements at 2000°F.

In all cases, bricks and concrete base must be dry; the temperature of the brick should be between 65 and 80°F. Resin and silicate are extremely sensitive to changes in temperature.

Resins and silicates must not come in contact with portland cement or any material having an alkali content. The surfaces must be neutralized with dilute hydrochloric acid or the surface primed with an acid-resisting bitumen approved by the manufacturer. An acid-soaked surface should be neutralized with a 5 per cent caustic soda solution, water-washed and dried.

All sodium silicate joints should be washed down with a 5 to 10 per cent solution of hydrochloric acid before use. In a food industry, the hardened joint should be treated with a 10 per cent solution of calcium chloride and then washed with water.

Resin and sulfur cements do not require any acid wash or curing. They are ready for service when hard.

Since the jointing material comprises a major portion of the cost of the floor, it is essential to select the lowest priced cement that will fulfill the requirements. Silicate mortar and sulfur-base mortars can be purchased for approximately one-fourth the cost of a resin mortar. However, the resin and silicate mortars are mixed cold, and the elimination of the heating process with its inconvenience reduces the labor cost for these mortars to a competitive basis.

When using either resin or sulfur mortars it is necessary to provide good ventilation and goggles. Some resin cements may cause skin irritation to those allergic to the cement, so the material should not be left on the skin for long periods of time. Yellow vaseline may be used as a good protection against skin irritation. Sand soap and plenty of water will remove the cement from the hands. Solvents should never be used on the skin. It is always advisable to consult a physician in case of irritations. Tools should be cleaned with 5 per cent caustic soda.

Resin solutions that have solidified are useless. Resin powder will not deteriorate in dry storage.

Resistance Data. SULFUR—STANDARD TYPES (1, 3, 5, 6, 7, Table 4-2). These cements are resistant to abrasion, mechanical abuse, and sudden changes in temperature. They are inert to such acids as sulfuric, hydrochloric, phosphoric, acetic, lactic, nitric, and corrosive salts of these acids. They are attacked by strong alkalies, chromic acid, hydrofluoric acid, and some organic solvents.

SULFUR—CARBON TYPES (2, 4, Table 4-2). These cements will resist attack of hydrofluoric acid; otherwise they have the same characteristics as the standard types.

RESIN TYPES (8 to 19, inclusive, Table 4-2). There are two types of resin cements in general use—phenol-formaldehyde resin and furane resin.

The phenol-formaldehyde type is subdivided into two groups, one without carbon (8, 15, 17, Table 4-2) and one with carbon (9, 13, 14, 19, Table 4-2). The plain phenol-formaldehyde resin is resistant to most acids, including hydrochloric, phosphoric, sulfurous, acetic, chloracetic, chlorasulfuric, oxalic, lactic, sulfuric up to 50 per cent concentration; neutral salt solutions, water, steam, and oil, to 350°F; also *mild* alkalies, ammonia, benzine, methylene chlorite, chlorobenzine, oleic acid, naphtha, ether alcohol, and acetone. Some of the resins require heating to 300°F to resist alcohol and acetone. They are *not* resistant to nitric acid, hydrofluoric acid, chromic acid, caustic soda, sodium hypochlorite, or for aniline or other organic bases.

The carbon-type phenol-formaldehyde resins have all the characteristics of the plain resin and in addition are resistant to hydrofluoric acid, sulfuric acid of any concentration up to 150°F, sodium carbonate, calcium hydroxide, ammonia, fats, oils, most organic solvents, and corrosive salts except chromates. They are attacked by nitric acid, chromic acid, and sodium hypochlorite.

The furane resins (10, 11, 12, 16, 18, Table 4-2) have more favorable characteristics than the phenol type. They are resistant to strong alkalis or alternate exposure to alkalis and acids. They are also resistant to inorganic acids such as sulfuric, hydrochloric, phosphoric, and hydrofluoric, as well as most solvents, oils, and greases.

The furane resins are *not* resistant to highly oxidizing acids such as nitric and chromic, phosphorous bromides, nitroglycerine, nitrotoluene, iodine, iodoform, and sulfur oxychloride.

While it is advisable to use the furane resins (10, 11, 12, 16, 18, Table 4-2) where it is known that alkalies are continuously present, the sulfur and phenol types will stand up if the solution is alkaline for short periods followed immediately by acid solution.

Sodium Silicate Type (20 to 26, Table 4-2). Silicate cements are resistant to all inorganic acids except hydrofluoric and to almost all organic acids, solvents, oils, paraffine wax, hot and cold water, and steam They are attacked by hydrofluoric acid, alkaline solutions, and acetone oil

The sodium silicate types are *not* recommended for floors owing to their high porosity The salts recrystallize and expand, thus destroying the joints. Neither should they be used in trenches where the liquid level varies sufficiently to permit drying of the liquid with resultant crystallizing

They are much more stable in strong acid solutions and where always saturated with the acid liquid

Installation Details Figures 4-6 to 4-11, inclusive, show typical acidproof floor and trench protection Note particularly the limitation on joint thickness Refer to the schedule for type of material and temperature limitations. Figures 4-8 and 4-9 have more resistance than Fig 4-7, and Fig 4-7 has more than Fig 4-6 The cost is in direct proportion to the quality Figure 4-8 is ideal for use in dairies and food plants

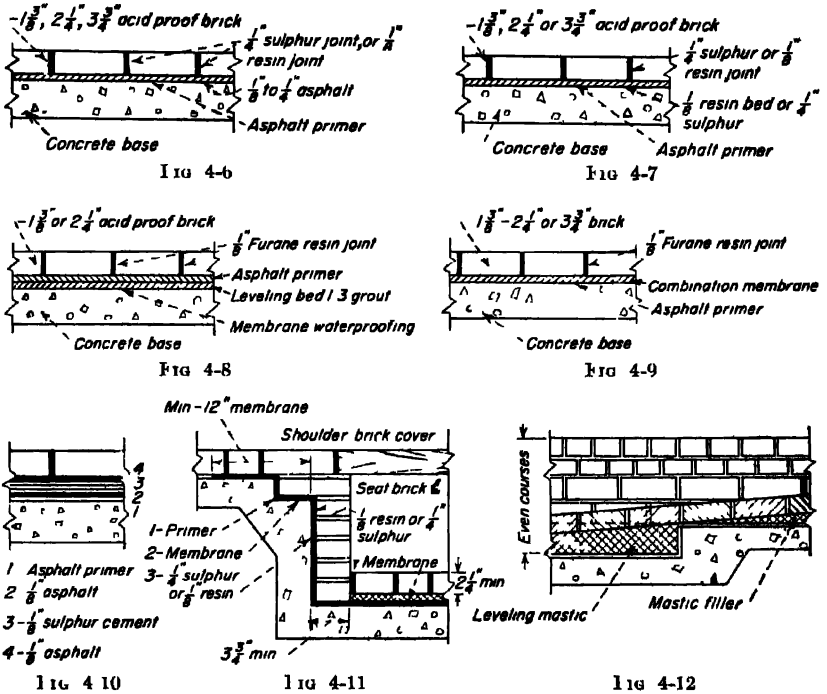

Fig 4-6 Fig 4-7 Fig 4-8 Fig 4-9 Fig 4-10 Fig 4-11 Fig 4-12

Figs 4-6 to 4-12. Acidproof brick floors

The membrane waterproofing should be constructed of alternate layers of impregnated cotton fabric and acid-resisting asphalt Glass cloth (Fiberglas by Owens-Corning) may be used with considerable advantage instead of cotton fabric, as poor workmanship often permits exposure of the cotton to the acid-bearing liquid with consequent deterioration

A typical section through an acid-bearing trench is shown in Fig 4-11 Note particularly that the shoulder and seat bricks are turned at right angles to the trench for rigidity The membrane, preferably of two-ply Fiberglas, is carried at least 12 in past the shoulder brick

The leveling acidproof mastic is used to permit the use of whole bricks for the side wall of the trench and at the same time to secure a uniform slope for the bottom course of brick. The method of stepping the depth at intervals so that only full bricks are used is shown in Fig. 4-12. Cutting of bricks is one of the most expensive labor items involved and should be eliminated. This is especially so when bricks are cut to a bevel. It is unnecessary, uneconomical, and results in a poorly constructed trench.

Similar materials are available from Haveg Corp., Newark, Del., La Clede Christy Clay Products Co., St. Louis, Mo., The Robinson Clay Products Co., Akron, Ohio.

Rubber. Rubber is a "dress-up" finish suitable for offices, laboratories (especially neoprene base), locker rooms, dining rooms, cafeterias (greaseproof type only), stores, public buildings, churches, hospitals, etc., where the surface is subjected to extensive foot traffic. It is only occasionally used in industrial work. It is a very comfortable floor finish and has good resistance to abrasion.

Rubber should not be used on ground floors or for exterior use. If it is desired on ground floor, membrane waterproofing or mastic underlayment should be provided to keep out moisture, and a waterproof type of adhesive should be used.

Rubber is supplied in thicknesses of ⅛ to 3/16 to ¼ in. Tile sizes are 4 by 4 in., 6 by 6 in., 9 by 9 in., 12 by 12 in., 24 by 24 in., and 25-yd rolls 36 in. wide. Some producing firms are Goodyear, U.S. Rubber, Ohio Rubber (Willoughby, Ohio), Armstrong Cork, American Tile & Rubber Co. (Trenton, New Jersey), Akron Rubber Co. (New York), B. F. Goodrich, and Selby-Battersby. (See Table 4-4.)

Plastic—Resin Type. Resin-type plastic is manufactured for both "dress-up" and industrial uses. It has characteristics similar to asphalt tile but has greater flexural strength and impact resistance. Hence it will stand industrial uses to a much greater extent than asphalt tile, cork, rubber, linoleum, or mastic. Plastic may be secured made of highly fire-resistant ingredients and also resistant to oils, gasoline, greases, acids, alkalies, and moisture. Installation is similar to that of other tiles, but it may be put in use immediately.

It comes in the same sizes and thickness as asphalt tile, although some manufacturers have sizes up to 18 by 24 in.

Since each manufacturer has his own specific mixture of plastic binders, plasticizers, asbestos fiber, pigment, etc., the chemical and physical resistances vary considerably more than any type of tile and should be thoroughly checked before purchasing.

Resin-type plastic is produced by Tile-Tex, Bird & Son, Armstrong Cork, Thomas Moulding, David E. Kennedy, Selby-Battersby, etc. (See Table 4-4.)

Linoleum. Linoleum is strictly an interior, above-grade floor finish. It will not stand subfloor dampness and should not be cemented directly to wood or metal, but installed over felt or mastic underlayment. Linoleum is supplied in rolls ⅛- to 3/16- to ¼-in. and 6-mm (0.236 in.) thickness, as well as medium gauge (0.095 in.) and standard gauge (0.079 in.), both plain and marbleized.

Linoleum is not suitable for rolling loads. In Bureau of Standards Tests, *Report* BMS80, however, marbleized linoleum withstood abrasion tests very satisfactorily.

It is not suitable where exposed to acids, alkalies, oils, gasoline, greases, or moisture. It is ideal for light foot traffic owing to resilience and resistance to abrasion.

Linoleum is manufactured by Armstrong Cork Co., Congoleum-Nairn, Sloan-Blabon, etc. An economical industrial grade ⅛ in. thick, identified as Mastipave, is also manufactured by Paraffine Industries. (See Table 4-4.)

Mastic Tile. Mastic tile is a general-purpose floor finish for both public buildings and industrial uses. It is economical in cost and maintenance if properly selected and installed. It is one of the few types of finishes that can be used on floors below grade and subjected to moisture.

Mastic tile should not be used for exterior exposure. The binder, filler, asbestos fiber, etc., may be changed to secure a considerable range of resilience, hardness, toughness, brittleness, colors, etc. It can also be secured with oil, chemical, and greaseproof resistance.

Although it is available in $\frac{1}{8}$-in. thickness, lower maintenance and longer life makes the $\frac{3}{16}$-in. thickness much preferred. Four price groups, A, B, C, and D are usually available, Group A, plain colors, being the lowest priced. Available sizes are 6 by 6 in., 9 by 9 in., 6 by 12 in., 12 by 12 in., 9 by 18 in., 18 by 24 in., and 12 by 24 in. Octagonal and hexagonal shapes may be secured on special order.

When placed on wood floors, an underlayment of at least $\frac{5}{16}$ in. should be used. Where installed below grade, it is advisable to use a mastic underlayment to reduce maintenance. Aluminum or brass edging strips should be used on stair treads or other termination edges.

Some producers are Tile-Tex Co., Johns-Manville, Armstrong Cork Products, Thomas Moulding, David E. Kennedy, Duraflex Co., Uvalde Rock Asphalt Co., Selby-Battersby Co., Mastic Tile Corp. of America (Newburgh, New York), etc. (See Table 4-4.)

Mastic Block. Both mastic block (bricks) and planks are available for interior or exterior use as

Industrial floors—Factories; airport hangars, runways, etc.
Piers and docks—Bridges and approaches
Roof decks—Parking space, miscellaneous traffic, storage
Warehouses—Packing and canning factories
Driveways—Courts, terraces

Blocks are obtainable in such sizes as 4 by 8 in., 4 by 12 in., 4 by 16 in., 12 by 24 in., and hexagonal (Hastings). Planks are obtainable in 12- by 24-in. and 12- by 36-in. sizes as standard.

The thicknesses of blocks generally available are $1\frac{1}{4}$ to $1\frac{1}{2}$, 2 to $2\frac{1}{2}$, and 3 in.

Planks are available from $\frac{1}{2}$ to 2 in. in thickness, and special thicknesses may be ordered.

The weight of the blocks usually averages 9.5 lb per sq ft per 1 in. thick; weight of the planks is somewhat lighter, usually 8.0 lb per sq ft per 1 in. Material consists of asphalt, asbestos or similar fiber, mineral filler, silica flour or crushed limestone, heated and pressed.

The advantages of mastic block are that it is self-healing, water-resistant, resistant to wear, acid, and trucking abuse It is resilient and free from decay and dry or wet rot. It is quiet, slipproof, odorless, and easily repaired. Special nonslip surfaces are available, usually identified as "mineralized plank" or "mineral surfaced." Johns-Manville, Carey Co , Asphalt Block Pavement Co., Servicised Products, and Hastings Co., are typical of the more reliable producers.

The usual thickness for heavy-duty floors where blocks are necessary is 2-in. For light-duty traffic the surface may be as thin as $\frac{1}{2}$ in., but in all cases the installation should be discussed with the manufacturer's engineers.

Blocks are usually bedded in a 1:3 portland-cement base $\frac{1}{2}$ in. in thickness. Blocks are set tight with staggered joints. Vertical joints in acid-resisting work should not be filled, but it is necessary to set the blocks or planks in asphalt or over a two- or three-ply waterproofing membrane. For nonacid work, the joints may be filled with fine sand or a cement grout. (See Table 4-4.)

Cork. Cork is a special-purpose floor finish usually selected for elevator cars, working space in high-occupancy offices, bathrooms, and stair treads and landings. It is exceptionally quiet and comfortable, but its resistance to abrasion is low. The resistance may be increased by applying lacquer.

Cork is obtainable in $\frac{1}{4}$- to $\frac{5}{16}$- to $\frac{1}{2}$-in.-thick tiles; 6- to 9- and 12-in. squares, which are cemented to floors with a special adhesive. A special cork-cellulose binder tile is made in ⅛-in. thickness by Bird & Son.

Rectangular sizes such as 6 by 12 in., 3 by 36 in., 12 by 18 in., 6 by 18 in., 6 by 36 in., 3 by 12 in., up to 18 by 36 in., etc., are also available

Cork is not recommended for below-grade installation or where the surface is subjected to continuous moisture or heavy moving loads.

Cork is produced by Bird & Son, David E. Kennedy, Armstrong Cork, Goodyear, Cork Insulation Co , Selby-Battersby, etc. (See Table 4-4.)

Magnesite (Magnesium Oxychloride). Magnesite has a high compressive strength varying from 8,000 to 12,000 psi. It is resilient, excellent for standing or walking operators; attractive, as it may be secured in many colors; and sanitary.

Table 4-4. Characteristics of Floor Finishes

Characteristic	Cement	Mastic	Wood block	Wood, laminated	Brick	Rubber	Plastic tile	Linoleum	Mastic tile	Mastic block	Cork	Magnesite

NOTE: Lowest number indicates highest quality, in cost index, the lowest cost. Y = Yes N = No or None

[a] Separate topping, metallic hardener

[b] With acidproof membrane under mastic

[c] Creosote-impregnated end-grain lug block (Kreolite)

[d] Tar-Rok

[e] Acidproof 2¼ in brick

[f] 24 hr for Lumnite cement

[g] Can be hardened if necessary, but increases tendency to crack or chip

[h] For hard type

[i] Soft base, tough top

[k] Hard to classify for toughness Will stand considerable mechanical abuse.

[l] Based on 1.2.4 mix. Regular 1:1.2 mix with fluosilicate wash should be approx. 0.012

[m] Based on maple finish

[n] High density, 5/16 in dark = 0.026 in 5/16 in light = 0.011 in., ½ in. light = 0.019 in.

[p] No available tests—probably about 0.035 in

[q] No available tests, probably about 0.005 to 0.010 in for shale

[r] Concealed or copper nails

[s] Cement, mastic, rubber, linoleum, mastic tile, and magnesite may be purchased with conductive quality to prohibit sparking from static discharges

[t] Moisture to extent that material cannot dry between periods

[u] Not recommended

[w] Without wax or lacquer

[x] Can be obtained on special order

[y] Dry surfaces, designed for traffic

* For thickness indicated.

When copper salts are included, growth of bacteria is discouraged, hence magnesite is excellent for locker rooms (Hubbellite, H. H. Robertson Co. patent). It is also avoided by insects. It is *not suitable* for exterior use owing to absorption of moisture and disintegration. It will stand flushing with water if drained or mopped off so that the material can thoroughly dry between wettings. It can be supplied with conductive quality (Kompolite Co., Thomas Moulding Co., etc.) to eliminate static discharge when desired for use around explosive vapors or solvents.

Magnesite is suitable for heavy loads such as trucking aisles—has a fast-trucking finish.

Thickness over concrete should preferably be ⅜ in. or over. When installed on wood, it should be approximately ½ to ¾ in. thick to permit the installation of a leveling underlayment over chicken wire tacked over building paper. Use a metal molding to separate plaster walls from a magnesite base.

Fillers such as wood flour, silica flour, etc., are often used to build up thickness.

Probably no type of floor finish has caused so much grief from improper use or more satisfaction from proper use and installation as the magnesium oxychloride type. It is essential that an experienced contractor install the floor and that the ingredients be properly blended for the intended use.

Other typical types are made by Selby-Battersby, Federal Flooring Corp. (New York), Marbleloid Inc. (See Table 4-4.)

ROOFING

Next to floors, there is probably no other part of a building, especially an industrial building, that causes as many maintenance headaches as roof covering, especially on large buildings.

In spite of this, the rules governing proper construction and repairs are well known by all the reputable roofing manufacturers and are available to all interested parties if they request assistance from the manufacturers' technical division and *not* every Tom, Dick and Harry who has applied a piece of felt at some time in his life. If your local roofer is capable of advising you, the manufacturer will so advise you.

Volumes could be prepared on proper installation, selection of proper bitumens, flashing, repairs, etc., so it will be obvious that the following data can describe only a few of the pertinent points to be observed for minimum maintenance.

Basic Application Requirements. The use of asphalt or asphalt-saturated felt on a roof of extensive area having a slope of ½ in. per ft or less should *not* be permitted. For slopes over ½ in. such material may be used if desired. No slag or gravel surface is required.

Coal-tar-pitch-saturated felts and coal-tar pitch with slag or gravel finish should be used for all flat roofs, especially those having slope of ½ in. per ft or less. A 20-year bonded roof can be secured with this type up to slopes of 5 in. in 12 in.

The mixing of asphalt and tar should never be permitted. If it is necessary to repair an old smooth-surfaced asphalt roof and convert it to a coal-tar-pitch roof, a 15-lb unsaturated felt or a 15-lb asphalt-saturated asbestos felt should be employed as the separating medium. In this case the felt may be cemented to the roof with asphalt, but the top mopping should be pitch. Asbestos felt is preferred because the amount of saturant is less than that of rag, and it is less liable to cause trouble owing to the presence of the asphalt undercoat and pitch overcoat.

No more pitch should be poured at one time than can be immediately covered with slag or gravel. It is essential that the pitch be hot to hold the slag properly.

The temperature of pitch should not exceed 400°F in the kettle. The proper temperature for placing is from 325 to 375°F. If the white vapor coming from the kettle turns yellow, the fire should be reduced and cold pitch added.

The temperature of asphalt should not exceed 450°F in the kettle. Pouring temperatures should be from 350 to 400°F.

The top coat of asphalt on smooth-surfaced roofs should not exceed 25 lb. Too heavy an application will result in checking or "alligatoring."

All masonry should first be primed before applying asphalt. Polished concrete surfaces should be primed with a creosote primer before applying pitch.

Manufacturers will not issue a 20-year flashing bond where 8-in. thick parapet walls exceed 12 in. in height owing to possible leakage through the walls.

Parapet walls over 12 in. high should be waterproofed with a transparent solution similar to Sonneborn & Sons Hydrocide Colorless if the flashing is carried up to the coping. Trouble is certain without it.

The flashing is the most difficult part of the roof to construct and the first to become defective. Each manufacturer has his own pet method of installation which he is willing to insure with a guarantee bond.

If a high parapet is necessary and a watertight installation is desired, a through-wall flashing should be used immediately above the counterflashing so that all water penetrating the wall will spill out over the roof and not under the flashing.

Don't put a new roof over a wood deck having warped boards or open joints. A reputable roofer will not guarantee the installation, and you are inviting perpetual trouble if you insist.

Don't waste your money on insulation by leaving out a moisture barrier under the insulation. If you use 3 in. or more, ensure the job by installing a barrier of at least two-ply saturated felt.

Considerable research has been conducted by the various roofing manufacturers during the past 5 years on the elimination of "blisters." One of the contributing elements is "green" concrete, especially where there is a "pressure head" within the building due to air conditioning or a fairly high temperature below the roof. The moisture is thus driven out of the slab, and the vapor makes its way upward and through the layers of roofing material, forming "blisters." It has also been discovered that, where roof insulation is blanketed off into *squares*, the tendency to form blisters is greater because the gas is sealed in within the "square." Roofing specifications should indicate the placing of the moisture seals in *parallel* strips about 20 ft 0 in. apart. In other words, the cutoffs should all run in the same direction. A cutoff is also recommended around large openings, not more than 18 in. away from the face of the opening, curb, or wall. The simplest method of making the cutoff is to divide a 15-lb sheet into three parts (about 11 in. each) for 1-in. insulation and two parts (±16 in. each) for 2 in. or over and install it as shown by Fig. 4-13.

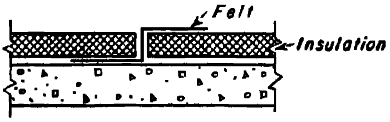

FIG. 4-13. Roof insulation cutoff.

In areas where wind is a factor and where you desire the most satisfactory roofing over wood, insist on the first felt being securely nailed with either "simplex" nails or nails with disks at least $\frac{7}{8}$ in. in diameter. The first felt should be 30 lb or two layers of 15 lb. Over concrete, the first layer may be 15 lb, but it should be thoroughly mopped under its entire area.

Where a slag or gravel roof is used, be certain that slag stops are used at the eaves and at the drain head. The roof drain, if properly selected, will have suitable slag and flashing rings. If the slag or gravel is properly installed, you will not have loose material to clog up your gutters or drains.

Where a metal deck is used, at least $\frac{1}{2}$ in. of roof insulation must be used in order to secure a guarantee-bonded roof. All reputable manufacturers have the same requirement.

Felts. With the modern methods used by manufacturers today, there is little difference in the efficiency or ease of saturation required for either rag or asbestos felts. In the case of rag felts, the fibers as well as the interstices are filled with pitch or asphalt, while in the case of asbestos the fibers are coated with pitch or asphalt and the remaining saturant is in the interstices. While this difference in impregnation may give the impression that the rag felt is superior because the fibers are filled with saturant, it should also be kept in mind that there is nothing in the chemical make-up of asbestos which would permit it to oxidize or disintegrate even if not saturated with bitumen, and its life will depend upon the tensile strength or quality of the fibers. Its waterproofing quality will depend only on the interstices being completely filled with a waterproofing medium. The degree of saturation and weights of the two types are as follows:

Asphalt-saturated asbestos felts—ASTM D250-39T; desaturated weight 9 lb min, saturant to be 50 per cent dry weight of felt, min

Asphalt-saturated rag felt—ASTM D226-38T, desaturated weight 5.2 lb min saturant to be 140 per cent dry weight of felt, min

Weights are for 100 sq ft of fabric

Rag felts have a higher tensile strength than asbestos felt, and their proponents contend that the field application of the hot asphalt or pitch adheres and spreads easier over rag than asbestos felts. In a long U- or L-shaped building, the rag-felt roofs withstand the strain from expansion and contraction at the corners better than asbestos felts. A saturated cotton fabric is stronger for this purpose, usually having a tensile strength of between 50 to 60 lb per in both ways.

Asbestos felts *are* more fire-resistive than rag felts, even though the asphalt or pitch may be inflammable in both cases.

Asbestos felts withstand direct exposure to the sun and heat much better than rag felts, especially when the roof surface is alternately wet and dry. Rag felts rot out rapidly if used on a flat or semiflat surface if alternately wet and dry, especially if not protected by sufficient bitumen, slag, or gravel.

Asphalt versus Pitch. There is no doubt that a good grade of either asphalt or pitch will prove absolutely satisfactory if used properly.

Even a medium grade of asphalt or pitch will last many years if protected from the sun by a slag or gravel finish, but if it is not protected, the oils will burn out and the surface will crack or "alligator."

Pitch should *never* be used on a steep sloping surface because it will run in hot weather. "Steep" pitch should be specified when used on a surface sloped more than 2 in. in 12 in.

Asphalt, on the other hand, should be used on steep slopes and may be used on any surface where water will *drain entirely off* the roof areas and not stand in puddles.

Pitch has a self-healing quality and the ability to withstand exposure to water and sun. The property of being self-healing is advantageous when water manages to get under a layer of felt through a leak or crack, as it does not prevent the layers from sticking together later after the water has evaporated and does not affect the waterproofing qualities of the pitch.

Material Specifications. Where reference to standard material is required, it is recommended that the following be used as a guide:

Table 4-5

Tarred felts, ASTM spec	D 227
Coal tar pitch for roofing	
U S Govt master spec	R P-381, Type 1
ASTM spec	D-450
Creosote primer, ASTM spec	D 43
Plastic roof cement Federal spec	SS-C 153-Types 1 and 2
Asphalt primer, ASTM spec	D 41
Asphalt felts (rag), ASTM spec	D-226
Asphalt for roofing, ASTM spec	D-312
Asbestos felts, asphalt-saturated with min 85 per cent asbestos fiber ASTM spec	D-250
*Cotton fabric—asphalt-saturated, ASTM spec	D-173
Cotton fabric—coal-tar-pitch saturated ASTM spec	D-173

* See below for more definite specification, which is preferred

The use of an impregnated cotton fabric for repairing flashing, especially eaves, corners, or long parapet walls where expansion and contraction occur is excellent because of the inherent tensile strength of the fabric. Lead flashing has proved unsatisfactory on long runs because of buckling from expansion.

An excellent specification for the fabric, where used as roof flashing, waterproofing membrane, or spandrel flashing, is as follows:

Asphalt- or Coal-tar-saturated Cotton Fabric. An asphalt- or coal-tar-saturated all-rag woven fabric shall have a tensile strength, both directions (grab method), of not less than 50 lb per lin in. and not less than 10 per cent elongation. The fabric shall weigh before saturation not less than 4 oz per sq yd and after saturation not less than 12 oz per sq yd and shall have a thread count between 18 by 18 in. and 36 by 36 in. In all other respects fabric shall conform to ASTM D173.

WALLS

Brick is one of the oldest of our building materials and is still one of the most extensively used. Our modern methods and constructions are the result of long usage instead of theoretical analyses, which is so essential with most building materials.

The masonry of this period has deviated somewhat from that of our ancestors in that we have combined brick with numerous shapes and types of units such as tile, concrete, terra cotta, etc. The greatest improvement, however, has been made by the development of textures and colors, especially in the ceramic field, and improvement in deairing and baking.

For industrial use, it is essential to select the most economical wall both in first cost and maintenance and one that is suited for special conditions such as extremes in weather, moisture, acid-fume resistance, and often for sanitary reasons such as in plants processing foods or medicines.

Structural requirements with hints on special precautions to be followed in construction will be discussed followed by comparisons of various types of walls.

Structural Requirements. Usually local building codes limit the thickness, height, laterally unsupported lengths, etc., of all types of walls. However, for quick reference a few limitations are presented.

1. *Height of Walls.* Exterior nonbearing walls are usually limited to a height of twenty times their thickness for solid masonry, fourteen for cavity walls, and eighteen for hollow walls where the maximum horizontal distance between supports is not over 20 ft 0 in.

2. *Interior Partitions.* Considerable variation exists in the requirements for interior nonbearing partitions, but thirty times the thickness is usually considered maximum height where loads are not bracketed or supported by the wall, especially for industrial buildings where vibration is present. A few of the building codes are more lenient where an interior partition is built solidly against the ceiling.

3. *Masonry Walls.* For general code limitations on masonry walls an excellent bulletin, CP33, may be secured from the Portland Cement Association.

4. *Weather Tightness.* With the finest material and workmanship, an 8-in. wall *may* be made watertight, but the chances are about 10 to 1 that it will leak. A questionnaire to over one hundred of the largest and most reputable contractors in the entire United States failed to reveal a single contractor who would guarantee a tight wall under 12 in. thick. Experience has indicated that it is extremely difficult to make a tight vertical through joint.

For maximum impermeability, solidly filled mortar joints, low-absorption brick or tile, preferably shale, a minimum of 12 in. in thickness should be used, and a mortar having a high-plasticity lime, high water retentivity, and low shrinkage mix, as described below should be used. If an 8-in. wall is desired, besides the above requirements, a good stearate waterproofing admixture should be added to the mortar and then an extra 3 cents per sq ft spent in applying a good transparent waterproof wash to the exterior, similar to Sonneborn Sons' Hydrocide Colorless. Joints in all cases should be tooled to secure a dense concave joint.

For a good treatise on permeability, refer to Bureau of Standards *Report* BMS-82, and for strength, absorption, and resistance to freezing and thawing of bricks throughout the United States, BMS-60.

Brick and Tile. For maximum resistance to freezing and spalling, moisture penetration, strength and volume change, a dense deaired unit, preferably of shale, having a 5-hr boiling absorption of less than 8 per cent, should be used.

All brick having an absorption of over 20 g per min when the flat side of the brick (32 sq in.) is immersed in $\frac{1}{8}$ in. of water should be wetted sufficiently to decrease the absorption to that ratio when laid.

As a general rule, all-brick walls offer the greatest opposition to moisture penetration, brick and tile next, and tile last. Quoting from Bureau of Standards *Report* BMS-82:

> Twelve-inch walls faced with brick and backed with hollow units were more permeable than similar all-brick walls. The kind of hollow unit used in the backing had no consistent or important effect on permeability, but the walls containing end-bearing units appeared to be slightly less permeable than those containing side-bearing hollow units.

Bricks exposed to weather should conform to ASTM C62 grade MW; structural clay tile, to ASTM C34, grade LB for bearing walls or piers, grade LBX when exposed to weather; ceramic glazed tile, ASTM C126, nonload-bearing tile, ASTM C56; concrete hollow load-bearing masonry units, ASTM C90; concrete solid load-bearing units, ASTM C145.

Tile for exterior walls and interior partitions may be classified as (*a*) plain dense deaired red shale (often designated as red industrial tile); (*b*) buff, iron-spot (ferro glaze), or manganese-spot unglazed facing tile; (*c*) ceramic glazed tile of many colors, the most economical color of which is "clear glaze" or "lustre glaze," which is a buff or light ivory.

Salt-glazed tile is not due any consideration as the price differential does not justify its use over the "clear-glazed" unit. The salt-glazed finish is *not* an impervious finish but merely provides a "sheen." If it is examined under a magnifying glass, its numerous cracks will become evident. The clear-glazed tile has an impervious surface, is easily cleaned and pleasant in appearance. Manufacturers will provide the salt-glazed finish upon request, but they much prefer to supply the clear glaze because greater satisfaction will ensue.

Sizes. The standard brick is $2\frac{1}{4}$ by $3\frac{7}{8}$ by 8 in. for smooth-surfaced; $2\frac{1}{4}$ by $3\frac{3}{4}$ by 8 in. for common and rough-faced brick as established by ASTM. Space does not permit discussion of the many methods of manufacturing or classifying the types and surface finishes.

The Glazed Brick and Tile Institute has classified tile sizes as shown in Table 4-6.

Uses. For excellent appearance, low maintenance, good housekeeping with minimum effort, dustless, sanitary construction for food or pharmaceutical processing, ceramic or clear glaze should be used. A disadvantage is its high first cost.

Table 4-6

Face size	Series	Thickness
5 × 8 in	N or D Series	$1\frac{3}{4}$-$3\frac{7}{8}$-$5\frac{7}{8}$-8 in
5 × 12 in	T Series	$1\frac{3}{4}$-$3\frac{7}{8}$-$5\frac{7}{8}$-8 in
$2\frac{1}{4}$ × 8 in	S Series	$3\frac{7}{8}$

For modification of the above, as required for manufacture of dustfree products, the buff unglazed facing tile may be used to within about 5 ft 0 in. of the floor, the wainscot being either clear-glazed buff, iron spot (ferro glaze), or manganese spot. This provides a clean light-reflecting surface above and a wainscot that will not show elbow or hand smudges down the trucking corridors and will eliminate the usual 3- to 5-year periodic maintenance painting. It is sufficiently hard to withstand mechanical abrasion. A disadvantage is that it is medium high priced.

For good appearance, impervious exterior and interior, low maintenance, low cost, and good housekeeping, deaired red shale facing tile (industrial red tile) may be used. Walls have the color of normal red brick but have fewer mortar joints owing to larger size and a smoother and more dense face. It has been demonstrated that a mason can lay up 10 sq ft of this type of unit in the 5- by 12-in. face in the same time it takes him to lay up 7 sq ft of brick wall. Immunity from attack by acids may be afforded by pointing the mortar joints with a phenol- or furane-resin mortar (see Brick for floors, pp. 148–149).

For maximum strength, maximum impermeability for the same thickness, maximum mechanical abuse, good to fair appearance, good resistance to freezing, thawing, and acid atmospheres, the dense shale brick is hard to beat. Some disadvantages are that housekeeping is more difficult, and there is no decorative appearance without maintenance painting. Also more numerous mortar joints are exposed to attack from acid vapors and liquors, but this may be remedied as noted above for tile.

Mortar. Next to workmanship, the quality of the cementing medium is most important. The conclusions expressed herein are the result of 30 years of intimate observation. Strange as it may appear, substantiation appeared in an excellent article by Watstein and Seese in the August, 1947, issue of *ASTM Bulletin.*

There are four important types of masonry mortar, which for the purpose of this article will be designated as types I, II, III, IV.

Type I—1:0.25:3 mix by volume of portland cement, lime, sand

Type II—1:1:3 mix by volume of portland cement, lime, sand

Type III—1:1:6 mix by volume of portland cement, lime, sand

Type IV—Commercial masonry mortars meeting Federal Specification SSC-181B-type 2

Type I has the highest compressive strength—approximately 6,000 psi, with types II, III, IV decreasing in order to about 1,000 psi. Bond strength of type I is approximately 65 psi, decreasing in order to about 40 psi for IV. Water retentivity is approximately 70, 75, 80, and 80 per cent in order. (Type I is frequently varied by some authors to 1:0.1:3)

For all types of tile, with the possible exception of glazed furring tile, whether horizontal or vertical cell, type II is emphatically recommended. Where the fineness of the sand is suitable, a 1:1:4 is also satisfactory.

Type III is recommended for all brick walls except where walls are over twenty feet high, run over one hundred feet, or where high winds are frequent. In such cases a 1:1:5 or even a 1:1:3 should be used to secure the necessary compressive and bond strength with reduced volume change. Watstein and Seese, in the *ASTM Bulletin,* have expressed the following conclusions:

> There was no consistent relation between the shrinkage of the various mortars and any of their other properties. However, for mortars of similar composition, such as the portland cement-lime mortars, the shrinkage increased roughly with the *amount of mixing water* required. Of these mortars, the minimum shrinkage was shown by the group 1PL (type I) in which the average for five mortars, after 6 months' drying, was about 0.12 per cent.

(The average shrinkage of the 1:1:6 mix was 0.148 in ; 1:2:9 mix was 0.157 in., and type IV was 0.143 in. On the basis of proportions, the type II should therefore have a shrinkage value of between 0.13 and 0.14 in.)

For ceramic glazed furring tile, type I would be preferred if the mason could be influenced to mix an additional type.

Mortars are no different from concrete. The more water put in the mix, the greater the amount of water that must be eliminated, with consequently greater volume change. Volume change induces *cracks.*

Lime. Lime should conform to the National Lime Association specification for mason's hydrated lime type S, having a plasticity of more than 200 after wetting (not soaking) and a water retentivity of more than 85 per cent when tested in a mortar made from the dry hydrate. The ordinary run of commercial hydrated lime does not conform to the above requirements, however. If it must be used, insist on a soaking period of not less than 24 hr before use.

Typical examples of several very satisfactory commercial limes are Miracle by G. & W. H. Corson, Plymouth Meeting, Pennsylvania; Rockland-Rockport Lime Co., Rockland, Maine; Flamingo Hydraulic Lime by Riverton Lime & Stone Co., Riverton, Pennsylvania; Super Limoid by Warner Co.

Economic Comparisons of Walls. Fourteen of the most common combinations of brick and tile are presented on p. 162, and their cost factors are indicated.

Cost factors are based upon brick and tile prices for the Philadelphia area and are listed below. Labor rates are also indicated. Conversions are therefore readily made for any local costs. One hundred square feet of plain wall is used as the basis. Mortar quantities are minimum with no waste allowance. No profit or overhead is included. Therefore, cost factors are to be considered as *purely relative costs.*

One-quarter-inch mortar joints are included in all types except 1.0, 4.0, 4.3, 8.0, 8.1, 8.2, 11.0, 11.1, 12.0, 12.1, 13.0, 13.1, 14.0, 14.1, and 14.2 (see Figs. 4-14 to 4-22, inclusive, and Table 4-8), for which $\frac{3}{8}$-in. joints are necessary. Mortar costs are included with labor costs. Labor costs include tooled joints, both faces.

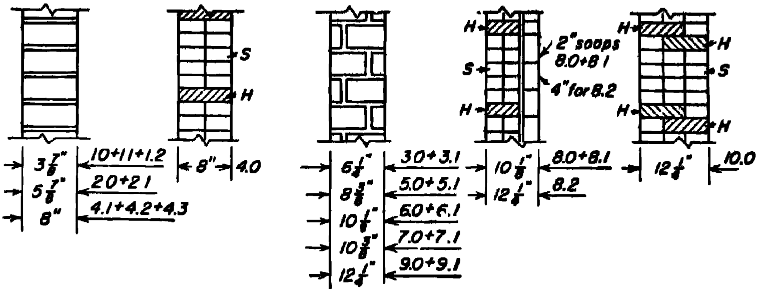

FIG. 4-14. FIG. 4-15. FIG. 4-16. FIG. 4-17. FIG. 4-18.

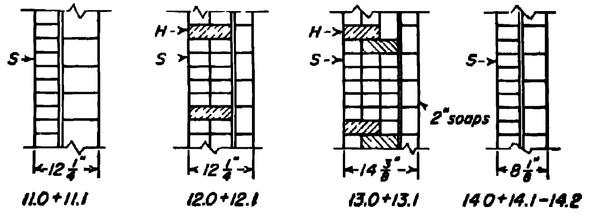

FIG. 4-19. FIG. 4-20. FIG. 4-21. FIG. 4-22.

FIGS. 4-14 to 4-22. Brick and tile walls. Proper bonding for plain and composite construction.

Basis of costs for tabulation:

Table 4-7

Type	Buff facing tile, /M	Ivory luster glaze—clear, /M	Iron spot-ferro glaze—facing tile, /M	Red shale facing tile, /M
TA—2 × 5 × 12-S1S	$ 90	$150	$ 92	$ 53
TAK—4 × 5 × 12-S1S	124	284		
T—4 × 5 × 12-S1S	116	197	119	81
TD- 4 × 5 × 12-S2S	130	292	132	88
T60 6 × 5 × 12-S1S	145	277	164	139
T60D -6 × 5 × 12-S2S	172	360	179	147
T80—8 × 5 × 12-S1S	195	333	210	151
T80D—8 × 5 × 12-S2S	220	449	336	162

Brick—red shale industrial, wire cut, smooth face, $30/M

Labor rates - mason at $2 25/hr and helper at $1 30/hr

Number of units per square foot of wall—4 in. brick wall = 6.25, 8 in. = 12.50; 12 in. = 18.5; 5 by 12 in. = 2.2.

Where 4- and 2-in tiles are used on same wall, it is assumed that 4-in. Kerfed tile (TAK) will be used for the 2-in. tile. Where 2-in. tiles are used with units other than 4-in , the 2- by 5- by 12-in. unit (TA) is used. Modular units are not considered, but their use will not alter the relative unit costs. No allowance is made for breakage or defects.

KEY: FT = buff facing tile, unglazed; GT = glazed (clear); FGT = ferro glazed facing tile; RFT = red shale industrial facing tile; H = header course; S = stretcher course.

The use of 4 + 2 or 6 + 4, etc., self-bonded walls with reversed or staggered joints results in a superior wall both structurally and physically as no through vertical joints exist, and both exterior faces may be easily lined up to secure a smooth, properly aligned face. Variation in size of tile is compensated for by variation in vertical mortar joint. Unbonded walls should be tied together with metal ties, preferably with bronze or monel wire ties, every 24 in. horizontally and every 15 to 18 in. vertically.

A saving in material price may be obtained by using a 4-in. Kerfed unit where possible, especially when both 4- and 2-in. units are used, as the 4-in. type may be split in half (tile symbol TAK).

Types T60D and T80D are not supplied by all manufacturers. Wall types 2.0, 2.1, 4.1, and 4.2 are not so satisfactory as other types of the same thickness because of the lack of uniform thickness with the resultant uneven appearance of the finished surfaces. They are inferior structurally and are more permeable than the staggered construction of types 3.0 and 5.0. Types tabulated are based upon having the same surface on both sides. For variation, the quantities tabulated with the corresponding price lists may be easily adjusted (see Table 4-8).

Five- by eight-inches D series tile is not tabulated, since the 5- by 12-in. T series has a lower labor cost. The D series, however, generally presents a better appearance owing to easier alignment and less variation in dimensions. There are 2.2 units of 5- by 12-in. tile per sq ft of wall and 3.3 units of 5- by 8-in. tile per sq ft. A ¼-in. mortar joint may be advantageously used with the 5- by 8-in., tile, but masons usually prefer the ⅜-in. joint for the 5- by 12-in. tile, although ¼ in. is preferable for both maintenance and appearance.

Table 4-8

Type	Wall, in.	Thickness, in.	Masonry units, 100 sq ft	Mortar, cu ft	Mortar cost	Labor, 100 sq ft	Total sq ft	Cost factor
1.0	4B	3⅞	18.75	7.0	3.29	42.00	0.61	1
1.1	4FT	3⅞	28.60	3.4	1.60	50.00	0.79	2

NATURAL AND SYNTHETIC RUBBER*

BY DR. E. R. GILLILAND

Department of Chemical Engineering, Massachusetts Institute of Technology

Owing to its unique properties, natural rubber has developed into an important material of construction. In the last 15 years a large number of rubberlike materials called "synthetic rubbers" have been developed. In a number of cases these are replacing natural rubber, but in a great many cases their unique properties are opening up new fields of application. These fields are so complex that it is impossible to outline any definite rules as to which material should be used for a given application. The following discussion will indicate the general types of materials available and their physical characteristics, but anyone interested in a specific application should consult an expert rubber technologist.

NATURAL RUBBER

Natural rubber has been employed as a material of construction for many years. It has basic properties which the technical men have been able to exploit in a great many ways. Elastically it is unique in allowing essentially reversible elongations up to 600 to 1,000 per cent. It can be compounded to give high tensile strength, *i.e.*, 40,000 psi of cross section at break. It is very water-resistant and has a very low permeability to water; it likewise has low permeability to a number of the more common gases; it is a good electrical insulator; it can be compounded to give material of outstanding abrasion resistance; and if desired, it can be converted into a hard material of low-percentage elongation of break.

While it is not possible to obtain all the properties listed above in the same sample, it is generally possible to obtain a combination of several of them. For example, in automobile tires and belting, it is possible to combine a high degree of flexibility or elasticity with superlative abrasion resistance. In inner tubes, balloons, and rubber gloves, it is possible to combine flexibility and high-percentage elongation with the impermeability to gases and water. For vibration damping it is possible to combine high strength with elasticity. Over a period of three to four decades rubber technologists have learned to exploit the properties of natural rubber to obtain the best combination of properties for a given use. Owing to the versatility developed in the products by this research work, rubber has become one of the important materials of construction.

In the last 20 years natural rubber has been challenged by a number of synthetic materials. This competition has been the result of two main factors—the high cost of natural rubber and the fact that in certain applications elastic or rubberlike materials were desired, but the conditions were such that natural rubber did not give satisfactory performance.

Natural rubber has varied widely in price. During the last 35 years the actual wholesale price has been as low as $3\frac{1}{2}$ cents and as high as 82 cents per lb. It is in the periods of high prices that the greatest impetus has been given to the development of rubber substitutes. Originally, the work of developing such substances was carried out along the lines of attempting to synthesize a material having the same chemical and physical constitution as natural rubber. Such materials were therefore called "synthetic rubbers." To date it has been impossible to synthesize a material identical with natural rubber, and a number of years ago the emphasis was shifted from trying to develop the same chemical and physical properties to synthesizing a material that could be used in a manner similar to natural rubber even though it did not have the same chemical and physical properties. The generic term "synthetic rubber" has been applied to this class of materials also.

*Superior numbers refer to specific references listed at the end of this subsection.

In the crude state natural rubber can be easily worked, molded, and shaped and then can be changed chemically into a strong elastic material that will resist deformation. As a result of intensive study, chemists have concluded that those materials having elastic properties of this type are composed of very long, thin molecules. The ratio of length to diameter of a fully extended molecule of this type may be as great as several thousand to one. Such molecules in the unvulcanized or uncured form of rubber are presumably greatly contracted in length and interwoven with one another. When a mass of such material is molded or shaped by being subjected to pressure or stretching, its individual molecules are displaced relative to one another. If, then, by chemical processes these long-chain molecules can be tied together, further displacement relative to one another becomes much more difficult, and the material acquires the property of resisting forces that would otherwise cause permanent deformation. However, owing to the contracted condition of the molecules, the material can still be extended. In this process the molecules are simply pulled out somewhat like a spring without causing rearrangement. In natural rubber the vulcanizing of the rubber structure is generally carried out by the addition of sulfur, although other materials can be used. The mechanism of this process is not definitely known, but it is believed that it is related to a special chemical characteristic of the natural-rubber molecule, which is termed "unsaturation." The sulfur reacts with the unsaturated portion of a molecule and forms some type of bridge with it to another molecule.

DEVELOPMENT OF SYNTHETIC RUBBER

The research on synthetic rubber has, therefore, been directed to the production of long-chain molecules which can be locked together by vulcanization or an equivalent process. In general, chemical substances that are easily available or can be prepared easily and economically are low in molecular weight. Only those capable of combining to form long chains are useful in the production of rubberlike substances. There are a large number of such substances, and in a great many cases they will combine with each other in a similar manner. Thus, it is possible to produce an almost infinite number of synthetic rubberlike materials. In general, none of these materials is identical with natural rubber, although in any one physical characteristic it is usually possible to develop a synthetic material that is superior to natural rubber. However, it is not always possible to produce a synthetic rubber that will combine several characteristics into a given product as well as it has been possible to do with natural rubber. This deficiency may be due to the rubberlike material itself, or it may be due to the fact that the rubber compounders have not had time to develop the products based on the new material as well as they have those of natural rubber. In a great many properties the synthetics are so superior to natural rubber that there is no real competition. For example, in resistance to solvents such as gasoline, resistance to acids and alkalies, permeability to gases, dielectric properties, heat resistance, vibration damping, etc., there are synthetics that are superior to the materials which can be made from natural rubber. In other cases the balance is the other way. For example, in heavy-duty truck tires, natural rubber combines the properties of elasticity, high resilience, high cut and tear resistance, and high abrasion resistance in a manner superior to synthetic materials.

PLASTICS

The foregoing discussion related to materials that have a high degree of extensibility similar to natural rubber. However, there are a great many cases in which rubber is employed that do not require this extremely high degree of elongation, and in this field a large group of materials called "plastics" can be similarly used. In general, the plastics are divided into two main classes—the thermoplastics and the thermal-setting plastics. In the thermoplastic class the materials are very similar to the synthetic rubberlike materials except that they are not in general vulcanized. Their use depends upon the fact that at high temperatures they soften sufficiently to be molded and shaped, but at lower temperatures they are able to hold this shape. Such materials vary widely in properties. They can be hard, such as the polystyrenes, polythenes, polyacrylates, and the various polyvinyl compounds. These materials can be heat-softened and then cast or molded. At ordinary temperatures they are relatively hard and can be used to replace hard rubber or ebonite in most of its uses, and they have the advantage of better physical properties in a great many cases. For example, some of them have excellent electrical properties, and some of them are transparent and can, therefore, be utilized where hard rubber is completely unsuitable. They can likewise be compounded into almost any desired color, which makes them much more suitable as materials of construction where appearance is important. While their flexibility is in general much less than that of the vulcanizable rubberlike materials, they can be compounded to give satisfactory characteristics in this respect. For example, they are flexible enough to make suitable insulation for electric wires and cables, and they can be formed in sheets which are as flexible as most woven fabrics.

The thermal-setting resins are a different class in that, after they are molded or formed, a chemical reaction is carried out which ties the whole structure together so firmly that it becomes an essentially rigid structure. The phenol-formaldehyde resins of the bakelite type are typical of this category. These resins can be molded or cast into almost any shape and have largely replaced hard rubber for this purpose. They combine high physical strength with good electrical properties and the possibilities of making products of almost any desired color. They are particularly suited for molded articles, such as electrical parts, radio cabinets, etc. They have gained wide acceptance in places where rubber was never particularly satisfactory. For example, they constitute a major portion of the film-forming materials in a wide variety of the modern paints and lacquers. They are being widely used as the bonding agent in various plywoods, and for these uses they are superior to the natural glues.

PRINCIPAL TYPES OF SYNTHETIC RUBBERS

While it is not possible to cover the extremely large number of rubberlike materials which have been produced, it is possible to review the main types and to compare their physical properties, uses, and costs with those of natural rubber. In the synthetic rubberlike materials, there are three types that are produced on a large scale, *viz.*, the buna, or diolefin, type of polymers, the neoprene type, and the butyl type. In addition, there are miscellaneous polymers such as thiokol and silicone rubber. Owing to the importance of these materials, the method of preparation and characteristics will be outlined.

Buna S (GR-S). The chief polymers of the diolefin type are those produced by the polymerization of butadiene either by itself or in conjunction with a limited amount of some other constituent. The group has been given the name "buna" rubber after the German terminology. The original buna type was made from essentially pure butadiene and was produced in Germany on a modest scale and in Russia on a very large scale. Very little of this type of material has been or is being used in the United States. The chief butadiene polymer utilized in this country is of the buna-S type, *i.e.*, it is a copolymer of butadiene and styrene. Buna S is again the German nomenclature, and the term is widely used in the United States to signify a butadiene-styrene copolymer. This type of rubber constituted the major portion of the United States government's synthetic-rubber program during the Second World War. It was given the official designation GR-S indicating government rubber of the styrene type. There are a number of different copolymers of butadiene and styrene, and the government program differentiated among them by using GR-S to indicate the whole group and adding a number to indicate the exact material, *i.e.*, GR-S-10. GR-S production capacity of over 700,000 tons (long tons) was built in the United States by the government, and an additional 30,000 tons of capacity was built by the Canadian government in Canada. The actual capacity of these plants is in excess of a million long tons per year. This capacity is larger than the annual consumption of rubber in the United States for any year prior to the Second World War. GR-S is a general-purpose rubber, *i.e.*, it can be used to replace natural rubber for most uses, and it was the chief general-purpose material used to replace natural rubber in tires and other rubber articles in the United States during the Second World War.

In the manufacture of buna-S-type rubbers (GR-S), it is necessary to produce the butadiene and the styrene. In the United States the large quantities of butadiene required during the war were produced chiefly from either alcohol or petroleum raw materials. In peacetime the cost of alcohol is such that it does not compete economically with the petroleum methods. Styrene is produced from coal tar and petroleum raw materials. Butadiene and styrene are mixed and emulsified with water by the use of soap as an emulsifying agent. They are then polymerized in emulsified form by adding a catalyst to the solution. In this manner a milky emulsion is obtained from which the unreacted butadiene and styrene can be removed. This emulsion is called the "latex" and in appearance is similar to the natural-rubber latex obtained by tapping the rubber trees.

The latex can be used directly for preparing dipped articles or for coating materials, such as cords and fabrics, or the emulsion can be broken by the addition of acids or other materials to obtain the solid rubber which can be dried and baled. Since the process involves a number of ingredients and a number of steps, it is possible by various modifications to produce polymers of different characteristics. Thus, the ratio of butadiene to styrene can be varied over a wide range, and this gives a variety of products varying from the rubberlike polybutadiene to the thermoplastic polystyrene. The general-purpose type of buna S generally contains approximately three parts by weight of butadiene to one part of styrene, although polymers containing much lower and much higher percentages of styrene are produced. Besides varying the ratio of the major constituents, it is possible to vary the type and amount of the emulsifying agent. These changes again make major differences in the property of the polymer. The operating conditions and the degree of polymerization can also be varied. Thus in the buna-S type it is possible to produce a wide variety of polymers of various characteristics, some of which are particularly suited to special uses. As a result of these variations, several hundred GR-S-type polymers have been produced in the government plants, and a number of these are produced as standard commercial grades. Several of these are available in latex form, but most of them are sold as dry rubber.

The cost of producing these materials is such that for large-scale production they can be sold at a profit for 15 to 17 cents per lb, which makes them definitely competitive with natural rubber.

Buna N. Butadiene can also be polymerized with a number of other materials besides styrene. The most widely used alternative ingredient is acrylonitrile, and the copolymer is usually classified by the German name, buna N. It is produced in a manner very similar to the buna-S polymers except for the fact that the acrylonitrile replaces the styrene. It was made to a limited extent by the United States government during the Second World War and was sold under the trade name of GR-A. However, the main production is by private plants, and in this case the material has been sold under a variety of trade names such as Perbunan, Hycar-OR, Chemigum, Butaprene, etc. Again a wide variety of different polymers can be produced, depending upon the relative quantity of the various ingredients and the operating conditions. Buna N is not employed as a general-purpose rubber, and it sells at a considerably higher price than does buna S. Its outstanding characteristic is its excellent resistance to solvents of the gasoline type. It is widely used in gasoline hoses and other elastic products that must come in contact with petroleum or other organic solvents.

Neoprene. Neoprene-type rubbers were developed by E. I. du Pont de Nemours & Company and have been produced in the United States for about fifteen years. Instead of employing butadiene, it employs a substituted diolefin called "chloroprene." The method polymerization is essentially the same as that employed for buna rubber, and the product is available in either the latex or the dry-rubber form. It is also copolymerized with other ingredients to obtain varied physical properties. Thus there are a number of types of neoprene each of which is specially suited for a different purpose. Its outstanding characteristics are resistance to solvents, resistance to aging, and resistance to burning. Because of these qualities it has been used in products requiring its solvent-resistant properties and for insulating electric cable. The cost of neoprene per pound is about twice that of the buna-S type. In addition, frequently more pounds of neoprene are required to produce a given article than with the other types of materials because of its high density.

Butyl Rubber. Butyl-type rubbers differ from the buna type and the neoprene type in that the main raw material is of the olefin type rather than the diolefin type, and this results in a product with significantly different properties. Isobutylene is the main ingredient, but in order to obtain the desired chemical reactivity, a small amount of diolefin is added. The polymerization is carried out in a nonaqueous medium at a temperature of around −100°F. The product is not obtained as an aqueous latex but is easily available as a dry rubber. It is an extremely elastic material and appears very much like natural rubber. However, owing to its structure, it has extremely low permeability to gases, and thus it has been widely used in automobile-tire inner tubes. Tubes made of butyl rubber require much less frequent addition of air than do natural-rubber inner tubes. It is likewise very resistant to chemical attack, but it has poor resistance to petroleum hydrocarbons, and its resilience is low. The low resilience is advantageous for certain damping uses, but in other cases it is undesirable. For example, it gives a high heat build-up within the rubber, and in automobile tires, for example, the high temperatures generated are detrimental. The cost of butyl rubber is roughly comparable to that of the buna-S type. It is available in large quantities as a result of the government program during the Second World War.

Thiokol. Thiokol is a trade name given to a series of organic polysulfides. The thiokol rubbers are not general-purpose rubbers but are special polymers which have solvent-resistant properties which make them extremely valuable for certain uses. Thus they are extremely resistant to solvents of the gasoline type, and they are, therefore, desirable for packings and gaskets that must operate in contact with such solvents.

Silicone. All the other synthetic rubbers are largely organic in nature, *i.e.*, the main backbone of their structure is a carbon-to-carbon chain to which hydrogen and certain other elements are attached. Silicone rubber is unique in that its basic structure is a silicon oxygen chain, and as would be expected. it has properties significantly different from the other synthetic rubbers. In general, its rubberlike characteristics, such as tensile strength, per cent elongation at break, tear resistance, abrasion resistance, etc., are decidely inferior to most synthetic rubbers, but it is able to withstand much higher temperatures than the organic materials. It has sufficient rubberlike properties to be used in gaskets, packings, and tubings, and it extends the upper operating temperature for rubberlike material by at least 100°F.

PHYSICAL PROPERTIES OF THE VARIOUS SYNTHETIC RUBBERS

The physical properties of any given synthetic rubber product depend not only on the rubberlike material itself but also upon the compounding and vulcanizing procedure which is employed. It is therefore possible to produce a fairly wide variation in properties with a given polymer, but in a great many cases the difference in the physical properties characteristic of the rubbers is so large that it is possible to give a relative comparison of their properties, and such comparisons aid in the selection of the proper material for a given use.

Tensile Strength. One of the most important properties of any rubberlike compound is its tensile strength. Such information is useful even when the product is not being used in tension, since it is an indication of the quality of the material.

Natural rubber has a high tensile strength, and in elastic products the value is of the order of 4,000 to 5,000 psi, based on the original cross section before elongation. This would correspond to 35,000 to 45,000 psi based on the cross section at break. These high tensile strengths can be obtained with natural rubber both in "pure-gum" stocks, *i.e.*, those with very little loading, and with loaded stocks containing carbon black, zinc oxide, and other materials. Butyl rubber and neoprene in general have tensile strengths slightly lower but approaching those of natural rubber. In the case of butyl rubber, these high tensile strengths can also be obtained both in pure-gum and loaded stocks. In the case of buna S, the tensile strengths are in general significantly lower than for natural rubber. Pure-gum stocks normally have tensile strengths of the order of 1,000 psi or less (based on original cross section). Loading the rubber compound with certain materials gives a marked increase in the tensile strength of buna-S compounds. With 100 parts of zinc oxide per 100 parts of rubber, it is possible to obtain tensile strength of the order of 2,000 psi, and with 50 parts of carbon black per 100 parts of rubber it is possible to obtain tensile strengths with buna S from 2,500 to 3,500 psi. Thus, in general, it is necessary to load a buna-S-type polymer with a relatively large amount of carbon black in order to obtain a product that has satisfactory physical properties. It is not a satisfactory material for producing pure-gum compounds. Buna N has tensile-strength properties similar to buna S. Thiokol and the silicone-type rubbers have low tensile strength and are not used in cases where high tensile strengths are required. In general, all the materials have satisfactory compressive strength.

Elongation at Break. In a great many cases the percentage of elongation of the rubber is an important factor in its mechanical use. This physical characteristic is very dependent upon the compound employed and the vulcanizing conditions, but in general natural rubber and butyl rubber give the highest percentage elongation at break, varying from 800 to 1,200 per cent. Buna S compounded with carbon black gives elongations at break of the order of 600 to 800 per cent, but as a pure-gum stock, this value is reduced to about 200 per cent. Thiokol and silicone rubbers have relatively low percentages of elongation in breaks.

Effect of Temperature on Tensile Strength and Elongation at Break. In general, increasing the temperature above room temperature decreases the tensile strength of all the rubber compounds, but the percentage effect varies greatly. For example, increasing the temperature from 70 to 212°F lowers the tensile strength of natural-rubber compounds from approximately 4,000 to 2,500 psi. The same temperature increase for a carbon-black-loaded buna S lowers the tensile strength from approximately 3,000 to less than 1,000 psi. Thus, while rubber at 212°F is weaker than at room temperature, it still has sufficient tensile strength to make it a desirable material of construction. The physical properties of buna S at the high temperature are becoming so poor that its desirability has greatly decreased under these conditions. With the exception of silicone, natural rubber and the other synthetic rubbers are not satisfactory for uses at temperatures above 250°F. If temperatures of this order are required for any extended period of time, silicone-type polymers have the most desirable characteristics. They will stand temperatures of 300°F for long periods of time without serious deterioration, and temperatures of 400 to 500°F can be withstood for a few hours. As indicated above, the silicone rubbers have low tensile strength, but they can be satisfactorily used as gasket material under compression at these elevated temperatures. The other rubberlike material decomposes very rapidly in this temperature region.

Density of Rubberlike Material. The density of a number of the most common rubberlike materials is given in Table 4-9. These densities are for the pure-rubber material and will be modified by the other ingredients in the compound. It will be noted that the rubbers based on hydrogen and carbon, *i.e.*, natural rubber, buna S, and butyl rubber, all have densities of between 0.9 and 0.95 g per cu cm at 25°C. Neoprene and thiokol have significantly higher densities, and this results in more pounds of these polymers being required to produce a given article than with the hydrocarbon rubbers.

Table 4-9

Material	*Density, g/cu cm at 25°C.*
Natural rubber	0.91
GR-S	0.93
Butyl rubber	0.92
Neoprene GN, CG, and E	1.23
Neoprene FR	1.14
Buna N and Perbunan	0.97-1.01
Thiokol RD	1.06
Thiokol A	1.6
Thiokol FA	1.33

Electrical Properties. The electrical properties are very dependent upon the compounding ingredients employed. The hydrocarbon-type rubbers as pure-gum material have high specific resistance (ohm per cubic centimeter), being of the order of 10^{12} to 10^{16} at room temperature. However, the addition of compounding ingredients usually lowers this resistance. The data of Yerzley[4] for a neoprene-type rubber are given in Table 4-10. Thus with acetylene-type carbon black it is possible to obtain relatively low resistance, *i.e.*, the material becomes a conducting rubber. Habgood and Waring[1] studied acetylene black in both natural rubber and neoprenes, and their results are given in Table 4-11.

Table 4-10

Type of carbon black	Parts/100 parts polychloroprene	Specific resistance, ohms/cu cm
Acetylene black	50	2.7×10^2
Acetylene black	100	1.2×10^2
Soft black	50	1.6×10^5
Soft black	100	2.0×10^7
Semireinforcing black	50	1.0×10^8
Semireinforcing black	100	6.7×10^4
Channel black	50	8.5×10^7
Channel black	100	1.7×10^6

Table 4-11

Material	Parts of acetylene black/100 parts rubber	Resistivity $\times 10^3$, ohms/cu cm	
		Through sheets	Along sheets
Natural rubber	100	0.31	0.01
Natural rubber	70	0.54	0.03
Neoprene E	75	1.08	0.13
Neoprene E	55	1.72	0.28

The dielectric constant, resistivity, and the electrical losses for several of the materials as essentially pure-gum vulcanizates are given in Table 4-12. In general, these factors can be widely modified by the particular compound employed. For example, with buna S with carbon-black loading, it is possible to increase the dielectric constant to as high as 40.

Table 4-12

Material	Dielectric constant	Resistivity, ohms/cu cm	Power factor
Natural rubber	2.7	10^{14}	
Butyl	2.5	10^{15}	2×10^{-4} (1,000 cycles/sec)
Neoprene	7.5	10^{12}	300×10^{-4} (1,000 cycles/sec)
Buna N	9.0	10^{9}	
Buna S	2.9	10^{14}	7×10^{-4} (50 cycles/sec)
Thiokol	4.6		

Low Temperature Properties. In general, all the rubberlike materials harden as the temperature is lowered. The resilience also decreases rapidly as the temperature is reduced. Natural rubber at room temperature has a very high resilience of the order of 80 to 85 per cent. Neoprene and buna S under comparable conditions have values of about sixty-five to seventy per cent, while thiokol and butyl have very low values. All the polymers show a decrease in resilience as the temperature is lowered. For example, at 40°F approximate values are natural rubber, 75 per cent; buna S, 50 per cent; buna N, 20 per cent; and butyl and thiokol have almost negligible values. At still lower temperatures the materials become very brittle and will break instead of bending or stretching. The temperature at which this phenomenon occurs is called the "freezing point" or the "brittle point." It is not a sharply defined temperature, and it varies materially with the length of time the polymers have been at the low temperature. The brittle-point temperature can also be modified by the use of plasticizers. However, general comparisons can be made between the different polymers, and Table 4-13, based on the data of Selker, Winspeare, and Kemp,[3] compares a number of the different polymers.

Silicone rubber is outstanding in its small variation in flexibility with temperature. Marsden[2] has reported that it is almost as flexible at −55° as at room temperature but that it hardens up in the region between −55 and −80°F.

Table 4-13

Compound	*Brittle point, deg C ± 0.5°*
Natural rubber:	
Gum stock	−59.5
20 parts channel black	−57.5
40 parts channel black	−56.5
100 parts zinc oxide	−60.0
Tire reclaim (vulcanized with 5.25 parts S)	−50.5
Tire-carcass reclaim (vulcanized with 5.25 parts S)	−46.5
Shoe-stock reclaim (vulcanized with 5.25 parts S)	−42.5
Polychloroprene (neoprene type):	
Milled 5 min	−36.8
Gum stock	−38.5
Gum stock + 3 parts soft black + 8 parts oil	−40.6
Gum stock + 5 parts channel black + 20 parts oil	−42.5
Gum stock + 100 parts soft black + 8 parts oil	−36.4
Gum stock + 200 parts soft black + 10 parts oil	−32.0
Butadiene polymer:	
Milled 5 min	−67.8
Gum stock	−65.5
Tire-tread stock	−71 to −69
Butadiene-styrene copolymer (buna-S type):	
Milled 2 min	−65.5
Gum stock	−65.5
Tire-tread stock	−66 to −70
Butadiene-acrylonitrile copolymer (buna-N type):	
American	−49 to −52
German	−45.5
Gum stock	−42 to −45
Tire-tread stock	−46.5
Organic polysulfide (thiokol type):	
Type I	+ 7.0
Type I, carbon-black stock	− 3.8
Type II, carbon-black stock	−22.5
Type III	−35.3
Type III, carbon-black stock	−34.0
Type IV	−35.5
Type IV, carbon-black stock	−39.5

Solvent Resistance. One of the important characteristics of a rubber product is often solvent and chemical resistance, and Table 4-14 gives some approximate values for the swelling of vulcanized pure-gum samples in various solvents. While swelling of itself might not be too objectionable, in general, the other physical properties, such as tensile strength, elongation at break, cut and tear resistance, abrasion resistance, etc., decrease rapidly when the material swells any significant amount. It will be noticed that natural rubber, buna S, and butyl rubber all swell excessively in light hydrocarbons of the gasoline type. Thiokol and buna N show very low swelling, and the value for neoprene is also low. Thus, these three polymers are good for products such as hoses, gaskets, etc., that come in contact with paraffin-type hydrocarbons. It will be noted that none of the materials is very satisfactory for resistance to aromatic materials similar to benzene. Thiokol A appears to be the best in this case. In the case of aniline, natural rubber, buna S, and butyl appear to be the most satisfactory. Thus the relative solvent resistance depends largely on the solvent encountered, and for each solvent it is necessary to have actual data in order to be certain which material is most suitable.

Table 4-14. Swelling of Vulcanized Elastomers in Various Liquids
(Volume per cent increase)

Liquid	Natural rubber	Neoprene	Buna S	Butyl	Buna N	Thiokol
Light gasoline	160	...	60	. .	4	0
Gasoline	230	8	80	200	5	0
Kerosene	...	60	...	...	...	0
Diesel oil	120	...	...	...	15	
Fuel oil	...	...	...	...	...	0
Lubricating oil	...	40	..	...	0	0
Paraffin oil	140	..	...	...	3	
Transformer oil	150	...	...	...	5	
Acetone	..	25	...	...	110	
Benzene	370	160	180	200	210	7
Carbon tetrachloride	670	160	320	...	120	0
Ethyl ether	130	50	50	. .	50

INDUSTRIAL-PLANT FIRE PREVENTION AND PROTECTION: COMBUROLOGY

BY GILBERT E. STECHER

Faculty Instructor, Center for Safety, New York University

An industrial plant may consist of a single building ranging from one story to several stories in height, or it may consist of a group of buildings of varying heights and area and include a diversification of construction and the necessary outdoor storage tanks and mechanical equipment. Regardless of its size or the product it manufactures, the establishment represents the investment of intelligent planning, time, and money, and as such it becomes part of the economic life of the nation.

The owners of the plant have created it for the purpose of profit, for a reasonable return on their investment, and because of a desire to be of service in the nation's economy. In so doing, they have assumed responsibilities to the city or town in which they have elected to do business. Taxes constitute one of these obligations. The payment for services such as water and electrical power, the employment of labor, the safeguarding of the lives of employees, and the maintenance of the plant and its premises to ensure the continuity of these obligations are other responsibilities. Within their own organization the owners may be responsible to invested capital, stockholders and bondholders, and to many liabilities which depend upon the successful and continuous operation of the plant.

The capital investment, profits, and pay rolls are subject to no greater jeopardy than that of fire which may occur from inherent possibilities in the process, lack of maintenance, or sheer carelessness.

COST ACCOUNTING

Destruction by fire becomes a factor in the economics of manufacture, in no less degree than any other item, because it involves the entire project and assumes many phases. As an item in plant management, the subject of fire should be set up as a major one, for under this title will come a factor in cost accounting that must be considered part of the price of the finished product. This will include the fire insurance and the attending coverages, such as windstorm, hail, explosion, riot, civil commotion, smoke, and automobile damage, business interruption, or use and occupancy, rent and leasehold, all of which are based as to cost upon the rate charged for the fire insurance.

The fire-insurance rate is based primarily on the burning rate of an individual classification, such as woodworking, metalworking, or chemical manufacture. This basic charge is part of the cost accounting of the insurance business and affects the cost to industrial plants only as the burning rate of the classification as a whole. If the fire loss in a classification is lowered or raised over a given period, this base charge is altered accordingly. The fire-insurance rate is set up by applying to the plant a scientific schedule made up of charges and credits plus the basic charge and attempting to measure thereby the inherent and maintenance hazards of the processes and equipment and the defects of construction as applied to the spread and control of fire. These charges and credits are of vital interest to plant management, not only as to fire-prevention measures but as a direct cost against the manufacture of the product.

Fire-insurance schedules apply basic principles in different ways to secure an end result. In order to secure the facts applying to the particular risk or plant in a particular section, it is necessary to apply to the rating organization having jurisdiction.

This is generally done by the insurance agent or broker who handles the insurance placements of the company. The schedules applying to the several jurisdictions are in the East, the Universal schedule; in the Middle West, the Analytic system; and in the Far West, the Factoral system.

The fire-insurance rate is an overhead charge against the product and is competitive in that a low rate, aside from being indicative of low hazard, will reflect a lower overhead charge against the product. This may appear small percentagewise in a moderate-sized plant, but where large values are involved, the fire-insurance rate will be a factor.

Two plants, making a similar product, with values of buildings, equipment, and stock amounting to $500,000, started in business about the same time. One plant, having built all buildings of brick, or occupying brick or fire-resistive buildings, with no exposed steelwork and all horizontal and vertical communications conforming to standard practice, will have a rate of insurance ranging from 10 to 75 cents per $100. The other plant, occupying a conglomerate group of ordinary brick and frame buildings, with steelwork unprotected and communications disregarded, will have an insurance rate ranging from $1 to $2 per $100. This will mean a maximum difference in overhead cost of between $3,750 and $10,000.

Other factors, which apply to both plants, are the location and safeguarding of processes of a hazardous nature. The effect on cost accounting of these features is the hidden charge for a nonstandard arrangement of the process and protective features.

Plant management must be on the alert to avoid placing hazardous processes where they will jeopardize large values, as this affects the insurance rates adversely.

In considering plant extensions, new construction and occupancy should not be placed where they will be exposed to hazardous processes, for the insurance rate will reflect this exposure.

Cost-accounting methods may differ in the application of the insurance rate or premium to manufacturing costs. These methods should be analyzed to ascertain whether the unit or over-all basis is used. Insurance rates are made on a specific basis for each building and its contents and include a charge for exposure of one building to another, this being computed from buildings in the same group or plant and also from buildings unrelated to the plant. This exposure is measured by type of construction and distance removed, plus a percentage reduction for the greater distance.

In considering any additions or new construction or the installation or shifting of processes or hazardous units, therefore, the insurance rate of the building and contents and the exposure charge should be analyzed as they may have an effect upon the cost accounting for that unit.

A spray booth, located in a building where the operation is nominal and the contents value is low, may be shifted to a building where the operation is on a larger scale and the values high. The insurance rate in the latter case is increased on the high values, and the exposure charge affects all surrounding buildings.

Also, in building new additions, the uninterrupted area may be increased and the insurance rate increased since there is a charge for area over a standard minimum. The erection of standard fire walls may be required to avoid this charge. New buildings, regardless of the occupancy, if placed within a given distance of another building, will be subject to an exposure charge as well as creating one for another building. Fifty feet is the minimum distance to avoid this charge, and height limits range from one to four stories; ground-floor areas range from 5,000 to 10,000 sq ft minimum. Exact details cannot be given as these factors vary in different schedules and jurisdictions.

The above details will indicate the principle involved and the general application of the insurance schedule which affects this feature of plant management.

For cost accounting, the following factors should be taken into consideration:

1. Raw stock—Valuable and hard-to-procure raw stocks in fire-resistive segregated warehouses reduce the possibility of replacement at higher costs and also plant shutdown.

2. Finished stock—Similarly treated finished stock reduces the possibility of loss of market, overtime production, and loss of profits.

3. Processes—Processes that are safeguarded in a standard manner against possible shutdown or disruption reduce the cost of the product, as there is no lost time, and guarantee deliveries of finished product.

4. Housing—All housing in fire-resistive buildings reduces maintenance, insurance costs, and rebuilding costs.

Fire-insurance Rates. The fire-insurance rate is a reflection of the features that are involved in plant construction and occupancy and also includes the elements that are responsible for the causes and spread of fire. The following details, taken from the schedule as applied to an eastern area because of the greater familiarity with that area, will cover the necessary factors to be considered by plant management.

In some of the schedules used in other jurisdictions, the charges and credits are by percentages, and the approach to the theory of rating is focused upon the occupancy. The standards used for building construction, however, are generally based on the National Board of Fire Underwriters Building Code, and all other features are based on the Standards of the National Fire Protection Association, Mutual Laboratories of Boston, and Underwriters' Laboratories of Chicago. All these standards are available to the plant manager, free or for a nominal fee. The application of the schedule at the onset assumes the following conditions to be present:

1. Building is to be well built, in good repair, and clean.
2. Exposures must not affect the plant.
3. Environment must be good, *i.e.*, free from all objectionable features, conflagration, and railroad trackage.
4. Public fire protection must be class A. This is the classification given under the application of the National Board of Fire Underwriters Grading Schedules for Towns and Cities.
5. Occupancy must be of single type—no other tenants.

The standards shown in Table 5-1 and in the material following are required minimums under the schedule, and charges are made for deflection from them.*

Table 5-1

Height of building stories	Minimum thickness for bearing walls of brick and stone or reinforced concrete, in.															
	Stories

Standard Requirements for Fire-insurance Rate

(Standards prescribed by the National Board of Fire Underwriters are to be used.)

Walls. *Bearing Walls.* To be brick, stone, or reinforced concrete.

Nonbearing Walls. May be 4 in. less in thickness than bearing walls, but no such wall shall be less than 12 in. in thickness for the uppermost four stories in height. Nonbearing walls which are supported by girders, at each story, and pilastered walls of one-story buildings may be 8 in. thick.

---

* Data courtesy of Fire Insurance Rating Organization, State of New Jersey

Party or Fire Walls. To be same thickness as required for bearing walls.

Parapet Walls. Where required, shall be not less than 12 in. thick and carry not less than 3 ft above the roof.

Height. Not over four stories and basement. Basement 3 ft above ground level to be considered a story.

Metal Columns. Iron and steel columns, when placed within exterior walls of a building, shall be protected by approved masonry not less than 4 in. thick, but the interior faces may be protected as provided for interior iron or steel columns as follows: 3¾ in. brickwork; 2 in. concrete, solid gypsum block, or hollow clay tile (if single shell, it shall be plastered with gypsum or cement mortar at least ½ in. thick); 3 in. hollow gypsum block.

Metal Beams and Girders. Iron or steel beams and girders, supporting walls, including lintels (except spans 6 ft or less having masonry or other suitable arch support above the lintel), shall be protected by not less than 2 in. of approved masonry. When not supporting walls, iron or steel beams and girders shall be protected by not less than 1½ in. of brickwork, concrete, hollow clay tile, gypsum, cement, or cement mortar on expanded metal lath. Roof trusses, unless protected as above, may be protected on the sides and bottom by not less than 1 in. of cement or gypsum mortar on expanded metal lath.

Floors. Ordinary wood joist with double floor boards in good condition.

Interior Finish. Open, walls and ceilings.

Roof. Flat, covered with metal, slate, or approved composition.

Skylight. Metal frames, ¼-in. wired glass, or heavy glass not less than ¼ in. in thickness, protected with wire screens of not exceeding 1-in. mesh and not less than No. 12 gauge.

Exterior Attachments. Cornices, porches, bridges, monitors, and saw-tooth-type roof structures and similar attachments shall be constructed of incombustible material.

Floor Openings. *Stairways.* Enclosed with 2-in. tongued and grooved planking, with automatic closing door of same thickness at openings, or stairway enclosed in single board if covered with lock-jointed tin on the side toward the room, with automatic closing door of same construction at openings, or open stairs with automatic closing traps at floor openings of same material and thickness as floor, covered on lower side and lapping edges with lock-jointed tin.

Elevators. In brick shaft with standard cutoff or open with automatic closing traps at every floor opening, of same material and thickness as floor, covered on lower side and edges with lock-jointed tin.

Area. Ground area to be not over 5,000 sq ft in brick and 2,500 sq ft in frame buildings.

Heating (except for mechanical purposes). Steam or hot water safely arranged and well set with steampipes on metal support, free from woodwork.

Table 5-2

	Class of fire			Protection from freezing required
	A	B	C	
Water pails, 12-qt type	5			Yes
Sand pails		5		No
2½-gal soda-acid extinguishers	1			Yes
1¼- or 1½-gal soda-acid extinguishers	2			Yes
1¼- or 1½-gal foam extinguishers	2	2		Yes
2½- or 5-gal foam extinguishers	1	1		Yes
2½-gal calcium chloride	1			No
2½-gal pump tank	2			Yes
5-gal pump tank	1			Yes
22-gal bucket tank with 5 standard pails	1			Yes
50-gal cask with 3 standard pails	1			Yes
1-gal loaded stream	2			No
1¾- or 2½-gal loaded stream	1	2		No
1-, 1½- or 2-qt carbon tetrachloride extinguisher		2	2	No
1-gal carbon tetrachloride extinguisher		2	2	No
2-or 3-gal carbon tetrachloride extinguisher		2	1	No
4-lb carbon dioxide cylinder		2	2	No
7½- or 10-lb carbon dioxide cylinder		2	1	No
15- or 20-lb carbon dioxide cylinder		1	1	No
2½-gal plain water extinguisher	1			Yes

Chimneys. Brick, built up solid from foundation extending at least 18 in. above the roof and at least 8 in. in thickness or 4 in. in thickness with terra-cotta flue lining.

Lighting. Incandescent electric wiring in accordance with National Electric Code or gas from public plant, well arranged.

Power. Steam boiler in outside building with standard cutoff.

Inside Standpipe and Hose Protection. To be in accordance with the general standards.

Inside First-aid Fire Appliances. For all practical purposes there are three general classes of incipient fires:

Class A—Incipient fires on which quenching and cooling effect of water is of first importance, as ordinary combustible materials, such as wood or excelsior.

Class B—Incipient fires on which the blanketing or smothering effect of the extinguishing agent is of first importance: *i.e.*, gasoline, oils, greases, etc.

Class C—Fires in electrical equipment, where use of nonconducting extinguishing liquid is of great importance.

A unit has been adopted for convenience in measuring the fire protection afforded by first-aid fire appliances. This unit is composed of from one to five first-aid fire appliances, depending upon the type used. One unit is required for each 2,500 sq ft of floor area or not over 50 ft of travel from any point to reach the nearest unit.

The classes of fire, the suitable appliances, and the number required for each 2,500 sq ft of floor area are set forth in Table 5-2 (see list of Underwriters' Laboratories, Inc., for approved devices).

Table 5-3 will indicate the penalty for infraction of the standard from which computations can be made for differences in cost of new installation or for existing violations.

Table 5-3

	Cents
Walls	
a. Brick, stone, or reinforced concrete, deficient in thickness, each side and end wall	0.01
b. For cement block, terra-cotta, tile, corrugated iron on steel frame, or other noncombustible material not specifically mentioned, each side and end wall	0.04
Note 1. *If satisfactory evidence is submitted that the construction is of cinder or concrete block, listed by Underwriters' Laboratories, make one-half charge.*	
Note 2. *Nonbearing outside curtain walls, make one-half charge.*	
c. For absence of parapet on each party or exposed masonry wall	0.03
d. Parapets not in accordance with standard, each party or exposed wall	0.02
Note 1. *Charges under c or d do not apply if wall and roof constructed of incombustible material, or where adjoining or exposing building is higher than risk being rated.*	
Note 2. *Reduce charge under c and d one-fourth for each 5 ft distance removed from exposing building.*	
e. Frame, brick-veneer, corrugated iron on wood sheathing or skeleton wood frame, or other combustible material. If main building, additions, or extensions constructed as above, charge:	
If not more than 25 per cent of wall area	0.08
26 to 50 %	0.16
51 to 75 %	0.24
Over 75 %	0.32
Height	
a. Buildings of other than *e* (above) construction, each story over four	0.05
b. Buildings 50 % or over of *e* (above) construction, each story over two	0.05
Columns, Girders, and Beams	
a. For unprotected metal columns, each floor	0.03
b. For unprotected metal girders or beams, each floor	0.01
Note. *No charge to be made when building is 50 per cent or over of e (above) construction.*	
Floors	
a. If not according to standard, each floor	0.02
Note. *If no basement, make no charge for first floor.*	
Interior Finish (any finish forming concealed spaces, each floor)	
a. Walls	0.01
b. Ceilings	0.01
Note. *Make no charge if building is 50 per cent or over of e (above) construction.*	
Roof	
a. Wood shingle or board	0.10
b. Combustible mansard, monitor, or saw-tooth-type roofs (cumulative with Skylights below)	0.05
c. Roof space or blind attic	0.03
Note. *No charge under item b if building is 50 per cent or over of e (above) construction.*	
Skylights (if not in accordance with standard)	
a. For 16 sq ft or less	0.05
b. If over 16 sq ft (not cumulative with *a*)	0.10

	Cents
Note 1. *Item a or b cumulative with b under Roofs.*	
Note 2. *If wood frame protected with standard screens, reduce charge one-half.*	
Exterior Attachments	
a. Wood-boxed cornice, porches, awnings, bridges, or similar combustible attachments	0.01
Note. *No charge if building is 50 per cent or over of e (above) construction.*	
Floor Openings (any kind)	
a. Each open floor opening, each floor pierced	0.03
b. Each floor opening enclosed, but not standard, each floor pierced	0.02
Note 1. *Where charge is made for multiple floor openings, use full amount of highest charge, one-half of next lower, and one-quarter of each additional.*	
Note 2. *Floor openings within 15 ft of other floor openings, take one (highest) charge.*	
Area	
a. Each 1,000 sq ft (or fraction thereof in excess of 500 sq ft) in excess of 5,000 sq ft of ground area in building of other than *b* or *e* (under Walls) construction	0.02
b. Each 1,000 sq ft (or fraction thereof in excess of 250 sq ft) in excess of 3,750 sq ft of ground area in building of *b* (under Walls) construction	0.03
c. Each 1,000 sq ft (or fraction thereof in excess of 250 sq ft) in excess of 2,500 sq ft of ground area in building of *e* (under Walls) construction	0.04
Note. *For buildings of mixed construction, charge for area on the basis of the direct percentage that each type of construction bears to the total floor area.*	
d. If area subdivided on all floors by division or cross walls of brick, stone, or concrete, built from ground, strengthening the building (even if with openings), deduct 10 per cent of area charge for each wall, not to exceed 40 per cent in all.	
Note. *Total charge not to exceed* 0.40.	
Heating (except for mechanical purposes)	
a. High-pressure steam boilers, well arranged	0.10
Note. *Not cumulative with charge for high-pressure steam boiler (see Power below).*	
b. Stoves or other unapproved unit heaters	0.05
c. Gasoline stoves.	
Chimneys (not in accordance with standard)	0.05
Lighting	
a. Not in accordance with standard	0.05
b. Acetylene and gasoline systems.	
Power (for manufacturing purposes)	
a. High-pressure steam boilers, well arranged	0.10
b. Other approved methods, well arranged	0.05
c. Metal boiler stack, through roof, properly arranged	0.10

Table 5-4, Credits for Construction, which is better than anticipated under the schedule, will indicate the possible saving in costs, if at present existing or contemplated. These are granted on rate at this point.

Table 5-4. Credits for Construction

	Credits, per cent
a. Better than standard, other than mentioned below	3
b. Fire resistive throughout, except roof	40
Note 1. *Not to apply to buildings one story in height without basement. If with basement, reduce credit one-half.*	
Note 2. *For floors of mixed construction prorate the credit on the basis of the direct percentage that the floor area of fire-resistive construction (disregarding the first floor of buildings without basement, and any floor, the total area of which is 25 per cent, or less, of fire-resistive construction) bears to the total floor area of the building.*	
c. Standard mill throughout, including roof:	
Height, stories	
4 (or higher)	25
3	20
2	15
1	10
d. Semimill throughout:	
Height, stories	
4 (or higher)	10
3	8
2	6
1	4
e. Height, for each story less than four in masonry buildings	2
Note. *Not to apply to boilerhouses.*	

Installation of protective features such as alarm systems, watchmen, standpipe systems, automatic sprinklers in basements, large-unit fire extinguishers, private fire brigade, and smokeproof tower (aid to fire department and protection to life) will indicate savings for present installations or future possible savings, by the credits allowed in Table 5-5.

Table 5-5

	Credits, per cent
a. Automatic fire alarm, central station (deduction not to exceed 30 cents)	25
b. Automatic fire alarm, auxiliary (deduction not to exceed 25 cents)	22
c. Manual fire alarm, central station (deduction not to exceed 16 cents)	9
d. Manual fire alarm, auxiliary (deduction not to exceed 15 cents)	8
e. Watchman and clock (deduction not to exceed 10 cents)	5
f. Watchman, central station ordinary supervision (deduction not to exceed 10 cents)	6
g. Watchman, central station compulsory tour supervision (deduction not to exceed 20 cents)	11
NOTE 1. *Reduce credit under c or d 50 per cent if no approved watchman service unless risk is under 24-hr operation daily.*	
NOTE 2. *Reduce credit under d to 6 per cent if system not approved by Underwriters' Laboratories.*	
NOTE 3. *Reduce credit under a, b, c, d, f, and g 50 per cent if risk is not located within 20 miles of headquarters furnishing approved continuous supervisory service.*	
NOTE 4. *All systems should be approved by Underwriters' Laboratories and installed, maintained, and supervised in accordance with the rules and requirements of the National Board of Fire Underwriters and Rating office.*	
NOTE 5. *When credit is allowed under a or b, one-half of credits under e, f, or g may be cumulative.*	
NOTE 6. *When credit is allowed under e, f, or g, full credit under c, or d may be cumulative.*	
h. Standpipe and hose in accordance with standard requirements:	
Class A	2½
Class B	5
Class C	7½
Class D	10
i. Automotive sprinkler system in basement (approved)	5
j. For approved 40-gal portable chemical extinguisher, installed in accordance with the requirements (deduction not to exceed 5 cents)	2½
k. For approved private fire department with standard outside fire hydrant and hose and drilled fire brigade (deduction not to exceed 10 cents)	5
NOTE. *Credit under k to apply only in class H or K localities, which are without public fire protection.*	
l. Smokeproof tower to aid fire department	1

The following charges are for multiple occupancy or additional tenants who may share a building with the original tenant:

Table 5-6

	Charge, cents
a. For each additional tenant or occupant, in buildings over 50 per cent of other than *e* (under Walls) construction:	
Manufacturing	0.07
Mercantile, storage, or vacant	0.03
b. In buildings 50 per cent or over of *e* (under Walls) construction:	
Manufacturing	0.12
Mercantile, storage or vacant	0.10
NOTE 1. *Make full charge as provided above for first two tenants or occupants and reduce charge 1 cent for each additional tenant or occupant over two.*	
NOTE 2. *For each additional family over 10 in building being rated, 0.003. Total charge not to exceed 25 cents.*	
NOTE 3. *Make no charge for barbershops, beauty parlors, etc., above the grade floor.*	

For grades of classification of public fire protection lower than class A, a charge is made generally (see Table 5-7).

A further credit is allowed, under this heading, for fireboat and standard h-p systems as shown in Table 5-8.

Charges are made, as in Table 5-9, for unsafe and unusual conditions which may exist or are permitted to come into existence and are really penalties for neglect or disregard of causes that may result in a fire. They are corrective and removable and can be complied with, thereby securing a saving and eliminating a fire hazard.

Credit for coinsurance will vary in different jurisdictions, and Table 5-10 is given as an indication of such credit on a particular schedule applied to this particular subject (see Table 5-7).

Table 5-7. Public Fire Protection

Town class	*Charge, cents*
A	0.00
B	0.01
C	0.02
D	0.03
E	0.04
F	0.08
G	0.20
H	0.45
K	0.50

Table 5-8. Deductions for Superior Public Fire Protection

	Deductions, per cent
a. Fireboat. Risk so located that city-owned fireboat can be of active and beneficial service NOTE. *Deduction not to exceed* 15 *cents.*	5
b. If risk is within 500 ft (over public thoroughfares) of hydrant on standard h-p system	10
c. As in *b*, but substandard system	5

Table 5-9

For conditions of building and occupancy, add as follows:

	Charges
Stoves or Heaters	
a. Poorly arranged	0.10
b. Absence of metal under	0.10
c. Hazardous arrangement	0.25
Stovepipes and Flues	
a. Combustible material less than 18 in. away, or less than 9 in. away with standard protection	0.10
b. Hazardous installation	0.25
c. Entering bottom of chimney vertically	0.15
d. Entering chimney in attic or any unused room	0.25
Terra-cotta chimneys	0.15
Defective chimneys	0.15
Defective steam-boiler installation	0.25
Lighting	
a. Swinging and otherwise unsafe gas brackets or lamps	0.25
b. Large center-draft oil lamps	0.10
Defective electrical installation	0.25
Empty boxes, rubbish, and odd accumulations adjacent to building	0.25
Hazardous packing materials not properly disposed of	0.25
Odd accumulations, crowded and dirty conditions	0.25
Crowded condition of merchandise preventing proper access to building	0.15
Obstructions to building or roof that may interfere with fire department	0.10
Paper, burlap, or miscellaneous combustible materials on walls or ceiling	0.10
Building not in good state of repair	0.10
Building dilapidated or in poor state of repair	1.00
Gasoline, Naphtha, Etc.	
a. Storage and use of gasoline and gasoline devices, as per general rules.	
b. Absence of safety cans	0.10
Hazardous manufacturing appliances or devices not properly installed or maintained	0.25
Absence of approved metal ash, rubbish, or waste cans	0.10
Absence of No Smoking signs	0.10
Absence of adequate first-aid fire appliances	0.10
Condition not anticipated under schedule	0.25

In class H and K towns, when coinsurance credit is not given for superior construction or approved private fire protection, reduce rates without coinsurance 5 per cent (not to exceed 15 cents) for use of 80 percent coinsurance clause. Coinsurance deserves careful consideration, for herein lies the difference in insurance costs between good and bad construction and proper safeguarding of the plant premises.

The application of coinsurance to the total amount of capital assets in the insurance program will affect the amount of recovery from any fire loss.

The insurance rate is based upon the assumption that the values subject to destruction by fire will be insured to a given percentage of those values. This percentage is placed most generally at 80 per cent of the values. As the coinsurance clause in the insurance

Table 5-10. Deductions for Coinsurance Clause for Specific Form of Insurance

	Deductions, per cent
The final rates for specific form of insurance are subject to following reductions for use of 80 per cent coinsurance clause, but not to exceed 50 cents, except in class A and B towns:*	
In all towns, except H and K*	25
The following deductions apply, regardless of location:	
a. When credit is given for fire-resistive construction throughout, except roof	40
Note. *When credit is given under b in Table 5-4, prorate the coinsurance reduction on the basis of the same percentage as is allowed at b, disregarding any percentage less than 20 per cent.*	
b. When credit is given for approved private fire protection	15
c. Buildings not over one story (no basement) with incombustible walls, partitions, staging, floors, and roof, contents incombustible, no environment and no exposures, shall be subject to reduction of 75 per cent for attachment of the 80 per cent coinsurance clause.	

* The reference to class A and class B, H, and K towns, is the rating given for the character of fire protection or the lack of it entirely.

policy becomes part of the contractural agreement, if the agreement to carry 80 per cent of the value is carried out, the entire amount of the loss is paid whether it is partial or total.

If the percentage of value insured, however, is less than the agreed-upon 80 per cent, the settlement of the loss is made on the basis of the ratio the amount of insurance carried bears to the required 80 per cent of the total value.

$500,000 = capital asset building, equipment, and stock
400,000 = required 80 per cent, to be carried under the coinsurance agreement
300,000 = amount of insurance carried, with the coinsurance clause as part of the contract of insurance

$$\text{Amount recoverable} = \text{fire loss} = \$50{,}000$$

$$\frac{300{,}000}{400{,}000} = 75 \text{ per cent} = \$37{,}500$$

Contents Rate. The contents rate is made by including charges for types and classes of manufacture or nonmanufacture and for hazardous processes or operations which are subject to scientific and standard application treatment. A list of these standards is appended, and they can be secured from the National Fire Protection Association, the National Board of Fire Underwriters, or Underwriters' Laboratories.

A credit is also allowed in the contents item if merchandise is on skids or platforms 6 in. in height. This credit applies only to stocks particularly damageable by water, contained in other than barrels, bottles, and waterproof cases. An additional credit is allowed if all shelving is offset from wall 1 in. and backed up with approved wire screening. These credits will generally amount to 2 per cent of the flat building rate, plus the charge for susceptibility at this point on the schedule. The above charges are numerous and changeable and so must be secured from the rating bureau having jurisdiction.

The credits allowed for any and all fire-fighting equipment —first-aid equipment, standpipe systems and yard systems, automatic sprinkler systems, and alarm systems—although part of the insurance rate, must be sought for this purpose from a cost-accounting standpoint, the same as all other credits. Those fire-fighting units coming under the heading of fire defense will be treated fully under Fire Protection.

Plant management, cooperating with the cost-accounting department and considering the details of construction, hazardous processes, and fire defense, will secure a low insurance rate which will reflect in the cost of the product and also reduce the possibility of destruction by fire of the capital assets of the plant.

Fire-resistive-construction Rates. In some jurisdictions fire-resistive-construction rates are made on special schedules. Table 5-11 gives the acceptable standards in an eastern area. The charges on the schedule are made for deviation from these standards and include the usual deductions for fire protection, alarm systems, and the charges for faults of management (see Table 5-9). Coinsurance credits, for use of (90/80 per cent) coinsurance clause, will produce reductions up to 75 per cent for superior types of construction.

Standard Requirements for Fire-resistive Construction[*]

Bearing Walls. *Brick.* Shall be not less than 12 in. in thickness for the uppermost three stories in height and shall increase 4 in. in thickness for each successive two stories in height, measured downward from the top of the wall.

Reinforced Concrete. Shall be not less than 6 in. in thickness for the uppermost story in height and increase 1 in. in thickness for each successive two stories in height, measured downward from the top of the wall.

Nonbearing Walls. *Brick.* May be 4 in. less in thickness than bearing walls, but no such wall shall be less than 12 in. in thickness for the uppermost four stories in height. Nonbearing walls, which are supported by girders at each story, and pilastered walls of one-story buildings may be 8 in. thick.

Reinforced Concrete. If supported by girders at each story, such walls may be, but shall not be less than, 5 in. in thickness.

Fire Walls. *Brick.* To be same thickness as required for bearing walls, except business and storage buildings exceeding two stories in height, no part of which wall shall be less than 16 in. in thickness.

Reinforced Concrete. (Public Buildings.) To be not less than 9 in. in thickness for the uppermost three stories in height and increase 3 in. in thickness for each successive three stories in height, measured downward from the top of the wall.

(Business Buildings.) To be not less than 11 in. in thickness for the uppermost two stories in height and increase 2 in. in thickness for each successive two stories in height, measured downward from the top of the wall.

Party Walls. *Brick.* To be same thickness as required for fire walls. Except when supported by girders at each story, such wall may be not less than 12 in. in thickness.

Reinforced Concrete. To be same thickness as required for fire walls. Except when supported by girders at each story, such wall may be not less than 8 in. in thickness.

Roof. Roof construction shall consist of a series of steel or reinforced-concrete beams with interposed arches or slabs of such material and construction as shall meet the requirements of the Building Code of the National Board of Fire Underwriters. Roof coverings shall be of approved incombustible materials.

Skylights. To be constructed of wired glass in metal frames, or plain glass protected by wire screen placed 4 to 10 in. above and extending on all sides the same distance beyond the glazing.

Height. Not over six stories and basement.

Floors. Floor construction shall consist of a series of steel or reinforced-concrete beams with interposed arches or slabs of such material and construction as shall meet the requirements of the Building Code of the National Board of Fire Underwriters.

Metal Columns. Iron and steel columns when placed within exterior walls of a building shall be protected by approved masonry not less than 4 in. thick but the interior faces may be protected as provided for interior iron or steel columns as follows: $3\frac{3}{4}$ in. brickwork; 2 in. concrete, solid gypsum block; 4 in. hollow clay tile (if single shell, it shall be plastered with gypsum or cement mortar at least $\frac{1}{2}$ in. thick); 3 in. hollow gypsum block.

Metal Beams and Girders. Iron or steel beams and girders, supporting walls, including lintels (except spans 4 ft or less having masonry or other suitable arch support above the lintel) shall be protected by not less than 2 in. of approved masonry.

When not supporting walls, iron or steel beams and girders shall be individually protected by not less than $1\frac{1}{2}$ in. of brickwork, concrete, hollow clay tile, gypsum, cement, or cement mortar on expanded metal lath.

Partitions. To be constructed of noncombustible material.

Area. Not over 10,000 sq ft ground area between intersecting fire walls.

Floor Openings. Stairways, elevators, and other shafts. When walls enclosing shafts are bearing and of masonry or reinforced concrete, they shall be of the same thickness as specified for bearing walls. When they are supported at each floor, they may be constructed of 4-in. brick or 6-in. hollow tile plastered on both sides or 4-in. cored gypsum block. Openings in such shaft enclosures shall be protected by approved automatic or self-closing fire doors.

Heating. (For nonmanufacturing purposes) Steam or hot water safely arranged and well set with steam pipes on metal supports, free from woodwork.

Chimneys. Brick, built up solid from foundation at least 8 in. in thickness for medium-heat appliances (h-p steam), or 4 in. in thickness with terra-cotta flue lining for low-heat appliances (l-p steam).

---

[*] See National Building Code, National Board of Fire Underwriters for complete details and time-temperature curves.

Lighting. Incandescent electric wiring in accordance with National Electrical Code, or gas from public plant, well arranged.

Power. Steam boiler in outside building with standard cutoff.

Automatic Sprinkler Protection. The rating of plants equipped with automatic sprinkler systems is based primarily upon the grading of the sprinkler protection estimated on the hazard of the occupancy. A system that does not grade 40 per cent or better is not considered eligible for a sprinkler rating but is put back on the schedule applying to the particular plant on a nonsprinklered basis, with credits that may apply for protection.

Credits and Charges. The schedule for grading automatic-sprinkler protection is a detailed affair and must be applied by the bureau having jurisdiction and may differ in its application in various parts of the country. The following fundamental details, however, as applied in an eastern jurisdiction, will cover the essentials, and the standards will be approximately the same for all installations. Reference is made to the "Standards for Sprinkler Equipment, Automatic and Open Systems," published by the National Board of Fire Underwriters.

SCHEDULE FOR GRADING AUTOMATIC SPRINKLER PROTECTION

1. Full standard equipment.

Water Pressure

2. *Primary pressure deficient* from gravity tank, giving less than 15 lb on highest line of sprinklers, but with tank bottom not less than 5 ft above the highest line of sprinklers (1 per cent deduction for each foot less than 35 ft), 0 to 30 per cent.

3. *Primary pressure deficient* from public water-works system, giving less than 15 lb on the highest line of sprinklers, but 8 or more lb pressure (2 per cent deduction for each pound less than 15), 0 to 14 per cent.

4. *Primary pressure* dependent upon approved central-station supervised automatic pump 5 per cent deduction.

5. *Secondary pressure deficient* from gravity tank with bottom less than 20 but 5 ft or more above highest line of sprinklers (⅔ per cent deduction for each foot less than 20), 0 to 10 per cent.

6. *Secondary pressure deficient* from public water works, giving less than 10 but 5 or more lb pressure on the highest line of sprinklers (5 per cent + 1 per cent deduction for each pound deficient), 5 to 10 per cent.

7. *Secondary pressure* dependent on nonautomatic pump, 5 per cent deduction.

8. *Water supply* common to two or more risks, charge risk not in control of supplies, 5 per cent deduction.

9. No recognized secondary supply, 30 per cent deduction.*

* Note—When public water works supply is of exceptional capacity and reliability (volume and pressure), reduce charge under 9, 50 per cent, but this reduction not to apply if any charges in grading are made under 2, 3, 10, and 21 to 29.

Capacity of Water Supplies

10. *Water supply deficient* in available capacity, 1 *to* 20 per cent deduct 10 per cent, and from 21 to 50 per cent deduct 30 per cent.

Equipment

11. Minor unsprinklered areas 10 per cent; important unsprinklered areas 10 per cent + 1 per cent deduction for each 1 per cent of total area unsprinklered.

Note 1. Make no deduction for absence of sprinklers at dynamo or switchboard when in fire-resistive rooms not containing other combustible materials.

Note 2. If building is of noncombustible construction and contents are noncombustible, make no deduction provided it is warranted that no combustibles will be located, temporarily or otherwise, in such unsprinklered area.

12. A small number of sprinklers with water shut off during cold weather, 5 per cent deduction.

13. Charge as follows when sprinklers are on dry pipe system in any one fire area:

	Per cent
a. 25 per cent or under	2½
b. From 26 to 50 per cent	5
c. From 51 to 75 per cent	7½
d. Over 75 per cent	10

Note. If any dry valve controls more than 300 sprinklers or the system has more than 375 gal capacity and does not have a quick opening device attached, double above charges.

14. Water distribution obstructed by shelves, tables, benches, partitions, or by piles of combustible stock or other contents, 10 per cent deduction (cumulative with 11).

15. Clear space of 2 ft below ceilings or bottom of joist not maintained throughout all sprinklered areas, 10 per cent deduction.

16. **Watchman and clock but no approved alarm valve, 5 per cent; no watchman and no approved alarm valve, 15 per cent.**

Note. Not to apply if central-station alarm and/or sprinkler supervisory system installed.

17. No steamer connections where necessary for use of public fire department, 5 per cent deduction.

Note 1. Not to apply if risk in unprotected location.

Note 2. Hydrants (private), if so connected as to be available for steamer connection, will be accepted in lieu thereof, if two or more double female couplings are provided.

18. Other deviations from equipment rules:

	Per cent
a. Unapproved sprinklers	5-25
b. Unapproved dry valve	5-25
c. Unapproved devices (other than above)	5-25
d. Pipe sizes in accordance with standard, previous to 1905	5
e. Supply connections not standard	5-25
f. Spacing in accordance with standard, previous to 1905	5

Note. Unapproved devices and standards are those whose field record has shown them to be serviceable but not approved by Underwriters' Laboratories. Deductions are made variable to cover the degree of probable efficiency, as follows: unapproved, 5 per cent; record, good, 10 per cent; fair, 15 per cent; indifferent, 20 per cent; poor, 25 per cent.

Vertical Openings

19. Unstopped openings between floors without approved curtain boards, 15 per cent deduction; with approved curtain boards, 10 per cent deduction; with semistandard enclosures or automatic traps, 5 per cent deduction.

Maintenance

20. Defects from lack of maintenance: minor, 5 per cent deduction; moderate, 10 per cent deduction; severe, 25 per cent deduction.

Occupations or Constructional Deficiencies

21. Large areas and unusual heights of room, with occupations likely to cause the operation of over 50 sprinklers, such as theaters, halls, erecting shops, foundries, etc., according to condition, 15 per cent deduction.

22. Contents notably preventing full sprinkler distribution, as stored cars (except when building equipped with "car line" sprinklers), barrels, tubs, coffins, large hollow piles of combustible stock such as furniture, etc., according to condition, 20 per cent deduction.

23. Unusual draught conditions, as from large blower systems or buildings with open sides, sheds, etc., according to condition, 15 per cent deduction.

processes, cotton, hemp, jute, or sisal storage, according to condition, 25 per cent deduction.

26 Occupancies allowing quick hot fires, not readily extinguished with water, as in varnish works, lard and oil refineries, and properties containing large quantities of grease, waxes, fats, nonexplosive oils, etc., according to condition, 20 per cent deduction.

27. Apprehensive explosion hazards due to presence of gun powder, dynamite, various chemicals, compounds, etc., according to condition, 30 per cent deduction.

28. Vapors from dangerous quantities of naphtha, gasoline, benzene, volatile oils, alcohols, etc., according to condition, 30 per cent deduction.

29. Manufacture of, or storage of, considerable quantity of pyroxylin products, such as "celluloid," etc., 25 per cent deduction.

FIRE

Definition of Fire. Chemical reaction in some materials is described and explained as the setting up of an activity within the molecule, which causes either the release of hydrogen or the absorption of oxygen.

Combustion. The latter phenomenon, in common parlance, is called "combustion" and as such has many phases, but the phase that presents itself most frequently is combustion resulting in fire or flaming.

Flammability of substances or liquids as the result of combination with oxygen* is termed "oxidizing," and the visible evidence of this is fire or flame, which is accompanied by the liberation or emission of heat. This flammability depends in a large degree upon the construction of the substance or liquid, its gaseous content, the elements subject to volatization, and their ability to absorb oxygen.

Combustion, therefore, takes place in the presence of oxygen, and the absence of this element or the temperature necessary to this reaction governs the intensity of

---

* Liebig names the gradual combination of the combustible elements of a body with the oxygen of the air Eramecausis.

Table 5-11*

1. *Grade of Occupancy*† . . . . *Charge as per Table*‡ . . . .

2. *Height.* For seventh story charge 5 per cent of occupancy grade; for eighth story, 10 per cent; and for each additional story, 15 per cent (cumulative).

NOTE. *Not to apply if building of fire-resistive construction and equipment grades 50 per cent or more standard.*

3. *Area.* If joisted construction for each 1,000 sq ft or fraction thereof in excess of 10,000, charge 1 per cent if grading is over 75 per cent and 1¼ per cent if grading is 75 per cent or under.

4. *Floors.* If single board, charge 10 per cent of occupancy grade for each floor of such construction, not to exceed 40 per cent.

5. *Floor Openings (any kind).* If not protected, charge for each floor opening, each floor pierced, 5 per cent of occupancy grade, not to exceed 80 cents. If protected with automatic traps and/or semistandard enclosure, one-quarter charge; curtain boards, half charge.

6. *Interior Finish.* Forming concealed spaces, charge 10 per cent of occupancy grade for each floor not to exceed 40 cents.

7. *Boiler.* (Over 20 lb steam pressure) if in building, unless in fire-resistive room cut off standard, charge 5 per cent of occupancy grade if fuel is coal and 25 per cent if shavings or refuse, not exceeding $2.

8. *Extra Hazards and Internal Management.* Charge as per extra hazard table,† deducting the following percentages according to the grading of the sprinkler equipment.

80% and above = 50%
60–69.9% inclusive = 35%
70–79.9% inclusive = 40%
50–59.9% inclusive = 30%
Under 50% = 25%

9. *Tenants.* If two or more tenants use (item 1) occupancy of principal hazard and for each tenant over one charge as per table page 5, of Sprinkler Schedule of Fire Insurance Rating Organization.

NOTE. *No charge under item 9 if building of fire-resistive construction with standard floor openings and having wired glass exterior windows.*

10. *Watchman.* Without approved watchman and approved watch clock service, 20 cents.

NOTE 1. *If watchman and approved clock service but rounds are substandard, charge in the proportion that service bears to standard.*

NOTE 2. *Make no charge if deduction 20 or 21 is allowed.*

11. *Location.* If risk is located outside public fire protection, charge 10 per cent of occupancy grade, but not less than 8 cents or more than 60 cents.

NOTE. *Make no charge under 11 if risk has an approved yard hydrant and hose system and an approved private fire brigade.*

12. *Conditions not anticipated,* 10 cents.

The building charge of 1 to 12, inclusive, shall be the following per cent of the sum total of such contents charges:

	Item	Building
13. "*Fire Resistive*" With all structural members protected, 30 per cent	-- -	- - ----
14. "*Fire Resistive.*" With part or all structural members not properly protected, or unprotected, 40 per cent.	- -	-----
15. "*Slow Burning*" or "*Mill*" *Construction*, 55 per cent.	--- -	- --------
16. "*Ordinary*" *Brick.* Ordinary joisted construction (including iron on iron frame), 70 per cent.	-	-- ------
17. "*Frame*" Wood construction throughout (including iron on wood frame), but not to exceed 40 cents less than contents rate, 90 per cent.	-	- --- ----

NOTE. *Frame sheds take same rate as contents.*

18 *Base rate* for fire-resistive or slow-burning construction, 10 cents; for all other types of construction, 12 cents.

(Further deductions applying to building and contents to reduce rate)

19. *For Applied Central-station Supervision of Watchman*, 2 per cent

19a. *For Auxiliary or Central-station Fire Alarm* with watchman and applied clock, 3 per cent.

NOTE *Make no allowance under 19 and/or 19a if deductions made under 20 and/or 21.*

20. *Central-station Water-flow Alarm* with or without watchman, 5 per cent.

21. *Full Automatic Sprinkler Supervisory* service and central station alarm, 15 per cent.

22 *Standpipe and Hose* for approved system, 5 per cent.

23. *Private Fire Brigade* For approved brigade with ample apparatus and equipment, 10 per cent.

NOTE. *No credit under 23 if risk is outside city fire protection. See note under* 11.

24. For approved inspection service by automatic sprinkler contractors, 5 per cent

25. *Wire-glass Approved Windows* throughout, 5 per cent

NOTE. *No credit under 25 unless building over one story and of fire-resistive or mill construction*

26. Building only one story high with or without basement and top of roof less than 36 ft above lowest ground level, 5 per cent

27. *Waterproof Scuppered Floors*, 5 per cent

NOTE. *If floors self-draining, floor openings curbed, and stock skidded, 5 per cent additional.*

* Table 5-11 is part of Sprinkler Schedule.

† The grading of the particular occupancy is based upon the rate as an unsprinkled plant and is predicted from a table that classifies the plant as fire-resistive, slow-burning, or ordinary brick or frame, plus the grading of the sprinkler equipment. This table is on file with the Fire Insurance Rating Organization.

‡ Table 5-11 is on file with the Fire Insurance Rating Organization.

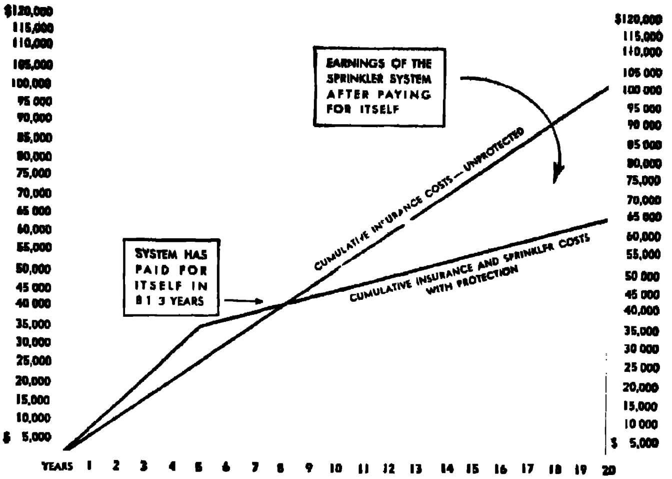

FIG. 5-1. Graph of possible insurance savings. (*Grinnell Company, Inc.*)

the heat liberation. The heat quantity is known as the "heat of combustion" (see Table 5-12), and the extinguishment of fire is therefore based upon the process of depriving a substance or liquid of its heat of combustion, thereby lowering its temperature and cooling it to a point below that at which combustion takes place, or by entirely shutting off the supply of oxygen and retarding the chemical reaction.

Table 5-12. Heat of Combustion—Nuckolls

Substance	Kg-cal	Kg-cal/ g-molecule	Kg-cal/ cu ft of mixture of gas or vapor with air*

§ Based on tests of ordinary gasoline having a mean vapor density of 3 5 (air 1).

NOTE Constant-volume values selected from University of Illinois *Bulletin* 139 and the available literature on the subject.

This process passes through three stages of flammability, which is common to most substances, reducing the temperature to the burning point or ignition point, further to the flash point, and finally to extinction. *Flash point* and *burning or ignition point* are the two indexes by which the danger of fire may be ascertained.

Flash Point Flash point is that temperature to which a liquid or solid must be brought to cause a volatization of its lighter elements, or vapors, which will flash but not continue to burn when ignited by an outside agency.*

Burning or Ignition Point. Burning or ignition point is that temperature to which a liquid or solid must be brought to ignite it and also make it continue to burn without the assistance of the outside agency.*

These stages of combustion differ with various materials and may show wide ranges, or they may be very close, which would indicate that low flash points are danger points with explosive possibilities if the two stages are of equal temperatures.

---

* These tests are made by open- or closed-cup method, Persky-Martens or Tagliabue (see *ASTM Codes* D56-21).

It is also important to consider another phase through which liquids and solids pass before reaching the flash point. This is known as the "melting or boiling phase," resulting from the application of heat. The initial stage brings about a physical change resulting in the absorption of heat and increases affinity for oxygen, liberation of flammable gases, and sometimes causes an ebullition or frothing. This action facilitates the flammability of the material and produces explosion possibilities.

The flash point shows whether or not the vapor of the liquid is combustible in the presence of air at atmospheric pressure and depends upon the volatility of the liquid and also upon the presence or absence of other volatile constituents, which may or may not mask the flash as previously mentioned.

> The flash point alone is not a measure of the fire hazard of a liquid in respect to its ignition point, flammable limits, hazards of combination, vapor density, toxicity, and chemical stability. It fails to differentiate between liquids of the exothermic and endothermic classes. It does not reveal a tendency of a liquid to spontaneous ignition.[1]

As high temperatures are needed to reduce some substances to their melting point and raise others to their boiling point, it is not to be assumed that combustion results only from the application of or contact with burning or glowing bodies or from electrical energies such as sparks or lightning. Fire or flaming may be brought about by spontaneous ignition induced by a very low degree of heat, such as solar heat or any heat of low temperature, setting up a reaction that results in raising the substance to its flash point.*

Table 5-13

Apex of outer cone	728*	1175*

* To change centigrade temperature to Fahrenheit, double the figure, deduct 10 per cent, and add 32. To change centigrade to Fahrenheit, multiply centigrade temperature by $^9{}_5$ and add 32. To change Fahrenheit to centigrade, subtract 32, multiply by $^5{}_9$.

Fire, therefore, is flaming combustion with the liberation of heat. This flame of combustion has different degrees of luminosity depending on the temperature, the presence of solids or unburned particles or carbon compounds in the flame, or the degree of oxygen present.

Flame Luminosity and Temperature. Flame luminosity indicates the intensity of combustion by the amount of heat liberated. Most visible flames liberate the smaller amount of heat, and the less visible flame, the greater amount of heat, showing a more perfect combustion and the absence of unburned carbon particles as well as a liberal supply of oxygen. The Bunsen-burner flame is typical of perfect combustion and shows the ratios between temperature and luminosity. According to Lewes these are as shown in Table 5-13.

Flame temperatures are given in Table 5-14.

There is also a slow combustion which is nonluminous and invisible except for the effects produced. Decaying processes and rusting come under this class. Certain bacterial activities which are described as slow combustion may result in flaming combustion if the action proceeds under favorable conditions for producing this result. Therefore, in the discussion of the "fire problem," we are dealing with a chemical action brought about by the application of heat, resulting in the liberation of gaseous components which burn in the presence of oxygen or air. In order to produce this burning, it is necessary to have a mixture of certain proportions of air or oxygen, and these proportions within which flame is propagated are called "the limits of flammability" or "ranges of explosibility." It is also said of a flame that

Table 5-14. Flame Temperature

* This is particularly noticeable in oily waste and in wood in prolonged contact with steampipes (see Combustion of Wood).

it travels through a liquid, and the speed of travel or burning varies according to the nature of the gas, the proportion of the mixture, and the character of its surroundings. This velocity is measured in meters per second as shown in the graph by Bunte (Fig. 5-3).

Explosive range refers to the definite limitations of combustibility and rate of burning of flammable vapor or dust mixed with the air. When the particles are so widely separated that those set on fire by the igniting medium will not set fire to others that are nearer, the mixture is called too "lean" for combustion and will not burn. When the particles are so close together that they exclude the oxygen necessary for combustion, the mixture is called too "rich," and it will not burn. The concentration, or per cent by volume, between the leanest and the richest mixtures that will burn is called the "explosion range" (see Table 5-15). Between the minimum and maximum limits of the explosion range will be found various phases of slow and rapid combustion.

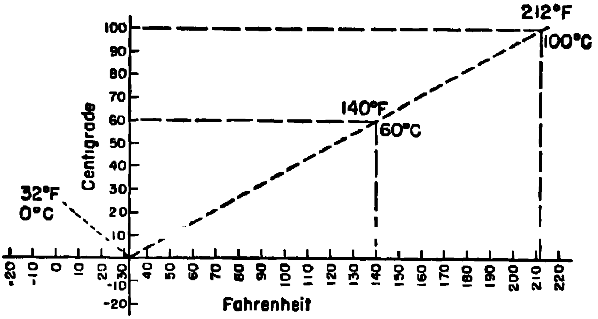

FIG. 5-2. Conversion graph, centigrade to Fahrenheit.

This "explosive wave," as it is termed, results from a vibratory movement which increases in intensity until finally these high velocities are reached. As has been stated, fire or flame, according to the latest experiments, is the result of chemical action, and its intensity is due to the speed of this action augmented by the temperature. As the temperature is applied at an increasing rate, the gases in combination with oxygen or air will supply additional heat, and as this proceeds it finally overcomes the loss of heat from radiation and then continues to burn. This final temperature is the ignition point of the gaseous mixture and will differ in its range from slow-burning

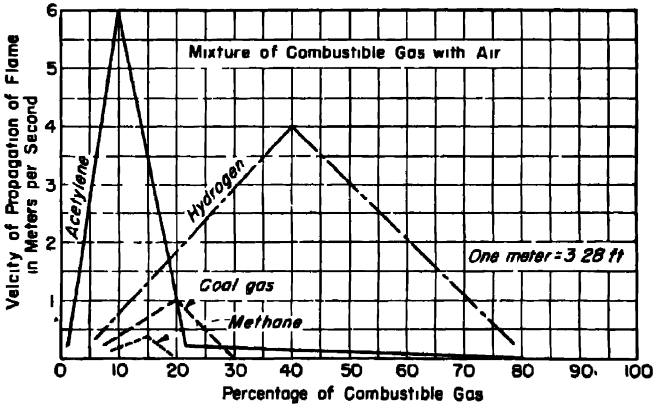

FIG. 5-3. Explosion ranges—Bunte.

to explosive action. This difference in the burning rates of substances or gases is demonstrated by experiments with flames produced by combining gases with air. As the mixtures approach the limits of flammability the cone, as it is termed, changes in luminosity and heat intensity. During this progress the presence of unconsumed material such as carbon produces a film flame which has a center of glowing gas with the outer film of unconsumed gases. As the mass begins to reach the proper mixture for complete combustion, however, the flame or cone becomes entirely luminous and is called a "volume flame."

Table 5-16 by Dixon and Coward, 1909, gives ignition points of a number of gases.

DEFINITIONS APPLIED TO THE PROPERTIES OF HEAT

Oxidation. Oxidation is the combination of other elements with compounds of oxygen or oxides and is also a change from a lower to a higher valence.

Convection. Convection is the act of conveying the diffusion of heat through a liquid or gas by motion of its parts.

Radiation. Radiation is the sending out of rays or direct lines from a point or surface, or issue in rays.

Conduction. Conduction is the slow progress of the vibratory motion from places of higher to places of lower temperature in the same body.

Explosion. When two or more substances, one of which is flammable and the others supporters of combustion, are mixed and ignited, combustion between these bodies takes place with extreme rapidity. The heat evolved increases the pressure of the gases produced and the shock to the surrounding air causes a loud detonation, which is called an "explosion."

FIRE PREVENTION

From the proceeding text it has been pointed out that fire or flame proceeds in some sort of ratio to the amount of heat energy which is developed or applied to a solid or liquid, and the chemical action can be rapid or slow owing to the conditions attending. These conditions may vary widely, some reacting with explosive violence where the flame propagation is rapid through a highly volatile material, or slow charring may continue for a long time and never result in anything more visible than an incandescence. This condition naturally is the result to be expected when dealing with a multitude of different kinds and classes of materials, ranging from the heavy solids to light and porous materials and from liquids of varying specific gravities and flash points. With the exception of a few materials it may be safe to say that all substances are in a preferred class under normal and good conditions. If substances were unexposed to outside influences and kept in a state precluding reactions from within, there would be little danger from any source, and the fire hazard would be reduced to a minimum.

There are three steps in the process of fire prevention.

1. The analysis of the disturbing forces or causes of fire which will lead to an understanding of them and, in consequence, a method for avoiding or preventing them. In analyzing fire hazards, the latest technique is to endeavor to visualize or measure "the heat of combustion" of the materials or mass of combustibles. The heat of combustion can be determined from tables that give the relative values of various materials in calories or British thermal units, and these can be used to ascertain the probable amount of heat which would be generated in a burning mass of material.

2. The protection of the materials from ignition by taking precautions commensurate with their flash and ignition points and susceptibility to spontaneous ignition, the segregation of quantities, and prescribing construction to prevent the horizontal and vertical spread of heat and flame.

3. The necessary fire protection to cope with any outbreak which might occur, measured in terms of the nature of the materials and the amount of "heat of combustion" to be overcome.

Fire prevention, as a science, is the preconception of conditions that may cause the heating of any material from within itself or from any outside source; the preconceived knowledge of the physical and chemical properties of materials to determine their ability to create a slow or rapid combustion and the amount of the heat of combustion which may be evolved; the understanding of the susceptibility of materials to moisture, mold, water (hot or cold), smoke, charring, and damageability by fire, water, or smoke, the visualization of the possible mass of combustible material which may be affected· and the study for the removal of the cause that may be responsible for any of the conditions outlined and the removal of the material from the cause.

If plant operations make it necessary to condone a hazardous process or hazardous material, the pertinent thing to do is to safeguard the process in a standard manner, protect the hazardous material from contact with other material, and then remove all other material to safe distances.

The science of fire prevention and fire protection is defined as *comburology*,* from the Latin word *comburo*, meaning to burn, to consume, as by fire. This is the study of the occurrence and augmentation or reactions due to the application of temperature by radiated and converted heat, friction, and pressure. It also includes the reactions that are due to fermentation, spontaneous heating, and oxidation and the disturbing of the molecular equilibrium of solids, gases, and dusts and the control of electrical energy. This is also the study of flash points, ignition points, kindling points, explosive ranges, and pressures and heat of combustion of the various elements. The visible heat of these reactions, caused by the absorption of oxygen or the liberation of hydrogen or causing incandescence, is called "fire."

This study also takes into consideration the natural elements which augment conditions inherent in these phenomena. This study is therefore directed to the maintenance of equilibrium; the occlusion of oxygen; the control of temperature, friction, and pressure; the prevention of arcing and heating by electrical energy; and the application of the knowledge of these physical facts to the protection of structural members, the segregation of combustible mass, both horizontally and vertically, and the protection of combustibles from these phenomena; and the use of various antidotal mediums to be applied in the control and prevention of these phenomena.

Causes of Fire. Von Schwartz, the eminent physicist, proposed a list under which causes or phenomena of combustion could be classified. This list covers practically all the common causes of fire prevalent in America. The causes, eleven in number, are as follows:

---

* This definition was proposed Dec. 27, 1943, at the Center for Safety, New York University, as a basis for a possible science.

1. *Direct Contact with Flaming or Glowing Materials.* Under direct contact it will at once be apparent that the open light is very important. Candles used for various purposes and left unguarded by plumbers and plumbers' torches for thawing pipes and sometimes used by electricians for soldering joints are examples of open lights. In industrial plants the open flame may be present in the form of an open forge, a gas stove, a pilot light at a water gauge (see *a* below), or a gas jet used for purposes of singeing or heating glue.

2. *Application of a Low Degree of Heat for a Prolonged Time.* The application of a low degree of heat for a prolonged time includes primarily the steampipe, both live and exhaust steam, which may pass through a floor or partition of wood without proper clearance (see *b* below) or may be located underneath a floor in close proximity to the wood floor or in such a manner as to cause dust to settle around it or to attract mice to build nests in contact with it owing to the warmth.

a. A disastrous fire was caused by the breaking of a gasoline supply line, the vapors extending across an open runway to the boilerhouse where they were ignited by a pilot light at a water gauge causing a flash back and an explosion.

b. The ignition point of wood is also a factor. Boiler stacks and breechings improperly insulated permit a heat radiation which is dangerous to wood structure in industrial plants and is a major source of danger. The head, or distance, between the breeching, or uptake, and the roof subjects the wood of the roof to a constant heat and will eventually produce serious results, as will the stack also as it passes through the roof. Ordinary stovepipes and hot-air heater pipes passing through or inside partitions are rightly under this heading. A simple application of this principle is the placing of paper around electric-light bulbs for decorative purposes or for shedding or shading the light. The latter is often done while working on motors in garages and is a dangerous practice.

3. *Spontaneous Heating and Ignition.* To avoid fires attributed to this cause requires some knowledge of the character of materials and their tendencies. For, although it may be said that it is difficult to avoid entirely conditions that may result in spontaneous ignition, this statement can be proved somewhat erroneous by using simple precautions. Oxidation is produced by many causes and may be in process for a long time before the temperature is raised to the flash points. Pressure such as found in stacks of printed paper, cardboard, or treated leather, as well as in coal stacks, principally soft coal, will prompt this action. Other causes of spontaneous ignition are friction between organic members due to vibration or wind motion; bacterial activity set up by the slow heating of a mass owing to pressure or germination, such as improper curing of hay or grains; chemical reactions due to the improper storage of various substances that set up an activity if in combination, such as any organic material with acids, oxygen carriers, picrates, chlorates, nitrates, fats, or oxidizing oils. Dampness or the possible wetting of materials such as lampblack, metallic oxides, and lime will cause heating and ignition. Oxidizing oils and, under certain conditions, any oil thinly spread over a surface, especially of porous material, will heat and flame. This action is noticeable in rags and waste used for wiping machinery and oily parts in industrial plants, as well as in metal turnings or iron filings coated with oil, and in various types of floor mops and wiping cloths.

4. *Explosion or Rapid Propagation.* To treat this classification properly would require a larger treatise than this, as it covers a vast number of possibilities, both chemical and mechanical, so that reference to the more common causes only will be attempted. Explosions result from rapid decomposition with release of large quantities of heat and rapid flame propagation through released vapors or by instantaneous release of pressures. To avoid this possibility, materials should be analyzed for properties that may produce one of the three characteristics mentioned. Among the principal materials which are met in the daily activities of industry and commerce[1] may be cited explosives used for blasting, such as nitroglycerin and nitrogen compounds, picrates, chlorates, and fulminates, guncotton, pyroxylin plastics, collodions, celluloids, and gases and vapors of highly volatile liquids as indicated by low flash

points or explosive ranges, dust formed by mechanical processes, and accumulations due to storage or handling. Also finely divided dust particles of almost any character can be ignited by contact with flame or sparks, but organic dusts and some metallic powders, such as magnesium, aluminum, and iron, are more susceptible.

5. *Lightning.* Lightning is a so-called "act of God." Lightning strikes according to no set rule. All are subject to its dangers, and as a cause of setting fire it is perhaps the most potent. It will ignite almost any material as its own temperature is comparable to an electric arc, and the speed of its flight provides little time to avoid it. Lightning rods serve only to assist lightning in its course, and such, when properly installed, have proved 95 per cent efficient. In addition, arresters, circuit breakers, or fuse plugs are helpful.

6. *Dust Explosions.* Dust clouds can be formed by simple combustion of materials, *e.g.*, lampblack; dry distillation or sublimation of sulfur or napthalene; mechanical pulverization, grinding, pounding, beating; mechanical purification, screening and blowing, of flour and grains; transporting materials from place to place; and bursting of bags, etc.

The following materials are susceptible to dust explosions:
Carbon of almost any kind
Lampblack
Wood dust, cork, tanbark
Grain, bran, malt, spices, medicinal barks, roots, etc.
Flour, starch, sugar, dextrin
Wool, fibers, tow, fluff from shearing
Metal or bronze and aluminum powders
Colophony, resins, celluloid, pyroxylin plastics
Sulfur, naphthalene

Any kind of organic and a great many kinds of inorganic dust floating in air can be ignited by the simplest flame or by electric or other sparks.

7. *Electric Sparks.* Electricity or electrical energy is a source of intense heat and, if released in the form of sparks or arcs due to poor insulation or broken connections in the installation, will ignite materials or vapors. Insulation may be broken down by friction or disintegrated by fumes or vapors or moisture, and short circuits are caused because of contacts of the naked wire with other conductors. Overloading of circuits through faulty installations or lightning charges will also break down the insulation. The use of incandescent lamps in places subject to mechanical injury will result in breakage and arcing.

8. *Chemical Reactions.* Chemical reactions include any and all the phenomena incident to the use, handling, or storing of substances involving even the slightest possibility of chemical change either within themselves or in combination with other materials. These reactions take place because of the inherent characteristics of the substances, *e.g.*, spontaneous ignition when slightly warmed or explosion by percussion. In combination with materials, the most prevalent cause of chemical reactions is due to affinities and natural reactions. Most of these combinations are understood by chemists and users of hazardous chemicals; but there is a wide field of industrial pursuits which involve the use of many substances which require careful handling and storage. Even in small quantities, some chemicals may cause an initial blaze sufficient to ignite surrounding material. To list these substances would make this a lengthy study and rather a duplication, for there are many chemical handbooks to which reference can be made. To exemplify the principle involved, attention is directed to dangerous combinations such as nitrate of soda with organic material such as gunny sacks or cellulose; lampblack with water; unslaked lime with water; nitric acid with organic or carbonaceous material; or sulfur with charcoal.*

9. *Friction, Pressure, Shock Falls, or Concussion.* Friction, pressure, shock falls, or concussion are closely allied with temperature and should be studied with this in mind as the production of heat is the ultimate result from each. In the case of friction and pressure, the action may be slow in the first instance, while concussion may pro-

---

* A recent fire was caused by the perspiration of a workman dropping into the contents of a barrel he was mixing, presumably a peroxide.

duce a rapid action. Friction (see also Static Electricity below)[5] produces heat. The rubbing together of organic or metallic surfaces will raise the temperature and if continued will ignite the material, if its ignition point is within that possibility, or will release vapors which may be ignited, or, as in the case of wood, will reduce the cellulose to a pyrophory carbon causing ignition. Belts or shafting at points of support and flowing volatile liquids in pipes are common producers of friction. Pressures may result from mechanical means such as pumping, compression of gases, or piling. These pressures produce heat which causes expansion or molecular activity which results in ignition or explosion.

Shocks or concussion may assume a variety of forms producing similar results, different substances reacting according to their composition. Gunpowder, detonators, and explosives of similar nature are very susceptible, while there are many materials which are not explosive but will ignite from concussion.

10. *Focused Rays.* The science of physics gives a clear explanation of the result of focused rays—that of applying heat rays to produce high temperatures. This can be accomplished by reflection or concentration. Polished surfaces or mirrors will reflect the heat rays of the sun, transmitting them to other objects which may be near enough to absorb them before they are cooled by the intervening currents of air. These reflected rays will cause a rise in temperature to ignition points if applied for a given length of time.

The concentration of heat rays is also accomplished by a combination of curved surfaces of materials which will transmit them. The burning glass of boyhood days is one example, and imperfections in sheet glass (bubbles) is another. The latter will direct a concentrated heat ray upon objects or substances and cause ignition. Many instances have been recorded recently of the ignition of celluloid articles in showcases and motion-picture films in vaults from these imperfections in glass.

11. *Static Electricity.* The demands of industry have brought into use many devices and materials that have developed causes of fire. One of the outstanding causes thus produced is static electricity. Its control has baffled the fire-prevention engineer until recent years when the study of processes and materials has shed some light upon the reason for its generation. Friction, or the rubbing together of two surfaces, will produce electric charges. There are so many instances of its generation that cannot be explained by the theory of friction, however, that it is difficult to analyze the law which governs it.[*]

Belting for transmitting power has been a source of static electricity and for a long time has caused fires in cotton mills. Today this continues to be the case in industries using flammable material and liquids. It is undoubtedly due to friction between the belt and the air or the pulley, or both. The built-up charge can be drawn off in a visible spark or current by placing a suitable conductor near the belt, thus proving its presence. In order to avoid building up too heavy a charge, it is necessary to install a permanent collector in the form of a comb composed of copper or other suitable material. This should be in contact with the belt and be connected with a good ground.[†]

Mixing materials by stirring or tumbling generates a charge which remains in the material after it is removed from the mixer and may not be discharged until further used in the process.[‡]

Dry-cleaning processes which use naptha or gasoline for washing garments develop heavy charges which have caused fires and explosions. Garments of silky material augment this charge, and if they are further ornamented with metal trim, the danger is increased because of possible contacts with metal parts of the machinery, causing spark gaps. Care must be exercised to avoid these spark gaps in removing the garments from the machines also. The best method is to place the hand under the garment to lift it from the liquid, thus permitting the static to pass through the arm and body of the operator. Grounds should be placed on the machines and also on the movable shafts connected to the revolving parts of the machines.

---

[*] The strange case of an enraged cat generating a sufficient charge to produce a spark that ignited an flammable gas cannot be said to have been produced by friction.

[†] A mixture of fish glue, glycerine, lampblack or ammonia hydroxide for leather belting or lampblack and spar varnish for rubber belting is said to reduce the static charge

[‡] In the rubber industry it has developed that, if milled or mixed rubber is laid upon a copper wire carpet for a length of time, there has been no development of static when the material was dissolved further for use in dipping processes.

Flammable liquids flowing through pipes will generate considerable static and also hold the charge if there is not an outlet for it. This has developed into a serious danger at gasoline filling stations and in tank cars and wagons as well as in certain industries. Where the discharge nozzle or tip of the discharge pipe is of copper and is grounded, the static is drawn off, and no trouble is experienced. There is not very much data on which to base a comprehensive explanation of this phenomenon, but the progress made so far indicates that it is a danger to be reckoned with and deserves the attention of the physiochemist.

Coating processes involving both the use of rubber compounds and pyroxylin plastics, where the application is by spreading, produce a severe problem in static-electricity control. Today these processes are safeguarded by various methods of grounding, the use of inert gases in the enclosures of coating machines, and the introduction of nonsparking metals at all friction points.

Equilibriums. Fire prevention is the study of "equilibriums" and the maintenance of those equilibriums by proper safeguards This resolves itself to a consideration of the temperatures by which materials, solid, liquid, and gas, are affected either in their structural stability, their physical form, or their action due to pressure. All materials under normal conditions may be said to be in a preferred class, or at "equilibrium." It is the disturbing of this normal condition which brings about a change which is classed as dangerous or hazardous.

Therefore precautions are instituted in almost all cases to protect the materials from outside influences, except in rare cases where a material may contain within itself the element for its own destruction, *e.g.*, metallic sodium. Standards are therefore devised to reduce to a minimum the outside influence which would disturb the equilibrium or to reduce the effects produced should the material be transformed from its quiescent state. This idea of the equilibrium of materials, if kept clearly in mind, will make the science of fire prevention an understandable one and will enable the use of standards that can be applied to all similar problems regardless of where they are located.

STANDARDS FOR THE SAFEGUARDING OF HAZARDS

The following standards have been adopted by the National Fire Protection Association and are also official standards of the National Board of Fire Underwriters:

Acetylene Equipment for Lighting, Heating, and Cooking
Air-conditioning, Warm-air Heating, Air-cooling, and Ventilating Systems
Blower and Exhaust Systems for Dust, Stock, and Vapor Removal
City Gas, Installation, Maintenance, and Use of Piping and Fittings
Combustible Fibers, Storage and Handling
Dip Tanks Containing Flammable Liquids, Including Hardening and Tempering Tanks; Flow-coat work
Dry-cleaning and Dry-dyeing Plants, Safeguarding of
Dust Explosions in Industrial Plants, Fundamental Principles for the Prevention of
Dust Explosions in Starch Factories, Terminal Grain Elevators, Flour and Feed Mills
Electric Wiring and Apparatus. (National Electrical Code)
Gasoline Vapor Gas Machines, Lamps, and Systems
Gas Shutoff Valves, Emergency
Gas Systems for Welding and Cutting
Internal-combustion Engines (Gas, Gasoline, Kerosene, Fuel Oil) and Coal-gas Producers (Pressure and Suction Systems)
Liquefied Petroleum Gases, Storage and Handling, Including Compressed-gas Systems for Cooling and Heating, Tank Trucks, and Liquefied Petroleum Gas as a Motor Fuel
Nitrocellulose Motion-picture Films, Storage and Handling
Oil-burning Equipments and the Storage and Use of Oil Fuels in Connection Therewith
Ovens for Japan, Enamel, and Other Flammable Finishes
Paint Spraying and Spray Booths
Photographic and X-ray Nitrocellulose Film, Storage and Handling
Pulverized-fuel Systems, Installation of
Pyroxylin Plastic, Storage, Handling, and Use of in Factories Making Articles Therefrom
Pyroxylin Plastic, Storage, and Handling in Warehouses and Wholesale Jobbing and Retail Stores
Small Heating and Cooling Appliances (Kerosene and Fuel Oil)

CONSTRUCTION

The high temperatures recorded in conflagrations reach between 2200 to 2300°F. Any material that is used in construction for the purpose of protection or the prevention of the passage of fire and heat, therefore, must have a resistance sufficient to withstand the "hazard of the occupancy" and the "fire severity" to which it may be subjected.

Fire ratings are based upon the time element of exposure to fire and heat and range from ½ to 4 hr. (These fire ratings and construction details for buildings are set forth in the National Board of Fire Underwriters, Standard Building Code.) The standard methods of fire tests of building construction and materials are E119.47 of the American Society for Testing Materials, American Standard A21-1942 as approved by the American Standards Association, and British Standard Test for Fire Resistance (BSS 476). In the American specifications, average indicated furnace temperatures are required to conform to the following values within allowable tolerance limits:

1000°F	at	5 min
1300	at	10 min
1550	at	30 min
1700	at	1 hr
1850	at	2 hr
2000	at	4 hr
2300	at	8 hr

The temperature should continue at 2300°F.

The fire-resistance point is taken to be reached if

1. An average temperature rise of 250°F or a maximum rise of 325°F, measured with thermocouples under asbestos pads, is attained on the unexposed side of the wall.
2. Passage of heat, flame, or gases hot enough to ignite cotton waste occurs.
3. Failure under the design load occurs (load-bearing construction only).

The fire resistance of building materials or the protective coverings for steel members used in construction should conform to the standard tests if their equilibrium is to be maintained.

Steel expands eight parts in a million for each degree Fahrenheit, which means that, if it is heated to 1000°F, it can expand 9½ in. in a 100-ft length.

Steel under tension can fail under a temperature as low as 1200°F, the critical temperature of steel. Steel columns have a maximum useful limit of 900 to 1100°F.

Maintaining the equilibrium of the building itself and its structural members is commensurate with the degree of volume of fire, heat, gases, smoke, and the effects of water used in the extinguishment of the fire. It is therefore essential to consider the factors that contribute to these conditions. These factors are area, height-horizontal segregation, and vertical segregation.

The confining of a fire and its effects to the smallest possible area is one of the first principles of fire prevention.

Table 5-17 is the standard table for area for square foot of the plot, depending upon the type of building and the type of construction.

Table 5-17. Area Limits per Floor of Buildings in Square Feet

Types of Construction

Fireproof	Semifireproof	Street fronts	Heavy timber	Ordinary and noncombustible		Wood frame	Unprotected metal
			Per story	One story	More than one story	Outside the fire limits	
No limit		One street	6 500	6 000	5 000		One story, no limit More than one story, same as noncombustible
		Two streets	8 000	7 500	6 000		
		Three streets	10 000	9 000	7 500	5 000	
		Four streets	10 000	10 500	9 000		

NOTE For area modifications and also for area limits for certain special occupancies for sprinkler requirements based on occupancy see National Board of Underwriters Building Code 1919

Table 5-18. Building Height Limits*

Classification of occupancy	Types of construction					
	Fireproof	Semifireproof	Heavy timber	Ordinary	Noncombustible	Wood frame and unprotected metal*
Public buildings	No limit	75 ft except no limit if less than 100 persons above 75 ft	Not to exceed 4 stories or 55 ft	Not to exceed 3 stories or 35 ft Churches 2 stories 45 ft Schools 2 stories		Not to exceed 2 stories or 35 ft
Institutional buildings	No limit	75 ft	Not to exceed 2 stories or 35 ft			Not to exceed 1 story or 35 ft
Residence buildings	No limit	No limit	75 ft	Not to exceed 3 stories or 45 ft*	Not to exceed 3 stories or 45 ft	Not to exceed 2 stories or 35 ft Dwellings other than prefabricated may be 3 stories
Business buildings	No limit	75 ft except office buildings no limit	75 ft	Not to exceed 4 stories or 50 ft		Not to exceed 2 stories or 35 ft
Storage buildings	No limit	50 ft 75 ft if sprinklered	35 ft 75 ft if sprinklered	35 ft 50 ft if sprinklered		Not to exceed 1 story or 35 ft

* National Board of Fire Underwriters Building Code also applies special heights within fire limits to certain special occupancies for sprinkler requirements based on occupancy

NOTE With a 2 hr noncombustible first floor height may be 4 stories or 55 ft in multifamily houses with a 2 hr noncombustible first floor and other floors 1 hr with fire partitions subdividing floors into areas not exceeding 3 000 sq ft the height may be 5 stories or 65 ft

Wired Glass. The first patent for wired glass was granted in 1855 to an Englishman Owing to difficulties of manufacture, however, its use did not materialize until 1893 when the award was made to Scott and Sherman by the Franklin Institute for the machine and process for making it

Its fire-resistive qualities were discovered by accident. It will stand up to a temperature of approximately 1400°F (by test). There are two types of wired glass—smooth and roughened surfaces.

Wired glass is generally installed in frames of solid metal or hollow metal specially designed to hold the glass under fire conditions. Although the standard requirement for wired glass recommends its use in moderate or light exposures, it has stood up well under many adverse conditions. With a double retardment (such as a fire shutter), it is recommended for severe exposure.

Wired glass does *not* prevent the passage of radiated heat.

Sizes of individual glass lights are limited in the standard for its use.

Class E—moderate exposure, 720 sq ft exposed area, 54 in. vertical, 48 in. horizontal

Class F—light exposure. 2,916 sq ft exposed area, 54 in. in either direction (Underwriters, Laboratories)

Window openings at outside fire escapes should be protected by wired glass in metal frames.

Glass Blocks. Glass blocks are good for panel walls but not for bearing walls. They are acceptable for protection in light exposures, *i.e.*, class F (above). They have a relatively high thermal insulation and are suitable for window openings not exceeding 120 sq ft in area or 12 ft in width and height. Expansion joints must be permitted at sides and tops.

Roofs. Roofs should have a degree of fire resistance equal to or greater than that of the buildings on which they are placed.

A classification of roof coverings as set forth by the Underwriters' Laboratories is as follows:

Class A—Effective against severe fire exposure. Not readily flammable; do not carry or communicate fire. Afford a slight degree of heat insulation. Do not slip; no flying-brand hazard. Do not require frequent repairs to maintain their fire-resistive properties.

Class B—Effective against moderate fire exposure. Same as class A with moderate degrees of heat insulation. May require infrequent repairs.

Class C—Effective against light fire exposure. Same as class B with at least a slight degree of heat insulation. May require occasional repairs.

Various materials are acceptable to meet these classifications, and they are listed in the standards of Underwriters' Laboratories.

Wood Shingles. Wood shingles have contributed to 59 conflagrations in the United States and Canada. The reasons for the susceptibility of wood shingles to fire are their dryness and high winds. Fire retardants for wood shingles or wood in general are

Diammonium phosphate
Monoammonium phosphate
Monomagnesium phosphate
Phosphoric acid
Zinc chloride

Snow Loads. Snow loads constitute an important factor in roof construction. Snow loads for some sections of the United States are shown in Table 5-19.

Table 5-19. Snow Loads

	Psf area
Southern and Pacific states	5
Central states	30
New England states	40
Northwestern states	45

Skylights. Skylights should be so constructed as to prevent the entrance of falling firebrands. They should also act as vents over elevators, stairways, and stages in theaters and over fire sections of piers and wharves. Skylights in flat roofs should be constructed of wired glass in metal frames or ribbed glass (plain) in metal frames protected by wire screening of No. 12 gauge set on angle irons 1 ft above the sky-light and extending 1 ft on all sides. Texas or monitor skylights should be protected by screening of not less than No. 12 gauge or wired glass in horizontal sides if possible.

Skylights over stages in theaters are of special design and are usually equipped with automatic devices for quick opening in case of fire. These devices are of sliding-track or butterfly design with fusible link and weights under remote control. Similar devices should be installed on piers and wharves.

Exits. The standard for exits is set forth in the Exit Code of the National Fire Protection Association.

There are three additional elements which must be taken into consideration in relation to fire prevention as applied to buildings for the maintenance of the equilibrium of the structure and its equipment which is attached to or supported by the structure, *viz.*, hurricanes, termites, and dry rot. The latter two elements may undermine the integrity of the structural wood members and may cause collapse because of wind movement, excessive weights from stock piling, or water used in fire extinguishment.

Hurricanes. Tests at the U.S. Bureau of Standards have shown that, as wind blows against a building, it produces a positive pressure on the windward side (the direction from which the wind is coming) or on some portion thereof but produces a negative or suction pressure on the other sides of the building (the leeward or direction in which the wind is going). A roof will have an area of positive pressure on a windward slope if the pitch approximates 30 deg or steeper, but other portions of the roof will also be under suction pressure. The wind-tunnel tests have indicated that positive wind pressures vary up to a maximum of what is known as "wind velocity pressures." Suction pressures, on the other hand, have been shown to exceed the velocity pressures in some instances. The total wind force acting on a building as a whole is the sum of the positive force on the windward area plus the negative force on the leeward area. External projections, appendages, and openings should therefore be avoided. A reasonable amount of streamlining is desirable.

In cities and towns subject to hurricanes, except for buildings and structures where height does not exceed $1\frac{1}{2}$ times the least width, the design wind pressure upon vertical surfaces shall be as shown in Tables 5-20 and 5-21 which are to supplement Standard Building Code requirements.

Table 5-20

Maximum height above ground, ft	*Normal wind pressure over entire height, psf*
25	25
75	35
Over 75	45

The wind pressure on sprinkler tanks, sky signs, or other similarly exposed structures and their supports shall be taken as not less than 50 psf of the gross area of the plane surface, acting in all directions. On circular tanks, towers, or stacks the pressure shall be assumed to act on six-tenths of the projected area.

Table 5-21. Wind Velocity Pressures*

(Based on air at 15°C and 760 mm Hg)

True wind speed, mph	*Velocity pressure, psf*
30	2.30
40	4.09
50	6.39
60	9.21
70	12.5
80	16.4
90	20.7
100	25.6
110	30.9
120	36.8
130	43.3
140	50.2
150	57.5
160	65.8
170	74.2
180	83.0
190	92.6
200	102.4

* National Board of Fire Underwriters, 1937.

Dry Rot. The U.S. Department of Agriculture defines dry rot as follows: Dry rot is the term given to decay in wood which is the result of a fungus which attacks the wood structure. Wood that has been kept dry, weatherproofed, or thoroughly saturated with moisture is not subject to decay. Dampness or mild to warm weather are favorable conditions for the growth of fungi. The fungus is a plant, and although wood is the food of the plant, it cannot become active unless there is at least 20 per cent water present, based upon the weight of oven-dried wood. The fungus *Poria incrassata*, however, has the ability to seek water and promote its own growth. Posts and poles set in the ground will become rotted at the ground line if this fungus is present, regardless of the type of wood.

Postings in buildings are subject to rot at the floor level where the floors are damp or mildewed. The sapwood of all timbers is subject to this decay, but the cedar, catalpa, chestnut, southern cypress, juniper, black locust, and redwood resist the decay longer. Wood preservatives that penetrate to the heartwood will prevent this decay and maintain the integrity of the wood. Creosote treatment is recommended.

Termites. In the spring and occasionally in the fall, male and female termites, white-winged with black or brown bodies, seek points for the establishment of new colonies. These swarming or flying termites are not capable of attacking wood. The descendants of these winged migrants, the workers, *i.e.*, cream-colored insects, are the wood-mining and destructive members of the colony. These insects shun the light and are concealed in the shell of the wood. With the common ground-nesting or subterranean form of termite, the invasion of buildings is mainly direct to the woodwork in contact with the ground from outdoor colonies through tunnels made by the workers under the ground.

From the report and the work of the U.S. Department of Agriculture,[6] the conclusion is drawn that proper construction or reconstruction is the most effective method of prevention of or remedy for attack by termites. In the construction of new buildings, maximum immunity from termite infestation can be secured by eliminating all wood from foundations, cellars, and basements. Where it is not feasible to eliminate all such wooden members, reasonable security can be secured by treating all structural wood within 18 in. of the ground with creosote or an equally effective toxic preservative.

Wood treated with coal-tar creosote under pressure and in accordance with the specifications of the American Wood Preservers' Association will give satisfactory protection under all known conditions.

Zinc chloride, although not so effective as creosote, is used on structural members, particularly when the wood is to be painted. The introduction of poison dusts into the termite galleries is the most effective known remedial treatment for wood infested with the dry-wood termite. The most effective poison dusts are Paris green, arsenical smelter dust, and finely ground sodium fluosilicate. Sodium fluosilicate is nonpoisonous to man but is effective only if the infested wood is dry. Subterranean termites cannot be satisfactorily controlled by poison dusts. This is particularly true where the infested wood on or in the ground is damp. Cleanliness should be observed and care should be taken in handling poisonous dust. It should not be breathed nor allowed to get on the clothing. If either arsenical smelter dust or Paris green is swallowed, an emetic should be given and a physician called. The danger to firemen in buildings that have been treated with poison dusts is only slight and not so great as carbon monoxide so frequently encountered.

The use of insecticides or fumigants, if flammable, for termite control introduces a severe fire hazard if they flash below 100°F. Precautions include thorough ventilation to prevent combustible mixtures of air and vapor and elimination of open lights and all devices that may produce an arc or a spark. All liquids used for termite control should be tested and approved by Underwriters' Laboratories. The use of such soil poisons as orthodichlorobenzene in liquid or crystal form placed in hollow trenches about exterior foundation walls will give temporary relief.

Horizontal Separation—Walls. For exterior walls of brick or concrete the standards for walls, as set forth in Building Codes should be followed.

An 8-in. brick wall has a rating of 4 hr. The equivalent in reinforced concrete is 11 in.

1. *Bearing Wall.* A bearing wall is a wall that supports any vertical load in addition to its own weight.

2. *Nonbearing Wall.* A nonbearing wall is a wall that supports no load other than its own weight.

3. *Curtain or Panel Wall.* A curtain or panel wall is a nonbearing wall between columns or piers, not supported by girders or beams.

4. *Fire Partition.* A fire partition is a partition that subdivides a building to restrict the spread of fire or to provide an area of refuge. It is not necessarily continuous through all stories or extended through the roof. It has a fire resistance of at least 2 hr.

5. *Fire Wall.* A fire wall is a wall of brick or reinforced concrete which subdivides a building or separates a building to restrict the spread of fire. It starts at the foun-

dation and extends continuously through all stories to and above the roof, except where the roof is fireproof or semifireproof, and the wall is carried up tightly against the underside of the roof slab. The height of such a wall above the roof should be 3 ft (parapet) and be properly coped. Wall thickness should be 12 in. (insurance standard).

6. *Parapet.* Parapets are required on all walls with the following exceptions:

Walls connecting with roofs of fireproof construction or semifireproof construction

The adjoining wall of a building, the roof of which is 3 ft lower than the roof or any opening in the side wall of the building adjoining or adjacent to such wall

Walls facing on a street having a width of 50 ft or more

Walls of a building that is 50 ft or more distant in all directions from property lines and from other buildings on the same property

Walls of a detached dwelling or building not exceeding 1,000 sq ft in area

Walls of a building where the roof has an angle of more than 20 deg with the horizontal

On 8-in. walls of dwellings, parapets should be 2 ft. On 12-in. walls of dwellings, parapets should be 3 ft. A parapet is not only a separation but also acts as a barrier for use by fire departments.

7. *Wing Wall.* If a building has frame sides, the fire wall should extend 5 ft beyond the frame outside wall. This is termed a "wing wall."

If a wall is of brick but with wood cornice and roof, the fire wall should be corbelled out at the eaves and extend 3 ft above the roof. Exterior walls at intersections with fire walls should be blank for a distance of 20 to 30 ft. If any windows are in exterior walls, these windows should be protected by wired glass in metal frames for 20 ft on each side of the wall. This also applies to roof structures. A fire wall is a special device and should have special consideration.

Openings in Fire Walls—Fire Doors. Openings in fire walls should be protected in a standard manner. The protection of such openings can become valueless unless the protective device is designed to cope with the heat of combustion which may be generated on either side of the wall. Flash fires and radiated heat will pass through openings too fast for ordinary devices.

For doorways, the standard calls for two class A fire doors, one on each side of the wall. This may be modified in the case of boiler and engine rooms of fireproof construction. Class A doors are three-ply wood with a lock-jointed tin envelope; class B doors are two-ply wood with a lock-jointed tin envelope.

The size of openings for standard doors, owing to expansion and other fire effects, shall be limited to 120 sq ft for class A three-ply doors and 80 sq ft for class B two-ply doors. Door laps should be 5½ in.

All sills, styles, and lintels should be of incombustible material. Fire doors should be automatic in operation and also equipped with devices for quick closing in case of flash fires or radiated heat. The attachment of thermostatic or rate-of-rise devices is desirable where conditions demand quick action.

Fire doors are constructed of sheet metal, tin clad, rolling steel, steel plate, and Kalamein Their fire rating is set by the rating bureau having jurisdiction.

Fire-door failures are due to one or more of the following reasons:

1. Fire doors not on each side of wall, thus not providing two lines of defense with air space between
2. Fire doors substandard
3. Poor hardware
4. Fire doors not closed owing to automatic-action failure, blocking, or human element
5. Combustible sills, styles, and lintels
6. Fire intensity too severe
7. Explosives
8. Fire travel too fast for automatic devices
9. Lack of care and maintenance
10. Dry rot

Belt Holes. Belt holes should be protected by standard tin-clad shutters and be equipped with automatic closing devices similar to doorways. Pipe holes should be protected by metal thimbles and collars extending at least 1 in. on each side of wall.

Piers and Wharves. Since piers and wharves are similar to buildings and incorporate flue action in their design, the areas of such structures should be restricted. Transverse fire walls should be installed at intervals of 300 ft, or to restrict the area of one fire division to 5,000 sq ft. Fire walls should extend through the pier deck and continue in the substructure to low water.

Vertical Separation. If a building is more than one story in height, the problem becomes one of superimposed horizontal area. The possibility of damage and destruction due to flue action, converted heat and fire, and smoke and water seepage are increased also (see Table 5-18).

Vertical Openings. Vertical openings consist of elevators, stairways, chutes, conveyors, pipe holes, pipe shafts, ventilating shafts, ramps, and fire towers.

1. *Elevator.* An elevator is a device within or in connection with a building that is used for carrying persons or things upward or downward. Elevators vary in size and are subject to much activity in an industrial establishment and therefore should have special treatment (see American Standard Safety Code for Elevators). The walls of an elevator should be of brick of not less than 4 in. or equivalent thickness (increased for height), extending above the roof not less than 3 ft, and having a fire-resistive rating of not less than 2 hr. The enclosure at the top should have skylights of $\frac{1}{8}$-in. wired glass or plain glass covered by a screen of No. 12 wire set 1 ft above the skylight and extending on all sides at least 1 ft. Windows in these enclosures, not less than 2 ft above roof, may be of plain glass unless the window is within 10 ft of a lot line. In that case it should be wired glass. If the elevator does not extend to the bottom of the building, it should be enclosed with the same construction as the lowest floor.

2. *Stairways.* A stairway consists of one or more flights of stairs and the necessary landings and platforms connecting them to form a continuous and uninterrupted passage from one story to another in a building or structure. There are many varieties of stairways, and standard treatment is difficult, except that the standards for elevator shafts also apply to stairways. All stairways should be of incombustible material and enclosed by wired glass in metal frames or fire-resistive partitions to suit the severity of the occupancy.

3. *Chutes or Conveyors.* Chutes or conveyors that cannot be treated in a standard manner may be treated by installing metal traps or flaps.

4. *Pipe Holes.* Pipe holes should be made as small as possible and closed off by close-fitting incombustible material at the ceiling and floor lines. Metal sleeves should extend 6 in. above the floor if the floor is waterproofed.

5. *Ventilating Shafts.* Ventilating shafts should be constructed of incombustible material, and windows in the shafts should be of wired glass in metal frames.

6. *Ramps.* Ramps present the same problem as any vertical opening and should be treated as such if possible.

7. *Fire Tower.* Smokeproof Tower. Philadelphia Tower. The enclosing walls of a fire tower should be of approved masonry or reinforced concrete, and there should be no openings in such walls, except for the necessary doors and windows. A fire tower should have a roof of fire-resistive construction. The fire tower should extend to the street level. Self-closing fire doors, swinging in the direction of travel from the building to the fire tower, should be provided at both building and fire-tower ends of the balcony or vestibule. Fire towers should be accessible and should never be used for storage. The doors should always be kept free (see Fig. 5-4).

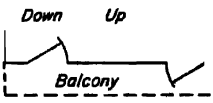

Fig. 5-4. Smokeproof tower.

Frame construction should have the end of wooden transverse beams or joints resting on masonry walls cut to a bevel or chamfer of 3 in. in depth so that release of beam will not destroy the integrity of the wall (see Fig. 5-5).

Water Seepage and Drainage. Water from broken pipes and sprinkler ruptures caused by freezing and breakage and water for extinguishing fires causes great damage, and its elimination by gravity is essential, particularly where floors have been waterproofed. Water is not only destructive because of its wetting quality, but it will be absorbed by stocks, even though they are skidded. Also, its weight (62.5 lb per cu ft) will increase the dead load and cause collapse of building.

*Scuppers.** The installation of scuppers is essential to permit the water to drain off, and floors should be pitched slightly from the center to the outer wall to assist the flow. A scupper is a cast-iron assembly set in the wall at floor level, with an opening 4 by 4 in. closed by a hinged flap at the outer opening. Care should be taken to keep scuppers clean and free from obstruction of any kind. Birds will make nests in them if flaps are not seating properly.

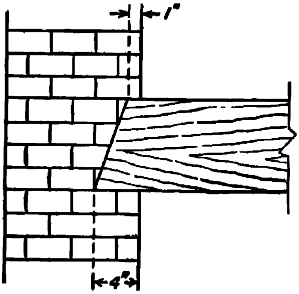

Fig. 5-5. Self-releasing beam.

For floor areas of 500 sq ft or less use two scuppers.

For floor areas of 750 sq ft or less use three scuppers.

For floor areas of 1,000 sq ft or less use four scuppers.

For floor areas over 1,000 sq ft additional scuppers should be used, one to 500 sq ft of area in hazardous locations; one to 1,000 sq ft of area in moderate locations; and one to 2,000 sq ft of area in ordinary locations.

Two scuppers are needed to discharge water from one 2½-in. hose stream (250 gpm).

FLAMMABLE LIQUIDS AND GASES

Fire prevention, as applied to flammable liquids, gases, and dusts, is a study that must take into account the physics of the materials. Complete equilibrium as to temperature and pressure, as in closed containers, can be used as a basis, for it is the disturbance of the equilibrium which presents the problem in the control of these materials. To enumerate all the factors involved in this study is beyond the limits of this chapter, but certain features are presented which will be of initial value to those in plant management.

Flammable Liquids

There is no sharp line of demarcation between a liquid and a gas. Any liquid at a high temperature and low pressure becomes a gas. Any gas at a sufficiently low temperature and high pressure becomes a liquid. The essential physics of flammable liquids is to maintain the equilibrium of the material at atmospheric pressure. This requires the exclusion of sources of ignition, the prevention of evaporation in enclosed spaces or in proximity to combustible material, and the protection of liquids or gases in closed containers from fire heat or the sun's rays which may cause expansion of the contents and the bursting of the container, resulting in widespread fire. Heat is absorbed when a liquid is evaporated to form a gas. Heat is given off when a gas is condensed to a liquid.

In general, the rate of diffusion of liquids and gases varies with the density. Vapor density is the relative density of the vapor as compared with air, a figure less than 1 indicating a vapor lighter than air, a figure greater than 1 indicating a vapor heavier

---

* Scuppers of larger dimensions can be used, but the above requirement will suffice to cover a normal condition.

Propane	0.509	4 24
Water, at 60°F	1.	8.34

than air. Vapor density is one-half the molecular weight. Vapor density of a gas is the ratio of the weight of the gas to the weight of an equal volume of hydrogen. Molecular weight (mol wt) of a gas is equal to twice its vapor density.

Specific Gravity. For liquids, specific gravity is based on the specific gravity of the liquid tested at 60°F as compared with water at 60°F.

Degree Baumé. According to the U.S. Bureau of Standards degree Baumé is as follows:

For liquids heavier than water, degree

$$\text{Baumé} \quad 145 - \frac{145}{R}$$

For liquids lighter than water, degree

$$\text{Baumé} \quad \frac{140}{R} - 130$$

R is the ratio of the density of a liquid to that of distilled water, both taken at 60°F.

Hazardous Locations. A hazardous location is defined as one in which there is present any highly ignitable material, including gases, liquids or dusts. The analysis of the existing or contemplated process or mechanical operation to ascertain whether any hazard of fire or explosion may be present calls for the application of standard treatment set forth* for ameliorating these conditions, including the mechanical equipment such as electric motors, ventilation, grounding, and explosion venting.

Under the National Electrical Code and Underwriters' Laboratories, hazardous locations are defined as shown in Table 5-25.

Table 5-25. Hazardous Locations

National Electrical Code	Underwriters Laboratories	Hazardous locations
Class 1	Group A	Atmospheres containing acetylene
Class 1	Group B	Atmospheres containing hydrogen or gases or vapors of equivalent hazard such as manufactured gas
Class 1	Group C	Atmospheres containing ethyl ether vapor
Class 1	Group D	Atmospheres containing gasoline, petroleum, naphtha, alcohol, acetone, lacquers, solvent vapors and natural gas
Class 2	Group E	Atmospheres containing metal dusts
Class 2	Group F	Atmospheres containing carbon black, coal, or coke dust
Class 2	Group G	Atmospheres containing grain dusts
Class 3		Locations handling ignitible fibers, combustible flyings
Class 4		Locations where easily ignitible combustible fibers are stored

Only liquids having a flash point lower than 200 F are generally termed "flammable," but any combustible liquid, when heated to above its flash point, will produce flammable vapors, e.g., heavy fuel oil when heated above 300°F may release vapors as flammable as gasoline at its flash-point temperature, which is about 0°F (see Table 5-27). All combustible liquids, therefore, must be treated as hazardous with special treatment given to those of a density of 1.25 or lower.

Table 5-26. General Classification for Flammable Liquids*

Class	*Numerical scale*
Ether†	100-110
Gasoline	90-100
Kerosene‡	30-40
Paraffin Oil§	10-20

* Underwriters Laboratories.

† Pure ether is rated 100.

‡ A standard kerosene of 100°F (closed cup) is rated 40.

§ A paraffin oil of 440°F flash (closed cup) is rated 10.

Ventilation

Ventilation may be either natural or artificial. Natural ventilation has the advantage of being in continuous operation and is not dependent upon manual starting or on power supply. For liquids heavier than air, the floor venting should be for a height of 7 ft and may consist of pipes set in the enclosing walls at floor level, pointing slightly downward and venting to the outer air, and other practical apertures. For liquids lighter than air, the venting should be at the ceiling and roof and above 7 ft from the floor for convection currents pushing upwards. Pivoted windows without fixed latches are a desired type of ventilation medium. Mechanical ventilation is more positive and should be used where operations are extensive. It does not depend on temperature and wind conditions. Mechanical ventilation should follow the principle noted above and be figured on the rate of diffusion of the vapors, e.g., 1 gal of solvent evaporated in 2,300 ft of air.

Explosionproof Electrical Equipment (see Motors). Since it is impractical to construct airtight enclosures for motors and other electrical equipment, it is necessary so to construct the enclosure that, if gas or vapor within it is ignited, the resulting flame is prevented from propagating to the outside surrounding atmosphere. This is a fundamental requirement for motors and other electrical equipment of the explosionproof type. The design of equipment to meet this requirement is based on the principle that the propagation of flame through an opening is prevented when the dimensions of the opening are within certain narrow limits.

Explosion pressures of many vapors or gases show wide differences. Explosions

* Flash point is subject to an error of plus or minus 5°C.

of acetylene, for example, may be weak, developing little pressure, or violent, developing a high pressure. If explosive mixture is in a state of mechanical agitation or turbulence at the time of ignition, a higher explosion pressure is developed. It has been found that mixtures containing approximately 1.8 per cent by volume of gasoline vapor in air are much more likely to produce discharge of flame at the joints or other openings than mixtures of the order of 2.2 per cent by volume.[7] It is difficult to make a standard to fit all conditions, so tests should be made and equipment approved for the hazardous location in which it is to be used.

Explosions. The violence of an explosion depends upon the concentration of a vapor with air, and the explosion range is determined by this concentration. For gasoline these proportions range from slightly over 1.4 to about 6 per cent by volume, or a range of 4.6. Therefore, 1 gal of gasoline completely vaporized and mixed with air will form an explosive mixture in volume of from 500 to over 2,000 cu ft.

Table 5-28. Explosion Pressures for Gasoline Vapor and Air Mixture

Per cent of vapor in air by volume	*Pressure, psi*
1	56
1½	65
1¾	73
2	83 4
2¼	100
2½	90
2¾	85
3	68
3½	50
4	30

The curves for vapors from other flammable liquids are similar in form, although the explosion limits vary considerably.

To avoid the possibility of explosions in the use of liquids for dry cleaning or cleaning and washing of parts in factories and garages, the following mixtures are suggested:

Seventy per cent carbon tetrachloride plus 30 per cent or less of gasoline. (This mixture must be tested at intervals, as the carbon tetrachloride will evaporate faster than the gasoline.)

Three parts ethyl dichloride plus 1 part carbon tetrachloride is a safe mixture. Other solvents of low flammability are trichlorethylene, tetra chlorethylene, Stoddards Solvent, and B/L spirits.

Explosion Venting.[1] Properly designed and proportioned and properly distributed vents will release explosion pressures without structural damage. The diagonal scoring of double-strength clear-glass window lights on the outside with a diamond, starting the scoring about two inches from the corners and leaving a 2-in. gap in the center, reduces the strength of the lights to about one-fifth so that the scored glass will probably be blown out without severe damage to the steel frame.

The required ratio of explosion-vent area depends upon the strength of the structure. For reinforced concrete (heavy), provide 1 sq ft for every 80 cu ft of volume. For reinforced concrete (light), brick plank on timber construction, provide 1 sq ft for every 65 cu ft of volume. For light construction provide 1 sq ft for every 50 cu ft of volume. These requirements are for dusts of grain-dust characteristics. Average heat content of flammable liquids is 19,000 Btu per lb. Average thermal expansion of flammable liquids is 4 to 9 per cent increase in volume per 100°F temperature rise.

Oil Burners

The primary hazard of the oil burner is the discharge of unburned oil into a hot firebox, where it may vaporize and form an explosive mixture. In domestic oil burners, the danger is faulty ignition or formation of carbon on ignition points. In industrial plants, burners may be turned off while the firebox is still hot, and oil continues to flow. The installation of oil burners in dwellings and mercantile and industrial properties where the chimney of flue construction has not been designed for this type of fire heat calls for rigid inspection to determine heat radiation which may expose combustible material.

Solvents

Any liquid with a flash point under 100°F may be classed as a solvent. In all mixtures where solvents are used, the same precautions and standards must be used as for flammable liquids.

Table 5-29

Fuel oils	Flash point, deg F	Ignition point, deg F	Extinguishing mediums (Factory Mutual)*
Fuel oil 1 (similar to kerosene)	100–165	490	2, 3, 4
Fuel oil 2	110–190	494	2, 3, 4
Fuel oil 3	110 230 125 200 110 230	498	2, 3, 4
Fuel oil 4	Not used		
Fuel oil 5 (industrial type)	130+ 150+		1, 2, 3, 4
Fuel oil 6 (industrial type)	150+	765	1, 2, 3, 4

* Extinguish mediums are (1) water spray or fog or automatic sprinklers, (2) foam, (3) CO_2 and (4) dry chemicals.

Notes. Fuel oils 5 and 6 are for industrial types of oil burners and are used with live steam and preheated oil for atomization. They may involve large storage tanks under and aboveground. Fuel oils 2 and 3 are for domestic use. Tanks for 550 gal are permitted indoors.

Solvent Recovery. Solvent-recovery processes involving materials in the liquid or vapor state are unusually hazardous and should be isolated in detached buildings. The recovery of the solvent from the vapor may be accomplished in three general ways.

1. Adsorption by materials such as activated carbon or silica gel, vaporization by means of steam, followed by condensation, by cooling, with subsequent recovery of the solvent by decanting the separated layers of condensed steam and solvent.

2. Dissolving the vapors in suitable solvents in scrubbing equipment followed by separation in distillation apparatus.

3. When vapors are in high concentration, they may be recovered by cooling either with water or refrigeration equipment or by first compressing and later cooling. In either case the solvent is obtained directly without further separation or purification by distillation.

Equipment. Although differing considerably in detail, solvent-recovery equipment may be classified into two general groups according to fire hazard.

1. The adsorption and scrubbing types, which involve vapor mixtures of low concentration, generally below the lower explosion limits.

2. The direct-condensation types, which involve much richer mixtures, so that the atmosphere is within or must pass through the explosive range whenever operations are started or stopped.

Low-vapor-concentration Methods. In the first group, particularly the adsorption method, the higher the vapor concentration, the lower the capital and operating costs and the more efficient the recovery. This involves a small margin of safety, and such operations can be permitted with every reasonable safeguard against explosion, including ample explosion vents, and should be under continuous supervision and control of vapor conditions by a reliable vapor indicator.

High-vapor-concentration Methods. Solvent recovery from concentrated vapor mixtures by cooling or by compression and cooling is especially hazardous because explosive conditions are encountered whenever the equipment is started, when it is shut down for repairs or for any other reason, and whenever air enters owing to some defect or breakdown in the equipment. Inert gas is commonly used to keep air out of the equipment.

Distillation. Separation or purification of the recovered vapors by distillation is generally accomplished by means of closed stills heated by steam and operated at low pressure or under a vacuum. The vapor is usually recovered in a water-cooled condenser and conducted directly by gravity to the solvent storage tanks. The danger from distillation equipment is mostly from possible explosion when the equipment is opened for repairs or inspection when it contains vapors mixed with air. Other dangers are from the bursting of the vaporizing tank owing to neglect or failure of auxiliary devices and from liquid escaping from glass gauges. Solvent stills should be equipped with relief valves set well within safe working pressure limits and piped outdoors. All solvent-recovery systems should be isolated and ventilated; all possible sources of ignition should be removed; vaporproof globes should be installed on all lights; and nonferrous metals and tools should be used around the equipment.

Dip Tanks. Painting or coating by dipping objects in tanks of paint, varnishes, or lacquers involves the hazard of exposed surfaces of flammable liquid and the evaporation of the solvents. This also applies to quenching tanks. Small dip tanks can be protected by automatic covers held open by fusible links or thermostats. Covers are not effective where they interfere with stock or stock conveyors. Drainboards should be treated as part of the dip-tank operation. Overflow pipes of such capacity as to drain the liquid without clogging should be provided on all dip tanks. Dipping operations in connection with large units and involving drying ovens are especially hazardous operations and call for special treatment. Fire protection for dip tanks and drainboards can be either foam, CO_2 gas, water spray, or automatic sprinklers. Water spray of high velocity will cool but will also emulsify the oil-reducing salvage. All extinguishing agents can be applied automatically. Quenching oils have a flash point of approximately 365°F. These oils have a good salvage value if allowed to settle for 24 or 36 hr after a fire.

Spray Booths. Spraying operations are hazardous because of the volume and concentration of the work and because spraying produces a residue of flammable character. The solvents used generally are highly flammable unless the spraying medium is a paint not using those solvents of greater volatility than kerosene. Spray operations vary in size from one booth to large assemblies which present special hazard conditions. A single booth may become dangerous because of its use in congested areas or hazardous locations other than that created by the booth itself.

The necessity of elaborate ventilating systems and special lighting arrangements add to the hazard of spraying. A separate exhaust duct should be provided for each booth, leading by the shortest route to the outside of the building. If more than one booth exhaust is connected to a manifold exhaust, this manifold should be treated as part of the entire installation. Exhaust fans should be of the nonsparking (nonferrous) type. Wooden fan blades can be used in emergencies. Motors should be located outside the booth, with the fan drive by shaft or enclosed belt or chain extending through the wall of the booth. Explosionproof motors are no exception to this rule, as they may become coated with spray residue, reducing the cooling effect. Lamps should be of the vaporproof or explosionproof type and not placed where they can be contacted by the spray or broken. Booths should be cleaned frequently, the scraping being done with nonferrous tools, or cleaned with a solvent of no greater flammability than kerosene. Most spray residue, other than ordinary paints, if not thoroughly removed from the booth and if not disposed of, is subject to spontaneous ignition. The use of baffles in spray booths calls for frequent change and cleaning. Water-type spray booths, where flammable liquid spray passes through water to collect residue, should be treated as above.

Location. Spraying operations should not be carried on above large or susceptible stock piles or equipment. Large quantities of water are liable to be used in extinguishment of fire, and such materials would be greatly damaged if floors were not watertight. Spraying assemblies and the rooms in which they are located should be protected by automatic sprinklers.

Transportation. The Interstate Commerce Commission (ICC) has control over shipments of flammable liquids, gases, and explosives. The ICC issues a standard table showing substances that cannot be shipped together. The character of substances is designated by a system of labels as follows:

Red—Flammable liquids with flash points of 80°F or lower
Yellow—Flammable solids (except explosives) and oxidizing materials
White—Corrosive liquids (mineral acids)
Green—Nonflammable compressed gases
Explosives—Marked Explosives

This color scheme is also used within the industry to designate piping conveying hazardous liquids.

Tank-car Shipments. Tank-car shipments are classified in accordance with the vapor pressure of the liquid by the Association of American Railroads, with different tank construction for each class. Vapor pressure is determined by the ASTM, using the Reid Method.

Table 5-30. Reid's Specifications for Vapor Pressure

(Class 1—less than 16 lb vapor pressure, psi, at absolute 100°F. Class 2—not exceeding 40 lb vapor pressure)

Substance	Vapor pressure	Classification
Acetone	7.6	Class 1
Benzene, 60°Bé	0.5	Class 1
55°Bé	1.3	Class 1
Benzol	3.2	Class 1
Carbon disulfide	11.1	Class 1
Casing-head gasoline	15–40	Class 2
Gasoline	9.5–13.5	Class 1
Ethyl ether	16.8	Class 2
Ethyl methyl ketone	3.5	Class 1
Methyl acetate	7.1	Class 1
Naphtha (petroleum), less than	0.5	Class 1
Naphtha (VMP), less than	1.0	Class 1
Methyl ether (Pressure above 40-lb limit for class 2)	Above 103 lb	
Petroleum ether	16–17	Class 2
Toluol (toluene)	1	Class 1

Flammable Liquid Storage Underground. A tight substantial tank is the first requirement in storing flammable liquids underground. Tanks should be thoroughly coated on the outside with a rust-resisting compound. To minimize the danger of leakage from tanks seeping into near-by cellars and lower-than-grade floors or basements, the distances apply as specified in the flammable-liquid ordinance of the NFPA (see Table 5-31).

Table 5-31. Maximum Capacity of Tanks

Location	Maximum allowable storage	
	Class 1, 2, 3, under 100°F flash point, gal	Class 3, above 100°F flash point, gal
If top of tank is above the lowest floor level of any building that is		
Less than 10 ft away	550	50,000
10 to 20 ft away	2,000	75,000
20 to 25 ft away	5,000	100,000
25 to 30 ft away	15,000	150,000
30 to 40 ft away	20,000	200,000
40 to 50 ft away	50,000	500,000
More than 50 ft away	Unlimited	Unlimited

Flammable Liquid Storage Aboveground. Distances between aboveground storage tanks should be equal to at least the diameter of the larger of the two tanks for tanks of over 100,000 gal capacity. For small tanks see Table 5-32. For outside storage, attention must be given to the slope of the terrain from the tank storage to buildings or merchandise stored in yards.

Table 5-32

Capacity of tank, gal	*Minimum distances between tanks, ft*
0– 18,000	3
18,001– 24,000	5
24,001– 48,000	10
48,001– 75,000	13
75,001–100,000	15

Dikes. Dikes around tanks should be large enough to hold the entire capacity of the tank. Vents of standard capacity and design and flame arresters should be standard equipment.

Standards Applying to Flammable Liquids. Standards concerning flammable liquid set forth by the NBFU are the following:

Dry cleaning
Dip tanks
Paint spraying
Discharging flammable liquids
Containers for storage and handling
Installation of oil burners
Pyroxylin-plastic storage
Pyroxylin-plastic manufacture
Motion-picture film
Photo X-ray film

The National Fire Protection Association publishes the following pamphlets applying to flammable liquids:

Preventing welding fires
Combustible anesthetics
Spray application of flammable finishes
Flammable liquids

Flammable Gases

The hazard of flammable gases is generally similar to that of flammable liquids as previously noted (see gas, natural and artificial). The hazard of gases is the possibility of their escape into the atmosphere to form explosive mixtures with air and possible ignition mediums. This is occasioned mostly by breaks or leaks in piping or containers or the escape of unburned gases in gas-burning appliances. Gases lighter than air present a less difficult problem in ventilation than those which are heavier than air. Gases are more or less toxic and present a health hazard which calls for the supplying of oxygen to relieve asphyxiation. All gases expand when heated or increase in pressure if in a closed container of any design. All equipment designed for the handling or storage of gases should be strong enough to withstand any pressure to which they may be subjected and so located or protected as to minimize the danger of mechanical injury.

Pressure Releases. All containers should be provided with some form of pressure relief to prevent rupture or explosion if exposed to heat, sun's rays, or fire. Pressure releases may take the form of a disk of metal designed to rupture at a given temperature or a fusible plug designed to melt at a given temperature.

NOTE: Scharffenburger Bung release for barrels and small containers.

In larger systems various forms of safety-relief valves are used, including thermostatic alarms. See NFPA *Quarterly*, October, 1943. The relief capacity must be equivalent to the vaporization rate or the volume increase.

The volume of a true gas at constant pressure is directly proportional to the absolute pressure, or at constant volume (as in closed containers) the absolute pressure is proportional to the absolute temperature. The expansion of an unconfined gas lessens the velocity of the gas molecule, releases the kinetic energy, and lowers the temperature of the gas. Compression produces the opposite effect.

Flame Arresters. Flame arresters are required on tank vent pipes to prevent flash backs into the tank when an explosive mixture is present. A wire screen of 40-mesh psi will prevent the passage of flame through small openings. Screens of 40 mesh have a free area of about 35 per cent of their total area. This must be allowed for in the design of vents. Screens have a tendency to clog because of dirt and oily residue. Arresters constructed of banks of parallel metal plates or tubes, having a large surface of metal to dissipate heat, are more effective with openings larger than screens and are less liable to clog.

NOTE: Flame arresters are not required by NFPA.

Atmospheres in Tanks. Tests of atmospheres in tanks may be made by chemical methods or by flammable-vapor indicators These indicators, which are useful not only in tanks but in manholes or in locations where the presence of flammable vapors may be suspected, measure the amount of flammable vapor present and are generally calibrated in terms of per cent of low explosion limits They give different readings for different gases and therefore should be used only within the limits of their suitability. Carbon bisulfide gives low readings and requires special calibration Flammable-vapor indicators must be carefully operated and maintained and should be checked and calibrated periodically to assure correct readings.

A common type of indicator operates by combustion within the apparatus of a sample of the atmosphere in a small enclosure in the presence of an electrically heated resistance element The change in resistance due to the heat of combustion determined by a thermocouple or a Wheatstone bridge is measured to indicate the relative amount of flammable vapor present In another type the amount of vapor is determined by the thermal conductivity of the mixture electrically measured Instruments available for determining the percentage of flammable vapors in the atmosphere are Factory Mutual flammable-vapor indicator, Gasoline vapor indicator, Hall (devised by H H Hall of Standard Oil Company of California), the UCC combustible-gas indicator (Union Carbide & Carbon Company) and the U S Bureau of Mines indicator[9]

Table 5-33. Dangerous Gases Found in Sewers and Manholes*

Gases	Properties	Source
Ammonia	Poisonous	Refrigerator plants
Benzol	Poisonous explosive	Automobiles tanks
Carbon dioxide	Suffocating	Combustion decomposition
Carbon monoxide	Poisonous explosive	Fuel gas flue gas automobile
Ethane	Explosive	Natural gas mfrd fuel gas
Gasoline	Poisonous explosive	Automobiles tanks
Hydrogen	Explosive	Artificial fuel gas electrolysis of water
Hydrogen sulfide	Poisonous	Coal gas decomposition
Methane	Explosive	Nat gas and mfrd gas decomposition
Natural gas	Suffocating	Natural gas mains
Nitrogen	Suffocating	Combustion decomposition
Phosgene	Poisonous flammable	Decomposition combustion
Sulfur dioxide	Poisonous	Burning insulation
Unsaturated hydrocarbons	Explosive	Manufactured fuel gas

* *NFPA Quarterly* April 1930

Flammable gases may be produced in

Oil burners
Industrial furnaces
Range oil burners
Oil-burning stoves
Gasoline stoves
Dry cleaning
Finishing processes
Gasoline engines
Coating and spreading processes
Reclaiming
Solvent recovery
Degreasing
Extraction processes
Rubber cement and varnish mixing
Impregnating under pressure

Manufactured gas contains carbon monoxide Natural gas does not ordinarily contain carbon monoxide

Acetylene Acetylene has a calorific value in Btus of 20,700 per lb

The quantity of calcium carbide[10] permitted to be stored inside a building is 600 lb In a one-story building outside the main buildings, 5,000 lb may be stored

Acetylene may react with copper to produce

Table 5-34. Commercial Gases

Gas	*Calorific value, Btu per cubic foot*
Natural gas	710–2250
Gas oil	510– 800
Coal gas	450– 670
Producer gas	100– 180
Water gas	300– 670

an explosive compound; therefore, iron or steel piping should be used on all installations. Acetylene has the widest explosive range of any gas used in industry, from 2.5 to 82 per cent. Acetylene can explode by decomposition without the presence of air at pressures above 15 psi. The calcium-carbide-to-water type of acetylene-gas generating systems is the best type. Calcium carbide residue must be disposed of in a safe place; its reclamation is said to be a practical process. Calcium carbide fires can be extinguished by CO_2, but the carbide must be removed to avoid reignition due to remaining moisture.

Hydrogen. Hydrogen has a calorific value of 61,060 Btu per lb. Its ignition temperature is from 982 to 1000°F. All piping used in installations where hydrogen is present must be gastight to prevent leakage. Hydrogen evolved from zinc-coating processes can be a source of fire. Battery charging causes the dissociation of hydrogen. Therefore it should not be done within 10 ft of an open flame.

Oxygen. Oxygen under pressure should not be brought in contact with oil, oil lubricants, or greases.

Liquid Petroleum Gases. Liquid petroleum gases have a calorific value of 20,000 Btu per lb. Their thermal expansion is 9 per cent volume increase per 100°F. Butane and propane are heavier than air. Cylinders of such gases aboveground must be kept from freezing.

Nitrocellulose Film. Nitrocellulose film consists of such substances as celluloid, pyralin, fiberloid, xylonite, viscoloid, nixonite, and pyroxylin plastics. The difference between these substances is their nitrogen content, which ranges from 10.5 to 13.5 per cent. Tests made on nitrocellulose film for X-ray purposes, showed gases produced by decomposition to be as shown in Table 5-35.

Table 5-35*

	Per cent by volume
Nitrogen peroxide	6.9-8.9
Nitric oxide	1.4-8.2
Carbon monoxide	47.4-59.1
Carbon dioxide	21.3-24.5
Oxygen	None
Hydrogen	0.9-3.2
Methane	1.0-2.7

* Chemical Warfare Service, United States Army, after Cleveland Clinic Fire, 1929

Note: At high temperatures 1,000 lb = 8,500 cu ft of gas.

Common Refrigerants. Table 5-36 lists most of the substances used as refrigerants and gives data on their flammable and toxic properties. For purposes of comparison, similar data are given on carbon tetrachloride, a commonly used extinguishing agent.

These data are taken from Underwriters' Laboratories Report MH2375 on the Comparative Life, Fire, and Explosion Hazards of Common Refrigerants and from the supplementary Report MH 2630 on dichloromonofluoromethane. For more complete information, see the original reports, which may be purchased from Kinetic Chemicals, Inc., Wilmington, Delaware, for whom they were made.

Other information of interest is given in the following paragraphs, also taken largely from Underwriters' Laboratories Report MH2375.

Ammonia is an irritant gas having a sharp, penetrating odor which gives adequate warning of its presence.

Butane, ethane, and propane have practically no odor and do not give warning of their presence in air in dangerous concentrations. Butane and propane are anaesthetics.

Carbon dioxide is odorless, but its physiological effects when breathed in mild or moderate concentrations serve in a measure as a warning of its presence.

Dichloroethylene is an anaesthetic gas having an odor that resembles chloroform. It does not give adequate warning of danger.

Dichlorodifluoromethane (F-12, Freon) has an odor resembling that of chloroform.

Ethyl bromide does not give adequate warning of its presence in air in dangerous concentrations.

Ethyl chloride is an anaesthetic that gives some warning of its presence, but a person might tolerate exposures to it in dangerous concentrations until helpless.

Methyl bromide has an odor, but it is not distinctly unpleasant and does not give definite warning of its presence in dangerous concentrations.

Methyl chloride is an anaesthetic that does not give definite warning of its presence in dangerous concentrations, but when used as a refrigerant it usually contains substances that give adequate warning

Table 5-36

Name of substance	Flammability	Toxicity classification group No.*

Propane	†	5
Sulfur dioxide	Nonflammable	1

* Sulfur dioxide (group 1) has a toxicity that is comparatively high (concentrations of the order of $\frac{1}{2}$ to 1 per cent for duration of exposure of the order of 5 min. will cause death or serious injury). Substances in group 2 are less toxic, in group 3 still less toxic, etc. An idea of the danger from refrigerants in group 5 may be obtained from the fact that carbon dioxide, which is in group 5, has been extensively used in industry and as a fire extinguishing agent with a record that indicates that its actual life hazard under ordinary conditions is small.

† An explosion of ammonia air mixtures of high concentration (16 to 26 per cent ammonia by volume) is possible, but usually under practical conditions combustion of ammonia is slow and weak.

‡ In a class with illuminating gas and the vapor of gasoline.

§ Moderately flammable; much less hazardous than gasoline but more hazardous than ammonia.

‖ These refrigerants are decomposed by contact with flame or very hot surfaces, producing fumes which are toxic and irritating but which give definite warning of their presence before dangerous concentrations are reached.

¶ Fire hazard is very small from a practical standpoint.

Methylene chloride (dichloromethane or Carrene No. 1) has a physiological action which gives some warning of its presence.

Methyl formate is an irritant and gives definite warning of its presence.

Sulfur dioxide is exceedingly irritating to the eyes and throat even in very low concentrations, so that persons breathing it make every effort to escape before serious injury occurs.

In considering flammable gases and vapors, one of the important points is whether they are heavier or lighter than air, and if so, how much heavier or lighter. Table 5-37 gives in one column the vapor density relative to air under the same conditions of temperature and pressure. The vapor density of acetone, for example, is given as 2.0, which means that acetone vapors are twice as heavy as air. That of methane is given as 0.55, which means that methane gas is about one-half as heavy as air.

Gas escaping from a pipe or tank and vapor given off by a liquid, such as gasoline, tend to diffuse in the air in about the same way that a drop of ink in a glass of water diffuses through the water so that all the water becomes colored. Some vapors diffuse very slowly, while others diffuse rapidly. It will be noted from Table 5-37 that ammonia gas diffuses in air about twice as fast as carbon bisulfide and that the lighter the gas, the faster it diffuses. Hydrogen, the lightest of all gases, diffuses about $3\frac{1}{2}$ times as fast as carbon monoxide.

It has been found that flammable gases and vapors will burn or explode only when the proportion of gas or vapor to air is within certain limits, known as the "flammable" or "explosive" limits. Looking, for example, at the figures in Table 5-37 for gasoline, it is seen that gasoline vapor will burn or explode when the proportion of vapor to air is between 1.4 and 6 per cent. This means that, if the proportion is less than 1.4 parts of vapor to 98.6 parts of air or is richer than 6 parts of vapor to 94 parts of air, there can be no burning or explosion. However, with mixtures too

Table 5-37. Some Characteristics of Certain Flammable Gases and Vapors and of Common Refrigerants*

Gas or vapor	Vapor density (air = 1)	Rate of diffusion (air = 1)	Explosive limits in air by volume	
			Lower	Upper
Acetic acid	2.1	0.69	4.0

* NBFU *Bull* 52

† Practically nonflammable at ordinary temperatures

rich to burn there is a possibility of some portion of the mixture being diluted with additional air so as to bring it within the explosive limits

At or near the explosive limits the explosion will be mild or there will be quiet burning, but between these limits explosions of varying degrees of violence will occur For gasoline the most violent explosion will occur with a mixture of about 2 25 per cent In general, it may be said that the wider the range between the lower and upper explosive limits the greater the hazard of explosion Vapors with a lower limit below 2 per cent have also been shown to have a high hazard even though they have a relatively narrow range

A vapor such as gasoline that is heavier than air tends to settle in low spots and, although gradually mixing with the air, if not affected by drafts will remain in such low spots for a considerable time. Such heavy vapors will flow in a stream along a floor and down stairs or along the ground and, if reaching a source of ignition, will propagate flame back to the source even from considerable distances. In one fire, the vapor was reported to have ignited in this way from a point 162 ft from the source. The vapor in such low spots or in such a stream will frequently be too rich to explode, but even where this is true there will be, above and around the rich mixture, a mixture that is in the explosive range, and as the vapor diffuses a greater amount will come within the explosive range. If ignition is delayed until the vapor is diffused sufficiently to get a flammable mixture over a considerable area, ignition will then result in a serious explosion. The higher the relative rate of diffusion, the more quickly will the scene be set for such an explosion; and the larger the space that contains such a flammable mixture, the more violent will be the explosion.

A gas such as illuminating gas that is lighter than air tends to rise but diffuses fairly rapidly so that in a building the gas would be soon distributed throughout the room or space in which it is discharged. A small gas leak in a room with some ventilation might not be sufficient to produce an explosive mixture, but if enough is liberated, an explosive mixture will be formed over a large area very quickly.

If the temperature of a gas or vapor is higher than that of the air in which it is liberated, the gas or vapor is in effect made lighter and will act accordingly.

Need for Gas Masks in Fighting Fires, Their Value and Limitations[11]

Noxious and poisonous gases of various kinds are encountered in fighting fires. The most common of these is carbon monoxide, an odorless product of combustion which is present in varying degrees depending upon the material and the location of the fire. Cellar and basement fires and those involving oil or material in a compact form are producers of large quantities of carbon monoxide, and as such fires can seldom be ventilated, it is obvious that some form of protection must be provided against these and other gases. One source of other gases is mechanical-refrigeration equipment which is now found in many stores and restaurants and in a great many apartment houses and residences. Many systems contain ammonia or sulfur dioxide, both toxic refrigerants. Although these, through their distinctive odor, give adequate warning of their presence before dangerous concentrations are reached, fire service may require that entrance be made.

Because of the irritant and poisonous nature of the gases occurring during a fire and the further probability of other gases being liberated, no modern fire department can be considered as being properly equipped if it does not have sufficient protective equipment for its men.

Subsequent to the development of gas masks for war work, there has been material improvement in the canister type of mask, which consists of a rubber face covering and a canister so arranged that all the air breathed comes through the canister which contains absorbing substances for removing poisonous gases. Type N, as approved by the U.S. Bureau of Mines, gives protection against all the poisonous gases that firemen are likely to encounter, including carbon monoxide. This mask is sometimes called an "all-service" mask.

All canister-type masks have two important limitations which must be well understood if they are to be used with safety. (1) They are utterly useless in atmospheres deficient in oxygen. This condition is found in tanks that have held readily volatile material, such as gasoline, in sewers and manholes in which gases may accumulate and there is very little ventilation, or where carbon dioxide or other gas has seriously diluted the oxygen of the air. (2) If there are high concentrations of gases, the materials in the canisters are rapidly used up, and considerable heat is developed.

For those infrequent occurrences where a gas mask is not suitable, an oxygen breathing apparatus must be used. This is a self-contained breathing apparatus which supplies oxygen from a small cylinder and which purifies the air breathed.

Modern fire-department practice recognizes that the use of gas masks and oxygen breathing apparatus is an essential feature of effective fire fighting. Its value in preventing injury or death to firemen is primary, but material reduction in fire loss is also possible because of the ability to penetrate to the seat of the fire. Less ventilation of the structure is required where they are brought into use, and rescue work can be performed with masks where otherwise there might be loss of life.

For effective operation two gas masks should be provided for each company, and the members trained in their use. In the larger departments these would be supplemented by oxygen breathing apparatus, carried either by ladder companies or on special apparatus.

The effective use of gas masks and helmets requires training and practice. The men must know how to use them as well as when not to use a gas mask but to use oxygen breathing apparatus.

Inert Gas Systems

Fire and explosion can be prevented by the creation of an atmosphere that will not support combustion by reducing the oxygen content of the normal air which contains 21 per cent oxygen. Any inert gas can be used for this purpose, but consideration of availability and cost limits such use to carbon dioxide, nitrogen, and mixtures of carbon dioxide and nitrogen produced by combustion, as in flue gas, internal-combustion-engine exhausts, and other inert-gas producers.

Table 5-38. Dilution of Atmosphere with Carbon Dioxide*

Substance	*Maximum permissible oxygen, per cent*
Pittsburgh coal dust	16
Pyrethreum flower dust	15.5
Acetone	15
Cotton lint or dust in air	15
Ethyl alcohol	15
Gasoline vapor	15
Methane	14.5
Cork dust	14.1
Wheat, corn, or oat elevator dust	14
Ground-oat hulls	13.7
Ether	13
Hard-rubber dust	13
Wheat starch	12
White dextrine	12
Sulfur	11
Ethylene	10
Carbon disulfide	8
Cotton in bulk to prevent smouldering and reignition	8
Jute	8
Carbon monoxide	5.9
Hydrogen	5.9

Note: If nitrogen is used alone, these percentages can be lowered 10 per cent.
* NFPA Standard.

Extinguishment of Dust Fires. The introduction of inert gas into grinding equipment and transport systems reduces the normal oxygen content to a point at which an explosion cannot occur. A reduction of oxygen to less than 15 per cent is necessary to prevent explosions of carbonaceous dusts and to less than 10 per cent to prevent smouldering fires.[12]

Carbon dioxide, carbon tetrachloride, and water should not be used on aluminum fires. During fire-fighting operations, caution should be exercised in use of heavy streams, as clouds of dust may be set up causing explosions.

DUSTS

Dusts have many states of division which range from particle sizes, which will hardly float in air, to the finely divided state known as "flowers," which will pass through a screen of 400 mesh per sq in. The finer the state of division and the more rapidly and violently the dust is formed, the greater the possibility of a powerful explosion.

Flammability of Organic Dust. The chief reason for the flammability of dust, according to Von Schwartz,[13] is the occlusion of atmospheric air or other gases by the minute particles of dust which act like an absorbent sponge. Laden with gas or vapor, these dust particles form a highly flammable material which ignites with

Table 5-39. Effects of Inert Gases and Low Oxygen Content on Explosibility*

Combustible gas or vapor	Formulas	Per cent of oxygen by volume below which explosions are impossible, at ordinary temperature and pressure			Volumes of inert gas necessary to render one volume of combustible nonexplosive under all conditions of dilution, with air at ordinary temperature and pressure		
		Nitrogen	CO_2	Flue gas	Nitrogen	CO_2	Flue gas
Hydrogen	H.	5.0	5.9	5.1	16.5	10.2	11.0
Carbon monoxide	CO	5.6	5.9	5.6	4.1	2.2	2.4

* Jones and Perrott U.S. Bureau of Mines

NOTE. The standards for reference from the National Board of Fire Underwriters are the following:
50 Acetylene Equipment
53. Gasoline Vapor Machines
54. Piping and Fittings for City Gas
51 Gas Systems for Welding and Cutting
58 Liquid Petroleum Gases

The standards set up by Pamphlets from the Underwriter's Laboratories include Spontaneous Ignition and Prevention, List of Approved Gas and Oil Appliances

great rapidity forming an atmosphere of hydrocarbons and carbon monoxide that furnishes with the remaining air an explosive mixture, which is ignited and exploded by the flame of the burning dusts.

Consequently, dust explosions occur in two stages—the ignition of the dust particles and the explosion of the resulting and readily formed gaseous products. These phases follow in such rapid succession as to form one operation. Both organic and metallic dusts become far more explosive when mixed with substances liberating oxygen.*

The formation of dust is always accompanied by a liberation of heat (in contrast to gases), and if this heat is confined and is not dissipated, the temperature may reach the ignition point of the material of which the dust is formed.

Dust explosions from shock, percussion, or friction, unaccompanied by the production of sparks, cannot take place.

Dust-explosion Pressures. Tests were made by the U.S. Department of Agriculture to find out dust explosion pressures. The quantity of dust used in these tests was 5,000 mg per liter which corresponds to 500 oz per cu ft. The results of these tests are shown in Table 5-40.

Table 5-40. Dust Explosion Pressures

Type of dust	*Explosive pressure, psi*
Grain dust	37–46
Starches	38–47
Sugars	22–45
Woods	36–44
Sulfur and lime sulfur	31–32
Hard rubber	36–37
Cork	38–40
Metals	3–49
Fertilizers	34–51
Milk powders	31–42
Cocoa	23
Flours	26–42
Meals	21–42
Spices	28–43
Drugs	22–43
Rosins, waxes, soaps	31–42
Coal, carbons	24–48

Metal Powders. Ignitions and explosions of metal powder may occur under the same conditions required to produce explosions of carbonaceous dusts. Metal powder or dust in a quiescent state may be ignited by a spark or the application of sufficient heat to raise the temperature to the ignition point. If undisturbed, the powder will burn quietly, and the fire will spread at a rate depending to some extent on the availability of oxygen to complete combustion. The same sources of ignition are generally capable of starting a dust explosion, but to obtain such a reaction, the powder must be scattered in the air in the proper proportions. It is generally conceded that the finer the dust, the more flammable it is, the smaller the flame or spark required to ignite it, and the longer it remains in suspension in the air where it can be most readily ignited.

---

* This is confirmed by Dr. R. V. Wheeler, of the British Coal Mines Committee, Eskmeals. England writing on starch

The most widely used methods of producing metal powders is the milling process, which includes the production of powder in stamps, crushers, rolls, ball, bar, and disk mills, attrition mills, eddy mills, and jet pulverizers. In the last two types of equipment, air currents are employed in the grinding operation.

The Hall process provides for the mixing of a liquid with the material entering the mill to form a slurry or paste and thus eliminate dust ignitions within the mill. If it is necessary to dry or further condition the product after milling, the explosion hazard may be present to some extent.

The Hametag process employs a stream of inert gas to carry the powder away from the mill as it is produced. The purpose of this is to prevent both oxidation and explosions.

It has been estimated that 1 lb of some of the finest metal powders has an expanded surface of about 220,000 sq in.

Screening and packaging operations constitute dust ignition hazards similar to those in other dusty industries employing the same type of equipment, such as screens, bolters, sifters, reels, and dust collectors.

Experiments have shown that flame propagation occurs most readily in dust clouds in which the particles are small, of uniform size, and uniformly distributed. Under such conditions flame velocities of 2,000 to 3,300 fps have been measured, with indications of much higher velocities, even up to 6,000 fps. The ignition temperatures of the metal powders while in a quiescent state were found to range from 410 to 1742°F, 12 out of 16 igniting at temperatures below 932°F. Ignition of a dust cloud usually requires a higher temperature or a larger source of ignition than is necessary to cause inflammation of a quiescent layer of the same material. In a series of tests, it was found that the temperature necessary for ignition of a dust cloud generally ranged from 599 to 1652°F. Pressures produced in metal-dust explosions range from 20 to 72 psi.

Venting by explosion vents or hinged windows in buildings of substantial construction has been installed at the ratio of 1 sq ft of vent to each 25 cu ft of room volume.

In recent tests to determine the efficiency of inert gases to reduce the oxygen content of atmosphere, such as CO_2 and nitrogen used in preventing ignition of carbonaceous dusts or flammable gases, it was found that some of the metal powders could be ignited by sparks in pure carbon dioxide, and for a few powders pure nitrogen provides only a narrow margin of safety against ignition. Magnesium will burn in nitrogen to form magnesium nitride. Helium and argon were found to be more effective than CO_2 or nitrogen. The results of these tests indicate that dependence for protection against dust ignitions in metal powders of atmospheres with reduced oxygen content by the introduction of inert gases should not be accepted unless laboratory tests have demonstrated their effectiveness.

The following recommendations for the prevention of ignition and explosion are not conclusive owing to the lack of factual knowledge relating to metal dust, but some degree of protection can be obtained by their observance:

1. Hazardous processes should be segregated in small detached buildings or separate units with fire walls and fire doors.
2. Vents such as light roofs or large hinged windows should be provided, designed in the proper proportion to release explosion pressure without structural damage.
3. Equipment should be maintained as nearly dust-tight as possible and frequent cleaning should be provided for to prevent accumulation of dust at points where it may be thrown into suspension to form a cloud.
4. All possible sources of ignition should be eliminated by using: (*a*) electrical equipment approved for such locations; (*b*) indirect heating to prevent dust from collecting on heated surfaces; (*c*) ground connections on all equipment to remove static electricity.
5. Inert gas should be used to prevent dust ignitions wherever feasible.
6. Conveying, collecting, processing, and cleaning equipment designed to perform

Table 5-41. Ignition Temperature and Explosibility of Metal Powders with Comparable Data for Several Carbonaceous Dusts

Substance	Ignition temp., °F, of		Maximum pressure, psi	Pressure rise, psi/sec

* Temperature rise in powder at 1292°. No other evidence of ignition up to 1652°.

† This extremely high value should be accepted with caution because of possible errors in determining maximum slope of pressure-time curves.

‡ This powder not ignited by standard spark in Hartman apparatus. Ignition produced by pallet of magnesium and barium peroxide.

§ Reaction noted at 1247°. No other evidence of ignition.

‖ Powder oxidized rapidly at 518°. No other evidence of ignition.

¶ Dust cloud ignited when blown through furnace at room temperature.

Note: In comparing the ignition temperatures for a quiescent powder and a dust cloud, it will be noted that there is no consistent relation between the two figures. The only explanation that can be offered at the present time is that in some cases prolonged heating of the powders on a hot surface produces a condition that permits the ignition at a lower temperature than is otherwise possible. On the other hand, in a moving dust cloud, the powder may come in contact with the heated surface for only a short period. Also, the shape of the powder permits the exposure of thin edges when the dust is in suspension, and thin edges or fine projections can be ignited at a temperature somewhat lower than that required to ignite the product when the particles are packed together.[14]

Bronze dust, if free from aluminum, is practically harmless. Sulfur dust or vapor forms explosive mixtures with air and is hazardous in contact with oxidizing materials. It should be isolated from chlorates and nitrates. [Gunpowder is formed from sulfur, saltpeter, and charcoal (carbon)]. Water spray or fog is effective on sulfur fires.

Table 5-42. Explosion Pressures of Coal, 24 to 48 Psi

Type of coal	Specific gravity	Density	Btu
Anthracite	1.4–1.8	97

Bituminous (sub)	....	..	8,690–11,140

its function with no possibility of producing metallic sparks or frictional heat capable of igniting the powder being handled should be employed.

7. Fire-fighting facilities of the type found best adapted to the particular needs of the plant should be provided.

Water and ordinary types of fire extinguishers are not effective on metal-powder fires, and in many cases their use will intensify the fire.

---

[1] Table is based on tests made in dust-explosion laboratory of Bureau of Mines, U.S. Department of Agriculture, Pittsburgh, Pa. (see Bureau of Mines *Report of Investigations No.* 3751).

[2] The powders are arranged approximately in order of decreasing dust-explosion hazard. All tests were made on minus 200-mesh dusts.

[3] 1 joule = 1 watt-sec = 0.00095 Btu. Dust clouds are ignited by static sparks from condenser discharge.

[4] Data on pressures and rate of pressure rise are for a dust concentration of 0.500 oz/cu ft.

[5] Samples included phenol formaldehyde, phenol-anhydro-formaldehyde aniline, and phenol furfural.

[6] Samples included cellulose acetate, cellulose acetate butyrate, and ethyl cellulose.

[7] Samples included polyvinyl acetate and vinyl chloride acetate copolymers.

[8] Ingredients of synthetic resins.

[9] Fillers for molding compounds.

Coal Pulverizing.[15] The chemical composition of coal varies greatly as does its physical structure, and both features contribute to the possibility of spontaneous ignition, the presence of sulfur, in the form of pyrites or marcasite, free gases, oxygen, and moisture being factors that contribute to this possibility also

Coal should not be stored in temperatures in excess of 75 to 80°F and should be kept free from combustible material Piles should be tested for heating at regular intervals Coal being a product of carbonaceous vegetable matter when pulverized creates a severe dust-explosion hazard, and all precautions suggested for explosive dusts should apply to coal particularly

PLASTICS

The relative combustibility of any particular plastic composition depends not only on the synthetic resin used but also on the plasticizers, fillers and pigments incorporated in it In a preliminary test, the various types of plastics subjected to test flame (yellow gas flame) were found to fall into three groups (see Table 5-43)

Group 1 Those plastics which are ignited by the test flame in approximately the same time and burn at about the same rate as cellulose acetate

Group 2 Those plastics burning with a feeble flame, which is extinguished by a slight draft and which may or may not propagate away from the point of ignition

Group 3—Those plastics which burn only during the application of the test flame

CAUSES OF FIRE

According to the latest statistics the classified causes of fires are as shown in Table 5-46

The per cents in Table 5-46 are for reported fires where the cause is ascertainable and do not represent either the total number of fires or the total property loss in the United States Excluded are all unreported losses as well as fires resulting from unknown causes It is estimated that the aggregate property loss in the United States during a decade was in excess of 3 billion dollars The causes of fire in productive industry of which there is definite knowledge are those taken from the enumerated fire losses where the cause is given, and the collection of these known causes is of primary importance

Electrical Fires. Some of the causes of electrical fires are arcing, sparking, overheating, switchboards, transformers, generators, motors, wiring, switches, lightning arresters, switchboxes, and panel boxes.

The National Electrical Code is the governing standard for all electrical installations in the United States. This code differs from most standards as it is unquestioned in its authority on the subject because of its wide use and approval by the electrical industries and engineering bodies.

Electricity passing over a circuit generates heat. This heat is generated in direct proportion to the resistance of the conductor and to the square of the current. Resistance of a conductor varies with its length. Double the length, and the resistance is doubled; treble the length, and the resistance is trebled. Resistance varies inversely with the cross-sectional area of a conductor. Doubling the cross-sectional area reduces the resistance to one-half. As the temperature rises, the resistance rises, except in carbon where the resistance falls as the temperature rises. The sizes of wires or conductors are expressed in the Brown and Sharpe Gauge "B-S," the smaller numbers indicating the larger wires.

Arcing. Arcing is caused by the interruption of the current, its intensity depending upon the amount of current and voltage. The arc temperatures can be very high, and if the arc comes in contact with combustible material, fire will ensue. To eliminate the possibility of arcing, all connecting joints and tie-ins must be made secure, and the possibility of exposed conductors (wires) should be avoided (see Motors). Ends of conduit should be properly nippled to avoid rough edges. There should also be proper insulation where conductors pass through partitions or are held on supports, particularly metal supports.

Sparking. Sparking may occur if conductors come in contact with metal, such as the conduit itself, the metal used in the insulation of the conductor, metallic supports, nails, or junction boxes.

Overheating. Overheating is usually caused by overloading the circuit. The National Electrical Code limits the current a conductor shall carry and therefore the amount of heat generated. The resistance of conductors depends upon four factors:

1. Kind of material
2. Length
3. Cross-sectional area
4. Temperature

Taking the resistance of silver, the best electrical conductor, at 1 ohm, the resistances of several other materials are expressed in Table 5-47

Table 5-47

Material	Ohms	Insulators	Billion billion ohms
Copper	1.1	Bakelite	0.031
Aluminum	1.8	Glass	20
Iron	6.5	Mica	30
Platinum	7.0	Amber	3,300
German silver (white copper)	18	Sulfur	10,000
Mercury	60	Hard rubber	100,000
Nichrome	70		
Carbon	2,300		

Switchboards. Switchboards should be examined for defects such as loose connections, lack of cleanliness, and freedom from combustible material. This also applies to panel boards. The use of marble or slate is not recommended because of the presence of iron in these materials. Ebonized asbestos or mica is preferable. Protection for over and under 600 v should follow National Electrical Code. Shunts or tie-ins on current, for purposes other than switchboard design, should be avoided. Features such as overloaded relays, lightning arresters, grounding, bus bars, and wiring should be constantly examined for defects.

Fire Streams and High-tension Electric Lines.[17] In this day of high-voltage lines and equipment, it is pertinent for every plant manager to have some knowledge of the danger involved when a fire occurs in electrical equipment or near electrical lines.

Numerous tests have been conducted on this question, and from these tests certain facts have been deduced. These are as follows:

A stream of water will carry current back to the nozzle, and this current may be sufficient to injure or kill a person.

The amount of current will depend upon certain conditions:

1. The voltage of the wire or device
2. The distance from the nozzle to the electrically charged line or device
3. The size of the stream
4. Whether the stream is solid or broken
5. The purity of the water

For voltage up to 600, which is classed by the National Electrical Code as the limit of low potential, there is no danger unless the nozzle is brought within close distance to the line or device. This is particularly true where the fire fighter is wearing rubber boots. For ordinary lighting wires of 120 v to ground, the nozzle can be within a few inches of the charged line. For such voltages as are ordinarily used for trolley service, *i.e.*, 550 v, the nozzle can be handled without discomfort at a point 3 to 4 ft from the wire. However, it is well to consider every wire as a hot wire because of the possibility, at fires, of crosses with high-voltage wiring.

For voltages higher than 600, the distance that a nozzle should be kept from the electrical line or device would be as shown in Table 5-48.

Table 5-48 applies to fresh water; sea or salty water or the discharge from a soda-acid extinguisher may have such high conductivity that no rule can be applied as to the safe distance for a solid stream. If it becomes necessary to use water known to have high conductivity, the stream should be broken up.

Table 5-48

Voltage	Safe distance, $1\frac{1}{4}$-in. nozzle, ft	Safe distance, $1\frac{1}{2}$-in. nozzle, ft
1,100	6	9
2,200	11	16
3 300	15	22
5,500	18	27
6,600	19	29
11 000	20	30
22,000	25	33
33,000	30	40

The spraying of a stream may be an important factor in electrical fires, especially those involving transformers, oil-cooled switches, burning insulation, and wood or other combustible material near electrical equipment. Tests indicate that the spray or fog nozzle gives protection to the holder and also that such a nozzle is very efficient in cooling the equipment and extinguishing the fire.

Some recent installations of substations, transformers, and switch points on high-tension networks have been equipped with spray or fog nozzle systems with thermostatic systems to give automatic operation.

Table 5-49

Voltages	Distance, in	Voltages	Distance, in.
7,500	6	88 000	52
15,000	12	110,000	64
25,000	17	132 000	77
37 000	24	154 000	89
50,000	32	187 000	106
73,000	44	220,000	124

The data available indicate that for fog or spray nozzles the general clearances between any portion of the equipment and live electrical apparatus should not be less than as given in Table 5-49, and whenever possible these clearances should be increased.

Of the various hand extinguishers listed by Underwriters' Laboratories, Inc., the ones suitable for electrical (class C) fires are those which discharge carbon dioxide and those with a carbon-tetrachloride base. Dry-powder extinguishers are also suitable.

Foam, soda acid, and hand-pump tanks with antifreeze solutions are not suitable for electrical equipment.

Transformer. Transformer fires are due to possible arcs in the casing, which also can cause explosions. Gauges should be checked to see that the oil is maintained above the arcing point of the contacts. The oil should be tested to ascertain whether a lighter oil has been substituted for a high-test oil. Oil used in transformers is for the purpose of conducting heat to the casing and thence to the atmosphere.

Generators. The operation of generators is attended by many hazards, the worst of which is the breaking down of the windings which causes a disalignment of the stator and the disruption of the apparatus. Oil-feed systems for lubrication should be checked for leaks. The transit oil used in generators has a temperature limit of 360 to 470°F. Cooling systems are of the air-blast type—with hydrogen and CO_2 gas. The presence of hydrogen increases the fire hazard.

Motors.[18] There are several hazards attending motors. Motors are liable to produce arcs and sparks from lack of maintenance and from burnouts due to overloads and to low voltage at terminals. There is often improper overcurrent protection. Motors of over 5 hp should be equipped with an overcurrent device not greater than 25 per cent of the rating of the motor. Single phasing of multiphase motors is another hazard. Overcurrent protection should be installed to prevent single phasing which is generally caused by blowing of a fuse where a multiphase motor is protected by fuses. Motors should be protected from dampness, corrosion, accumulations of dust and lint, combustible material, and oily waste. The location of motors should be studied and frequently checked as they may be found in out-of-the-way places, such as small enclosures and closets, or they may be supported from ceilings or on top of elevator shafts.

Motors in hazardous locations should be of the explosionproof type but preferably located outside of rooms or enclosures where flammable gases are present. Shaft drives through walls can be installed to accomplish this. Explosionproof motors in spray-painting atmospheres should be cleaned frequently so that cooling effect is not retarded. All motors should be adequately grounded. Where starting devices are used on d-c current resistances, the starting device should be free of combustible material because of its overheating possibilities.

Wherever specific maintenance instructions for a particular motor are available, they should be followed closely. In the absence of such specific instructions, the following periodic checks should be made. These are based on average conditions with regard to severity of duty and dirtiness of location. The frequency of the inspections can be varied to suit actual plant conditions.

Weekly inspections and operations:

1. Examine commutator and brushes.
2. Check oil level in bearings but do not overlubricate.
3. See that oil rings turn with shaft, and note any excessive end play in shaft.
4. See that shaft is free of oil and grease from bearings.
5. Examine starter, switch, fuses, and other controls, as well as ground connections and motor loads.
6. Open-type motors in dusty locations should be blown out thoroughly.
7. Check air gap between rotor and stator. The difference in width of gap around circumference will indicate extent of wear on bearings. This check should be made weekly on motors operating with excessive belt tension; otherwise check air gap semiannually.
8. Start motor and see that it is brought up to speed in normal time.
9. Check motor and bearing temperature under actual load conditions by feeling for heat.

Semiannual inspections and operations:

1. Clean motor thoroughly, blowing out dirt from windings, and wipe commutator and brushes.
2. Inspect commutator clamping ring.
3. Check brushes and renew any that are more than half worn.
4. Examine brush holders and clean them if dirty. Make sure that brushes ride free in holders.
5. Check brush pressure.
6. Check brush position.
7. Drain, wash out, and renew oil in sleeve bearings.
8. Check grease in ball or roller bearings.

9. Check operating speed or speeds.
10. See that end play of shaft is normal.
11. Inspect and tighten connections on motor and control.
12. Check current input and compare with normal.
13. Run motor and examine drive critically for smooth running, absence of vibration, worn gears, chains, or belts.
14. Check motor foot bolts, end-shield bolts, pulley, coupling, gear, and journal setscrews and key.
15. See that all motor covers, belt, and gear guards are in good order, in place, and securely fastened.

Annual inspections and operations:

1. Clean out and renew grease in ball- or roller-bearing housings.
2. Test insulation by Megger.
3. Clean out magnetic dirt which may be hanging on poles.
4. Check clearance between shaft and journal boxes of sleeve-bearing motors to prevent operation with worn bearings.
5. Clean out undercut slots in commutators.
6. Examine connections of commutators and armature coils.
7. Inspect armature bonds.

Motors should generally be given complete overhauling at intervals of 5 years or so, normally.

Arc-welding Sets. The general maintenance schedule relating to motors and motor controls will apply generally to arc-welding sets. Proper ventilation should be provided, and machines operated outdoors should not be covered with tarpaulins in such a way as to impede ventilation.

Wiring. Wiring in general should be protected against corrosion due to acids, corrosive vapors, or electrolysis, heat and moisture, and loosening of supports. The junction-box covers should not be removed, and wiring should not come in contact with metal. The first requisite is good workmanship and compliance with National Electrical Code.

Switches. The defects of knife and snap switches are arcing due to loose connections, pitting and burning of contact points, overheating, and poor mechanical conditions, such as corrosion. The mercury switch is adaptable for hazardous locations.

Lightning Arresters.[19] Lightning arresters should be inspected at connections in early spring just before the lightning season and every month during summer. If ground resistance exceeds 5 ohms make necessary improvements to lower it to 5 ohms or less. Never run ground wire through iron or steel pipe for protection against mechanical injury unless wire and pipe are bonded together.

Copper used in lightning arresters should have a weight of at least 3 oz per ft. Aluminum should have a weight of at least 2½ oz per ft. Steel should have a weight of at least 4½ oz per ft. Grounding should be to a plate placed at least 8 ft in the ground, if possible, and kept wet.

If lightning disables service, all switches should be turned off as resumption of current may start machines or apparatus at an inopportune moment.

Switch Boxes, Panel Boxes, Etc. All metal boxes of the wiring system should undergo monthly inspection; in locations that are particularly dusty, boxes should be cleaned out weekly. All covers should fit tightly and be in place. All unused knockout holes should be plugged tightly. Bond wires and ground connections should be checked.

Fuses and Switches. All fuses should be inspected twice each year to ascertain that circuits are not overfused. Fuse clips should be clean and tight, and all connections should be checked to prevent overheating. Fuses and switches should be inspected closely for any evidence of overheating as a result of high-resistance contacts or overloads. Refillable fuses should be examined, and charred cases replaced, after making certain that cases are refilled with links of proper rating and that fuses are assembled tightly. Switches should be inspected at same time fuses are checked. Operation of quick-break features should be checked.

Control Equipment. Control equipment should be kept clean. In dusty locations all starting switches, compensators, controllers, and air-circuit breakers should be cleaned and blown out at least weekly. Dust or dirt should not be allowed to accumulate on high-voltage bushings or terminals. An accumulation of dirt, oil, grease, or water should not be permitted on the operating parts of control equipment. In damp or corrosive atmospheres, control parts should be painted quarterly or semiannually. In clean locations semiannual cleanings will suffice. The mechanical condition of all control equipment should be checked weekly if subject to vibration, or monthly otherwise. All nuts and screws should be tightened, and electrical and mechanical connections on both panels and resistors should be examined. Condition of pigtail connections should be checked closely, especially in corrosive atmosphere. Any damaged or worn parts should be replaced, and condition of magnet contact surfaces should be inspected. Control mechanism should operate freely, and oil or grease should be applied if necessary. Contact surfaces should not be lubricated. Equipment subject to severe operating conditions should be checked; contacts should be inspected weekly. A monthly check is sufficient for average operating conditions. Contactor tips should be adjusted, filed clean, or renewed if badly worn or burned. Contactor circuit should be examined closely for any high-resistance joints. A new combustion a-c/d-c millivoltmeter is available for checking resistance of bolted joints and contact surfaces. A semiannual inspection of oil level and condition in starting compensators, oil switches, and circuit breakers should be made. Leakage and evaporation loss should be replaced; oil should be replaced if dirty or gummy. In dirty or damp location, oil level and condition should be inspected quarterly or monthly according to severity of condition.

The following overload devices should be tested:

Circuit breaker tripping points should be checked monthly. Dashpot oil should be replaced if thick and gummy. Orifices in plunger should be kept clear. Leather bellows should be kept soft and pliable with neats'-foot oil. Heater coils for thermal overload relays should be checked to see that they are the correct size. Overload relay settings should be checked every 6 months.

Spontaneous Ignition. Heating and ignition, involving a combustible material, due to chemical action rather than a heat source, such as a flame, spark, radiation, a hot surface, or friction, are known as "spontaneous." The process is known as spontaneous heating if the ignition point is not reached and as spontaneous combustion if the ignition occurs. Spontaneous heating starts with a slow oxidation or fermentation which generates heat. As the heat increases, the chemical action is accelerated until the ignition temperature is reached. The processes and conditions that may lead to spontaneous heating or ignition, taken in their widest sense, are

1. Moisture
2. Bacterial activity —Agricultural products, fodder, manures
3. Germination
4. Storage in large heaps—Agricultural products, coal, tobacco, oleaginous substances
5. Protracted drying—Wood, organic substances
6. Contained sulfur—Lampblack, coal
7. Contained finely divided carbon—Metallic sulfides
8. Containing fat or oil—Organic substances, fibers, colors (paints), clothing
9. Occlusion of oxygen—Coal and metals
10. Absorption of moisture—Quicklime, potassium, sodium, carbides (acetylene)
11. Fineness of division—Metals, bronzes, dusts, fats, and oils
12. Recent calcination—Carbonized substances, metallic powders, metallic sulfides, lampblack
13. Exposure to the sun—Phosphorus in fragments, oxyhydrogen gas
14. Concentration of the sun rays (burning glass)—All readily ignitable substances
15. Friction, pressure, shock fall—Numerous detonating, explosive substances; spontaneous ignition here generally results in explosion

16. Electricity (sparks)--Explosive vapor mixtures, dry-cleaning works, resinous bodies

Examples 1 to 9 mostly exhibit slow development (chronic spontaneous ignition). Numbers 10 to 14 progress with moderate rapidity, while 15 and 16 are sudden and of explosive character (acute).[30]

Substances liable to spontaneous ignition have been classified by A. H. Nuckolls of Underwriters' Laboratories as follows:

Group 1—Calcium oxide (unslaked lime), barium oxide, sodium peroxide (with water)

Group 2—Hydrides of phosphorous and silicon (in air), sodium and potassium (in water), turpentine and ammonia (in water), hydrogen and chlorine (in light), phosphine with vapor of hydride of phosphorous (in air)

Group 3—Vegetable oils and fats (rancid oils and fats more susceptible), metals in finely divided states (oil soaked), metallic sulfides, charcoal (hardwood by retort methods is worst; in new charcoal mostly; sacked charcoal should be piled 6 in. high only), coal (except hard) sprayed with a high-flash-point mineral oil prevents spontaneous ignition

Group 4—Hay and grain, owing to enzymes, ferment during germination period and when wet

Other Substances Subject to Spontaneous Ignition. Some other substances subject to spontaneous ignition are the following:

Fish scrap (green)
Hemp, jute, and sisal
Sugar and gunny sacks
Wood sawdust (in icehouses)
Lampblack
Leather scrap
Wool waste
Oily waste
Printed matter in piles, owing to linseed oil and ink
Nitrate of soda

Smoking. *Cigarettes and Matches.* There are manufactured in the United States every year 700 million miles of cigarettes. These are burned down to about one inch while being smoked and then discarded. This amounts to 513,520 million potential fires from this cause every year. It has become the leading cause of fire and involves the home, industrial plants, and the forests. The match is another contributing factor, as the type now used, the book match, has a wide distribution. The sulfur-head match, subject to ignition from dampness, is responsible for the mice and match theory and for fires where they are stored in poorly protected premises. It is suggested that signs be posted in industrial plants to discourage the discarding of lighted cigarettes and matches. These signs might read:

"Cigarettes are dangerous if not put out before throwing them away. Please be careful."

"Don't be a 'Ciggyflipper' " (an accepted word).

"Only smoke in safe places."

Oily Waste. The fire hazard of cotton waste and wiping rags impregnated with oil is due to the phenomenon of oxidation. Cotton waste that is "slightly" coated with oil presents a large surface within the mass to the process of oxidation, and the heat of this process will reach the ignition temperature of the oil and the cotton. Cotton waste or rag saturated with oil does not present this danger. Oily waste when not in use should be kept in a standard waste can, which is a metal can without any soldered joints. It has a self-closing cover and sets on legs 3 to 4 in. from the floor. (This is a standard piece of equipment for all machine shops.)

Packing Material. Any kind of packing material that is combustible, such as excelsior, should be kept in standard bins. These bins, designed to hold at least 1 bale of excelsior, are constructed of wood covered with lock-jointed tin (similar to fire-door construction) with automatic covers. Large supplies of packing material should be kept in fire-resistive sections of an inside area or kept outside the building.

Open Lights, Flames, and Sparks. Any open light or spark-producing apparatus is a possible source of fire, particularly in the presence of flammable vapors and on or in the vicinity of the leeward side of any air or wind motion which may carry flammable vapors such as gasoline, brazing torches, kerosene torches, welding torches, gauge glass lights, gas jets, pipettes of glass blowers, and inert-gas producers burning gas or oil. Salamanders used in buildings during construction or razing of buildings should be set on incombustible material and never left unattended. Chimneys, stacks, and refuse burners should be equipped with spark arresters.

Turpentine	85	(Vlackos)
Whale oil	77	(Vlackos)
Xylidines	63	
Xylol	88	

NOTE: Fifty grams of cotton impregnated with linseed oil rises in temperature to 23.5°C during the first hour. In 15 hr, however, it rises to 170°C.

Bearings. Bearings are a source of fire, particularly neglected bearings (from a mechanical sense) or ones not oiled regularly. On driven shafts, the offside bearing is the one most likely to heat. All shafting should be properly aligned to prevent undue friction at the bearing. Bearings that may be concealed on the inside of apparatus should be made accessible by providing hand holes for inspection and lubrication. Bearings should be kept clean and free of dust and lint.

Belts. Any moving belt is a potential generator of static electricity and should be tested for it. When it is present, the proper grounding apparatus should be installed. This consists of combs and points properly connected to the ground. Pulleys of wood should be kept clean and free of oil. Rope drives should have sufficient clearance from combustible material to avoid friction (see Static Electricity).

Belt Dressings. The problem with belt dressings consists in developing a material which can be easily applied to belts, which will have sufficient electrical conductivity to remove or neutralize static electrical charges as rapidly as they are formed, which will resist wear, which will not decrease the coefficient of friction between the belt and the pulley, and which will not be injurious to the belt. A good rubber belt dressing can be prepared by mixing 18 parts of lampblack with 82 parts of good spar varnish. The dressing must be dry on the belt before running. A nonflammable thinner for the varnish can be prepared by mixing equal volumes of carbon tetrachloride with VMP naphtha.

A good leather belt dressing consists of

100 cu cm liquid fish glue
100 cu cm sulfonated castor oil
80 cu cm glycerine

170 cu cm water
82 g lampblack
20 cu cm 2 per cent ammonium hydroxide

This can be applied while the belt is moving. If the belt has not been properly maintained, this dressing will cause the belt to stretch.

Cheap and low-grade stick or semiliquid belt dressings, which generally contain the ingredients shown in Table 5-51, should never be used on leather belting of any kind.[23]

Table 5-51

Stick type	Per cent	Semiliquid type	Per cent
Graphite	22	Tar	36
Rosin	27	Rape seed or cotton oil	54
Vegetable oil	44	Rosin	10
Paraffin	7		

Rubber belts[22] are more prone to the accumulation of static electricity than leather belts. The rubber belt has been given a certain amount of immunization by the incorporation of acetylene black in the friction compound. This makes the belt a good conductor, thus permitting the diffusion of the static charge. This type of belt is recommended for hazardous locations and can be installed without grounding.

Air-conditioning ducts and filters constructed of combustible material are subject to ignition from sparks, either from the internal apparatus or those sparks sucked into air ducts from bonfires and carelessly discarded cigarettes. Screens should be provided on all intake ducts.

Focused rays from bubbles in glass are frequent causes of fire, and where flammable or combustible material is stored, this feature should be checked.

Heating furnaces or cupolas of stationary types, whether coal-, oil-, or gas-fired, should have clearances as prescribed in the standard classification of furnaces (see Ovens and Dryers).

Overheated Materials. Overheated materials such as boiling or cooking resins, greases, asphalts, or pitch are liable to froth and flow down to the combustion unit or chamber and ignite. Proper clearances should be maintained around all kettles. They should be set on incombustible material and properly diked to prevent the contents of the tank from flowing out if frothing occurs. Molten metals can be a source of sparks and radiated heat, they should be safeguarded and kept from contact with combustible material. Metal, lead pots, zinc coating (subject to evolution of hydrogen gas), forges, oil-tempering furnaces, and bonderizing furnaces (metal spraying) are types of molten-metal hazards.

Sparks on Roof. The antidote for the danger of sparks on roofs is noncombustible roofing, tin, tar, or gravel, and asbestos or copper shingles. Some wooden shingles are treated with chemicals to make them slow-burning, but in the course of time, the heat of the sun nullifies this feature so that all wood-shingle roof coverings become a serious menace. The exposure of one wood-shingle roof to another is a grave danger in sections where they are much used. This calls for drastic action for their elimination.

Defective Chimneys and Flues. (Direct ignition with flaming or glowing material, prolonged heat, sparks.) Chimneys and flues as a source of fire are associated with the heating of buildings or power plants and with carrying off heated gases and vapors. They are in a direct sense a passageway connecting the source of heat with the outer air. Their construction varies with the conditions, but they are most often constructed of brick, stone, or cement block, with a suitable burned-tile lining. Some are made of metal and in rare cases of wood, the latter construction being necessary for conveying corrosive vapors. Under this heading will also be found sooty and dirty chimneys originally designed for one purpose and used for another.* A defective chimney or flue, therefore, may involve any one of three conditions—poor construction, soot or dirt, or overburden of original design.

Defects of construction consist of poor design, poor cement between bricks, inadequate thickness, no lining, or insufficient draft, thus permitting the escape of fire or sparks or heat which will ignite flammable material adjacent to the chimney.

Sooty or dirty chimneys may result in the ignition of the soot or dirt and cause an intense fire in the chimney, thus inducing disruption by expansion, the escape of fire or sparks, or the dropping of burning soot into the connecting flue or breeching causing it to become overheated and set fire to flammable material.

Overburden of original design creates a condition similar to poor construction with similar results.

The construction of a chimney is of the utmost importance, for it is a flue passing up through the building from cellar to roof and through attics and roof spaces, some of which are open and others closed. In many instances such spaces are boxed in with lath and plaster or wainscoting. These concealed spaces make it difficult to observe defects such as mortar falling out between the bricks, thus permitting sparks and flame to ignite the woodwork. This is also possible where the flue from a stove enters the chimney passing through this boxing. A chimney should be built in a straight line from the ground up, extending well above the roof. The bricks should be laid with care in a good smooth cement mortar. Unless it has 8 in. of brickwork around each throat or flue, the chimney should be lined with a hard-burned-tile pipe laid in smooth cement mortar with all joints tight. A chimney should never be used as a support for beams or joists nor should these ever be permitted to enter the chimney.

Ovens and Driers. Under ovens and driers come all classes of heat-treating mediums involving enclosures, piping flues, and stacks and involving the source of heat, the material to be treated, and the method of removing gases and flammable liquids.

The various types of ovens are graded on a temperature basis:

Low grade—Those developing a temperature up to the melting point of lead 600°F

Medium grade—Temperature of 601 to 1500°F

High grade—Temperature of 1501°F and over

Almost all devices will fall within these grades, but owing to special function and performance, many devices will require special treatment. Box-type ovens include all ovens that are closed when in operation. Continuous-conveyor ovens include all ovens that are open at both loading and unloading ends. Ovens should be located abovegrade and so installed that an explosion can be relieved with the least damage to building and equipment. Ovens should be accessible on all sides. There should be sufficient space between the top of the oven and the ceiling to permit the installation of automatic sprinklers or proper use of hose streams. Ovens should not be in contact with posts, beams, trusses, or other structural supports for the building. Regardless of the type of oven or furnace, certain clearances must be maintained. These clearances are shown in Table 5-52.

Table 5-52

	Without setting of brick or equivalent			With setting of brick or equivalent		
Grade	Above	Sides and rear	Front	Above	Sides and rear	Front
Low	48 in.	36 in.	48 in.	36 in.	24 in.	48 in.
Medium	48 in.	36 in.	96 in.	36 in.	24 in.	96 in.
High	15 ft	10 ft	30 ft	15 ft	10 ft	30 ft

---

* The introduction of oil burners has put a heavy burden upon the ordinary dwelling chimney many were never designed to resist the intense heat or constancy of flame.

The front end of the oven or furnace is the loading end; because of the opening and closing of doors and the possible emission of heat and flame, the clearance is naturally greatest at this end. Ovens and furnaces in certain industries will be constructed on the earth or solid brick or concrete foundations.

Where ovens are supported on wooden or combustible floors, they should be separated therefrom by a space of at least 18 in. or insulated by one, two, or three courses of 4-in. hollow tile, the tile cells laced end to end to form ventilating ducts to permit circulation of air under the oven. In large furnaces in which the material is melted by straight fire heat or an oxidizing flame, incombustible areas should be maintained around the furnaces in case the furnace walls should break permitting the contents to flow out.

Core Ovens. Core ovens are used for drying cores or sand molds in foundries. They should be constructed of incombustible material, and the interior racks should be of metal. Flasks and fallow boards should be kept clear of core ovens.

Caul Boxes. Caul boxes are used for drying patterns and wood molds. They should be made of incombustible material with interior racks of metal. They should be cleaned frequently.

Dry Rooms. Dry rooms are of various types but involve similar hazards.

Lumber Driers. Lumber driers should be made of incombustible material and cleaned frequently as interior surfaces become coated with resinous distillates. They should be equipped with steam jets or fog, manually or automatically controlled.

Annealing Furnaces. Annealing furnaces run high temperatures and should be made of incombustible material and have clearances similar to ovens. If electrically heated, control apparatus should be of the temperature type to prevent overheating and should be equipped with pilot lights to show when current is on.

Special Types. Ovens using japan or enamels with dipping are a special type. They should be of brick, concrete, or steel and approved incombustible material. All walls should be free of hollow spaces to avoid accumulation of vapors. If heated by steam, this rule is not mandatory. Ovens of this type should be provided with explosion reliefs, hatches, or permanent openings having an effective area of not less than 1 sq ft for each 15 cu ft of capacity. Vent pipes should be treated as "heat flues" and kept well away from combustible construction or materials and be insulated where necessary. They should not pass through floors, if possible to avoid, but be as short as possible in passing to the outside of the building. To avoid an explosive atmosphere in box-type ovens and maintain a reasonable factor of safety (2), 4,600 cu ft of air should be provided for each gallon of solvent evaporated based on an oven temperature of 70°F. The lowest explosive limits of the vapors, from the commonly used naphtha, benzine, gasoline, and turpentine substitutes, are about 1.0 to 1.4 per cent vapor in air (by volume) at 70°F -or as an average, 1 gal of solvent evaporated in 2,300 ft of air.

Heating Units (see standards). A reliable pilot light or electric ignitor should be provided for gas or oil burners and should be so arranged that the main fuel valve cannot be opened unless pilot is in operation.

Grounding. All metal parts of ovens and conveyors that may be exposed to flammable vapors should be thoroughly grounded. Grounding conductors should be not less than No. 8 gauge copper and should be protected from mechanical injury.

Fire Extinguishment for Ovens. Water, carbon dioxide, or nitrogen, foam carbon tetrachloride, or steam can be used to extinguish fires in ovens. Where temperatures are over 250°F, open sprinklers should be installed which are controlled by automatic valve or releases. At temperatures over 250°F condensations from finishes will cause loading or coating of sprinklers.

The use of flammable solvents to clean ovens should be prohibited.

Welding.[24] Welding and cutting operations present hazards due to sparks of molten metal igniting paper, rags, oily waste, excelsior, and other loose material or the sparks lodging in cracks in woodwork or falling through holes in floors. The flame of the torch, a high temperature, 2000 to 2400°F in the range of orange yellow or yellow white, may come in contact with combustible material, or a backfire from the torch may cause a fire. Where welding is done by portable systems, such as those on trucks or near or attached to workbenches, all combustible material should be protected against sparks by metal plates or asbestos blankets, and a fire extinguisher or pails of water and sand should be kept near by. Canvas tarpaulins should not be used as covers. The welding equipment should be securely fastened in an upright position on the truck or at any bench, and only experienced operators should be allowed to use it. All hose should be kept in perfect condition and free from leaks. If there is any doubt of the integrity of the hose, it should be discarded. Tape should never be used to fix up a hose. Hose lines can become burned by the flame of the torch in moving equipment about. Oxygen hose is colored green; acetylene is red for identification. Where oxygen is used under pressure, all grease and oil should be positively kept away and removed if found to be present, as grease or oil in contact with oxygen under pressure will cause a violent explosion.

In fixed systems where welding is done as a prime process, the entire operation should be installed in a fireproof explosion-vented room, cut off from the rest of the plant.

Cylinders of oxygen should not be stored in the same room with cylinders of acetylene, unless separated by fire-resistive partitions (see Standard Welding Room Design in Standards). Cylinders should be kept away from stoves, heaters, radiators, furnaces, or forges. All space around them kept clear of combustible material, oil, and grease. When cylinders are stored in the open, they should be protected from accumulations of ice and snow and from the direct rays of the sun. Where the generation of acetylene is carried on, this should have positive protection and should be installed in a separate fireproof explosion-vented room, even if this must be a part of the enclosed area of the entire process room. This section should be kept dry and waterproof. The storage of 600 lb of calcium carbide is permitted in generator rooms or in a separate compartment near by in one-story buildings, preferably without cellar or basement. No water should come in contact with carbide outside the generator. No open lights should be brought near carbide or open containers. Water should never be used to extinguish a carbide fire.

Friction. Wherever there is metal-to-metal contact in mechanical apparatus, particularly in bearings, the use of the right type of lubricant is essential. A heating bearing is the sign of neglect, or it may be that the oil or lubricant is not reaching the points of contact. Drip and wick oilers are liable to clog; the ring or splash types are less liable to give trouble unless the oil gets low. Inspections should be made frequently to ascertain if drip cups are full, if the lubricant is reaching the bearing, and if sufficient oil or lubricant is present. Friction caused by the clogging or stoppage of conveyor belts in elevators at the pulleys is a cause of fires. To avoid the continuous operation of the power mechanism in such installations, it is recommended that a "Bethlehem starter" be set between the power unit and the belt mechanism.[25] This device is inherently a limit torque coupling. It will not transmit to the driven machine or impose on the motor more than the maximum load for which it is designed. It is therefore an absolutely dependable overload protection for the motor and the driven machine.

Rubbish and Litter (sparks, direct ignition with flaming or glowing material, prolonged heat, spontaneous ignition, focused rays). The undue accumulation of discarded material, whether it be the usual household rubbish or industrial-plant refuse, is always a breeder of conditions that may result in fire. The rubbish may contain oily waste or greasy rags and paper which can set up a reaction causing spontaneous ignition. Matches are frequently caught up with the rubbish and by dampness or friction may ignite the surrounding flammable material. A carelessly thrown cigarette, cigar, or match may lodge among the litter and cause fire.

If there is no specific place, such as a fire-resistive receptacle, to put rubbish, it may be thrown anywhere and come in contact with steampipes, defective electric wiring, or be subject to the focused rays of glass bubbles. All these direct causes of fire are rightly attributed to rubbish and litter because if it were not permitted to accumulate the fires would not occur. Rubbish and litter should be removed from the premises and kept in metal receptacles until final removal, which should be often. Wastepaper is a menace because of its heterogeneous character and the possibility of spontaneous ignition, for it may consist of greasy lunch papers, oil-soaked paper, and even wiping rags. Also cigarettes may be thrown into the pile or be gathered up when it is collected. Wastepaper should be kept in fire-resistive rooms and disposed of daily.

Static Electricity. Static electricity is generated by friction or the bringing together and then separating of two unlike substances. It is not altogether possible to prevent, but static sparks can be avoided by preventing the accumulation of the static charges. The static charges are found to be present in processes involving the flow through pipes or restricted orifices of flammable liquids such as gasoline, etc., in dust that is in motion, in finishing and coating processes, and on belts and dryers in motion. They are also found in mills employing spinning and roving operations. The usual methods of preventing the accumulation of static charges is by grounding all moving parts and containers and by bonding connecting apparatus. Humidity may also be applied in the form of vapor, spray, or evaporation at times when humidity is low (winter) or in sections that may become low in humidity. A relative humidity of 50 to 60 per cent may be sufficient, but the minimum for safety may vary with conditions. It is believed that a normal percentage of carbon dioxide must be present to make humidification effective.[26]

Neutralizing. Air is ordinarily a nonconductor of electricity, but if sufficient ionized conductivity is produced, it will prevent the accumulation of static charges. Ionization can be produced by electrical discharges or by radioactive substances. Static neutralizers employ a high-voltage transformer of small capacity to produce brush discharges. This equipment is liable to ignite flammable vapors or dusts. Gas flames produce an ionizing effect but should not be used in the presence of flammable vapors or dusts. The human element enters the study of static electricity as it has been found that some people are more subject to the accumulation of static charges than others. People with dry skin appear to be more liable to this accumulation than those having moist skins. Similarly, people of blonde coloring are more liable than those of brunette coloring, who are generally not negative to the charge. The grounding of the person by portable ground wires, using a metal-grounded plate to stand upon with metal-pegged shoes, and grounding portable knives on coating machines are effective. A method of grounding the personnel in a hospital operating room has held some attention because of the hazard that has developed in the case of anaesthetics which are explosive. A specially constructed floor, both grounded and of material to prevent static charges, has also been given attention.

Hospitals. The use of flammable and explosive anaesthetics in operating rooms is liable to cause damage. Such anaesthetics are ether, ethylene, cyclopropane, propylene, ethylene chloride, and nitrous oxide. Where oxygen is used, because it is a supporter of combustion, its presence may add to the rapidity and intensity of a fire. Fire in hospitals may be caused by the use of X ray, electric cauteries, radio knives, high-frequency machines, and open gas flames in nearby laboratories and kitchens.

Table 5-53. Properties of Anaesthetic Gas—Explosive Limits*

Gas	Per cent in air		Per cent in oxygen		Per cent in nitrous oxide	
	Lower	Upper	Lower	Upper	Lower	Upper
Ether	1.85	36.5	1.7	39.5	3.8	25.7
Ethylene	2.75	28.6	3.1	79.9		
Ethyl chloride	3.7	12.0				
Cyclopropane	2.4	10.3	2.45	63.1	3.0	28.0
Propylene	2.2	9.7		52.8		

* See *Anaesthetics in Hospitals*, NEPA.

Electrostatic Voltmeter. The ordinary voltmeter designed for measuring voltages of an electrical circuit is not suitable for measuring the voltage of a static charge.

For this purpose a reliable electrostatic voltmeter must be used. An electrometer or electrostatic voltmeter has been successfully used when calibrated to 10,000 or 50,000 volts. Although the calibration varies to some extent when the instruments are moved, they have been found to be sufficiently accurate for most electrostatic voltage determinations. Another voltmeter consists of a needle system with the needle moving over a graduated scale so arranged that the operator may arrest the movement of the oscillating needle without waiting for it to come to rest by natural damping. The voltmeter scale is graduated in equal divisions which, together with the calibration curve which accompanies the instrument, give the static voltage. This type is available for a range up to 5,000 or 10,000 volts. The range of these instruments may be increased by connecting one or more condensers in series with the voltmeter, but unless the condensers are each of the same capacity, a large error may be made in such measurements. Before each reading the condensers should be completely discharged in order to ensure accuracy.

Neon-tube Testers. Probably the most satisfactory and inexpensive portable instrument for detecting the presence of static electricity in manufacturing plants is the neon-type tester commonly used for testing automobile spark plugs. It consists of a small glass tube containing rarefied neon gas into which the two electrodes extend. The electrodes are protected by suitable resistors built into the equipment itself. The neon tube glows when one lead is brought into contact with a body charged with static whether or not the other lead is grounded. It is sensitive enough to glow when held in the hand of a person walking over a high-pile rug in a dry atmosphere when one of the leads is grounded or brought into contact with a conducting material.

One method of testing for static at any given location is to touch one of the leads with the hand and to hold the other lead in close proximity to the suspected equipment or material. A glow in the neon-tube tester indicates the presence of static. The amount of the charge cannot be determined by the neon-tube tester alone. The use of this type of tester may be hazardous at some locations where explosive dusts or flammable vapors are present, since the static spark may jump from the object containing an accumulation of static to the lead of the tester or the operator.

Gold-leaf Electroscope. The gold-leaf electroscope is another instrument that may be used to detect the presence of static. It is primarily for use in the laboratory, consisting as it does of two delicate pieces of gold leaf suspended from a single electrode in a glass tube or one piece and a permanent bar. In the presence of a static charge, the two pieces of gold leaf will be repelled from each other sufficiently to be seen very easily by the observer. It is sensitive enough to detect a very small charge. Since the capacity of the gold-leaf electroscope is so small, there is practically no spark when it becomes charged in the presence of static or subsequently discharged. For this reason it may be used with less hazard for atmospheres where flammable vapors or dusts may be present, but when used in the industrial plant, it must be handled with care since it is easily injured. The gold-leaf electroscope does not indicate the quantity of static but merely its presence.

Ohmmeter. Ground wires are often "rung out" by using a small hand-operated magneto and bell set. While this indicates that an electrical path to ground exists, it does not give any indication of the resistance of the path. Since it is essential that grounds for static have a low resistance, the use of the magneto-bell set or "ringer" is not recommended for testing static grounds. For this purpose an ohmmeter, or meter reading the resistance in ohms, must be used. A common type consists essentially of a direct-reading ohmmeter of the permanent magnet moving-coil type mounted in a suitable case with a hand-driven generator or provided with other means for supplying direct current at suitable potential for the test. The instrument is so simple and direct in its operation that anyone can use it successfully by following directions. The ohmmeter can be obtained with direct reading scale having ranges as shown in Table 5-54.

Table 5-54

Scale, ohms	*Smallest scale division*
0.0–1.0	0.01
1.0–100.0	1.00
100.0–10,000.0	100.00
10,000.0–1,000,000.0	10,000.00

Switches on the instrument change the scale. The instrument has two binding posts, one of which is connected to the equipment and the other to known positive ground such as an underground water main. The magneto built into the instrument is rotated by the small hand crank, and the resistance of the instrument is read directly. Since the current flowing is infinitesimal, the resistance of the instrument leads is negligible. Static grounds, to be most effective, should have a low resistance. Ohmmeter tests should not be made in operating buildings while any exposed flammable solvent or vapor is present in the equipment or immediate vicinity of the equipment being tested, since the ohmmeter itself may produce a slight spark. Readings of resistance should be made of all ground connections and all parts of grounding systems when the systems are installed, and regular and periodic readings should be made thereafter to make sure that high resistances do not develop over a period of time because of corrosion, broken connections, or loose connections caused by vibration or in some other way.

Infrared Driers.[27] Drying by the radiant heat from infrared lamps has now become common in industry. Lamp driers are used in a variety of industrial processes, especially in the automobile industry and where finishes of paint, lacquers, and enamels are used. The principle, in effect, is the utilization of the radiant waves from lamps whose light waves are at the red end of the spectrum in the nearly invisible field of light rays. The near-infrared field includes wave lengths of from about 6,500 to 14,000 Å. Most of the heating lamps used permit a utilized energy below 20,000 Å. The violet rays at the other end of the spectrum are about 4,000 Å.

The term Angstrom unit (Å) indicates a standard scale for measuring the length of light waves devised by Angstrom, a Swedish physicist. The Angstrom unit is one-billioneth of a centimeter. Another standard is called the millimicron, which is ten times an Angstrom unit. The temperatures usually listed at the filaments (of the lamp) are about 1500°K. The symbol K is used to indicate the color temperature, which is the same as Fahrenheit, so far as it can be measured by color-temperature measuring devices. The sun is 6000°K. Mazda lighting lamps are from 2600° to 3200°K. Carbon lamps are 2000°K. Some unenclosed resistance heaters are made as low as 1200°K. The 250-w heating lamps on the market rate at approximately 11,500 Å (770 Btu per hr). The temperatures of surfaces painted or being treated usually run 250 to 350°F.

Drying by infrared lamps has some advantages over ordinary gas- or oil-heated ovens. Some of these are quicker results on certain types of goods, low cost, better working conditions, less floor area required, less odor and smoke, no oil- or gas-fuel hazards. Explosions are unlikely to occur as enclosures are not required. The drying results from the heat of the infrared lamps. The lamps used are usually 250 to 260 w rated at voltages of 105 to 110. Some 500- to 1,000-w lamps are used for special purposes. This method of drying was first developed by the Ford Motor Company. The lamps are usually arranged in drying tunnels, in the form of open cages, to fit the particular type of work to be treated. The lamp bases are usually ventilated so that the mountings may be kept cool. The drying effect is due to the heat produced by the interruption of the rays by the metal or body of the work being treated so that it may be said that the paint or coating is dried from the inside out. The lamps are said to have a life of from 10 to 20,000 hr.

Suggestions for Installations. All electrical equipment should be in accordance with the National Electrical Code. Installations should not be confined to small rooms unless they are thoroughly ventilated. Ventilated hoods or enclosures should be built at the first part of the conveyor with exhaust systems to discharge the first evaporation of solvents where large amounts of solvents are used. Lamp drying units should be well separated from spraying and dipping processes. Controls should be provided to shut off the lamps automatically if and when the conveyor stops and also if stationary goods are not removed from the drier on time. Goods on conveyors should be rigidly supported. Fire protection may consist of automatic sprinklers or approved water-spray systems over the lamp tunnels and under ventilating hoods, or an approved CO_2 gas system should be provided.

Electrostatic Coating Process. The electrostatic coating process, or electrical "detearing," supplies an automatic method of freeing materials of accumulations and fatty edges, which are spray- or dip-coated with alkydsynthetics, oleo resins, or polymerized types of finishes. In the process the article on a conveyor is dipped or flow coated in any suitable manner. It is then carried over the usual drainboard and is permitted to air-dry or set sufficiently so that the flow has practically ceased. At this point the grounded article is carried over an insulating grid to which a high voltage can be applied. An electric field having a difference of potential of 50,000 to 100,000 volts or over between the grounded goods, being painted, and the electrodes is maintained. Only a low amperage is used, about 10 ma.

One type of apparatus consists of a small oil-immersed power pack requiring less than 4 amp at 220 volts (single-phase) in the primary. This pack can produce 72,000 to 126,000 volts (alternating current, 8 steps). The device has a rectifying tube to produce direct current from a-c power. It is wired to electrodes hung in the spray booths or to other electrodes near which painted goods pass on the conveyor. Sparks can jump to the goods if they are within 6 or 7 in. of the electrodes. This introduces a serious spark hazard in the painting area and process. This force is particularly strong at points where drainoff is apt to occur and the excess paint is removed from the piece and a smooth coating remains.

Tentative Suggestions for Installations of Electrostatic Apparatus in Painting Processes[28]

Transformers, power packs, and all electrical controls are to be located outside the immediate painting area (not inside spray booths, well away from dip tanks, etc.).

The electric installation is to be in accordance with the National Electrical Code in so far as it applies.

Electrodes are to be rigidly supported in permanent locations and well insulated.

Minimum spaces between electrodes and painted goods are to be at least twice the distance of the length of the possible spark gap.

Installations are not allowed where goods being painted are handled manually. All goods subject to the processes are to be handled on conveyors and be so fixed to the conveyors that the minimum spaces from goods to electrodes will be maintained under all circumstances. Also guards should be provided where necessary to produce this result.

Automatic control should be provided to make the entire electrostatic equipment "dead" when vent fans and conveyors stop.

Standard ventilation should be maintained for the areas containing the electrostatic apparatus; the exhaust-fan motors for the ventilating system are to be connected in series with the voltage pack primary (rules for blower, exhaust, and ventilating systems to apply).

All painting processes supplemented by electrostatic apparatus should be protected by automatic sprinklers or other approved automatic extinguishing systems.

Where necessary, adequate fencing, railings, or guards are to be provided to maintain safe isolation of the process from other work in the vicinity and to guard personnel.

Signs designating the work zone as dangerous as regards fire and accident shall be posted at the process.

Electrode insulators shall be kept clean and dry.

Drip plates and screens shall be removable and taken to a safe place for cleaning.

Cleanliness shall be maintained and stock or goods not stored within 5 ft of the process.

Exposure. In fire-prevention parlance this literally means the spread of fire from one building to another. As a cause of fire, *i.e.*, of causing other fires, it looms large on the records. A fire in progress, in order to spread and cause other fires, must have opportunity for so doing. This is given it by the failure to safeguard surrounding property or by using flammable material for construction or roof coverings. Brick or concrete construction will resist fire, but if the openings in walls are not safeguarded by wired glass in metal frames or standard metal-clad shutters, fire will enter the building. When wood construction is used, the safeguarding of the openings in walls as noted above, is a material help to the fire-fighting forces as the time element enters, and before the fire can burn through a frame wall, water can be applied to cool the surfaces. Water curtains on wood buildings are also of value, applying the same principle. Incombustible roof coverings also are essential to prevent ignition from falling brands or sparks, as is the protection of roof openings by wired glass in metal frames or metal screens over heavy ribbed glass. The prevention of fires from exposure therefore calls for construction safeguards which will not permit ignition or entrance of fire to buildings.

Steam- and Hot-water Pipes (prolonged heat, spontaneous ignition, chemical reaction). Faint but prolonged heat is the classification under which fires from steam- and hot-water pipes are placed. This type of fire is also recorded as spontaneous combustion owing to the fact that the process of decomposition or charring is very slow, and ignition resulting from this, not being easily understood, is characterized as such. Steam- and hot-water pipes maintain a constant heat of low degree. As a source of fire they are to be considered more as a means of causing other material to ignite by contact, which breaks down or volatizes the flammable constituents, igniting at the temperature of the radiated heat or, upon cooling, absorbing oxygen setting up rapid heat or *reaction*. Woodwork or any combustible material that is liable to remain in contact with heated pipes may be ignited at an unexpected moment. It therefore constitutes one of the fire causes that is to be feared, as it is not always detected in its most insidious stage. The inherent hazard of steampipes in contact with wood is the slow action of applied heat which produces pyrophoric carbon. The temperatures of steampipes which can produce this result are shown in Table 5-55.

Table 5-55

Atmospheric pressure, lb	*Temperature, deg F*
14.7	212
25	267
50	298
100	338
150	366
200	387
300	422
500	470
1,000	546

Clearances around steampipes of from 2 to 18 in. must be maintained.

Pipes Conveying a Heating Medium. Pipes conveying a heating medium, such as steam, water, or oil, where they pass through floors or partitions, must have a sufficient clearance around them to prevent their inclusion in the list of causes of fire. The prolonged heat will eventually reduce wood to a charcoal or pyrophoric carbon which will ignite, or when the heat is withdrawn the wood will absorb oxygen and set up a reaction resulting in fire.

Pipes running in a horizontal direction through concealed spaces are liable to come in contact with dust accumulations or siftings or because of their warmth may attract mice to build nests close to them which can be a possible cause of fire.

Woods of commerce, being nature's product, are complex things made up of various materials which go to form a composite whole which is called wood, but varying in degrees of construction to such an extent that no one wood is like another, either in its construction or action under various treatment. Wood is that product which is made up of cellulose or lignin in combination with various resins and aromatic substances which have served the living tree. Therefore, in analyzing the burning point of wood, we may reach false conclusions if we assume that all woods are alike in this respect.

The long- and short-leaf or winter or summer, growths will differ greatly in action under heat owing to the resistance to volatization of the resins and aromatics. For general purposes it may be assumed that the usual woods used in commercial structures will act in the same way with one exception, *i.e.*, the matter of bulk, for large members will not succumb to disintegration so quickly as smaller ones owing to carbonization of outer fibers whereby a protective layer of carbon is formed which will protect or envelop the inner layers and prevent further volatization. Therefore, the degrees of heat necessary to ignite the so-called "wood" would depend upon the construction or kind of wood and its bulk or volume.

It is a well-known axiom that wood which is slowly heated is more susceptible to a lower degree of ignition temperature than woods heated very rapidly. This is entirely due to volatization of the resins. In the former, this causes a complete volatization, leaving the cellulose in a very dehydrated state. In the latter it merely brings to the surface the resins which burn at their ignition point but eventually ignites the cellulose structure, thus bringing up the interesting subject of the ignition points of resins, aromatics, and cellulose, which vary in considerable degree.

Ordinarily it may be assumed that at 110°C the water and aromatics are dispelled. At 150°C the carbon monoxide (CO), carbon dioxide (CO_2), and resins are dispelled. At 230°C the external browning or carbonization starts. At 270°C pyrophoric carbon is formed. This is pure cellulose in punk form which has a tendency to self-ignition while undergoing this heat process. At 300°C charcoal or carbonized cellulose is formed. Where there is an actual contact of flame, the process is very rapid but the cycle remains the same.

Table 5-56. Density of Gases Lighter or Heavier Than Air (Von Schwartz)

(Density of air taken as unity: g = gas, v = vapor)

	Lighter	*than air*	
Hydrogen (g)	0.069	Wood gas (g)	0.700
Coal gas (g)	0.400–0.600	Acetylene (g)	0.898
Pit gas (firedamp)	0.553	Hydrocyanic acid (g)	0.945
Ammonia (g)	0.588	Ethylene (g)	0.967
Water vapor (v)	0.622	Carbon monoxide (g)	0.967
	Heavier	*than air*	
Ethane (g)	1.036	Butane (g)	2.004
Nitric oxide (g)	1.039	Carbon oxysulfide (g)	2.104
Oxygen (g)	1.105	Sulfur (v)	2.200
Methyl alcohol (v)	1.120	Chlorine (g)	2.448
Phosphuretted hydrogen (g)	1.185	Ether (v)	2.565
Sulfuretted hydrogen (g)	.192	Carbon disulfide (v)	2.645
Allylene (g)	382	Arseniuretted hydrogen (v)	2.697
Propylene (g)	451	Benzol (v)	2.770
Propane (g)	.520	Seleniuretted hydrogen (g)	2.784
Nitrous oxide (g)	.527	Amyl alcohol (v)	3.147
Ethyl aldehyde (v)	.530	Chloroform (v)	4.215
Hyponitrous acid (g)	.590	Phosphorus (v)	4.355
Alcohol (v)	.613	Telluretted hydrogen (g)	4.498
Methyl ether (g)	1.617	Selenium (v)	5.700
Methyl chloride (g)	1.738	Sulfur vapor	6.650
Cyanogen (g)	1.800	Tellurium	8.896
Butylene (g)	1.935		

Gas or vapor	*Approximate vapor or gas density, air = 1*
Hydrogen	0.069
Carbon monoxide	0.96
Alcohol, methyl	1.1
Alcohol, ethyl	1.6
Acetone	2.0
Ether, ethyl	2.6
Carbon disulfide	2.6
Benzene	2.7
Gasoline	3.5*
Kerosene	4.5*

* NOTE: These are mean values for gasoline and kerosene found in common use.

Hot Ashes and Coals (direct ignition with flaming or glowing materials or sparks). These causes of fire are readily apparent, as they involve one source, that of direct ignition from flaming or glowing material. Ashes or coal removed from furnaces contain sufficient heat and in many cases visible fire to ignite material with which they come in contact.* Placing them in wooden receptacles or in contact with combustible material is inviting disaster as is also placing them or permitting them to rest on metal-covered wood.

Ignition of Hot Greases, Tar, Wax, Asphalt (open lights, sparks, flames, and static electricity). Flammable materials, as has been stated, vary in their flash and ignition points, and fires resulting from the use of such materials are to be expected if they are subjected to heat or flame which will ignite them. The above-mentioned materials are in addition subject to ebullition and frothing, which cause them to overflow their containers, whether a frying pan or a pot used in industrial establishments. Flames or open lights are the usual source of ignition, and fire results from contact with these owing in most cases to lack of proper supervision and care, unless a defective vessel should break, permitting the contents to fall into the flame of the heating medium. This latter disaster is avoided only by frequent inspection.

---

* Ashes from a furnace piled on a concrete floor against a brick wall 12 in. thick caused a fire owing to the radiation of heat through the wall to a wooden guide track of an elevator on the other side.

Hot greases, tar, wax, and asphalt materials are flammable. Their flash points and ignition points are higher than petroleum oil or gasoline, but they will ignite at their own proper temperature. This should be remembered in order to safeguard them from any and all flame. Their use is very broad, so it is hard to lay down any set rules for avoiding fire except the one above. If they are being heated for any purpose, careful watching is necessary to avoid overheating. This is very essential if an open flame is used. Containers should also be carefully examined for cracks or defects.

Gas, Natural and Artificial (see Flammable Gases). (Open flame, sparks, pressure, lightning and static electricity.) Since the fire record encompasses the whole country, the fires from gas as a cooking and illuminating medium would naturally include natural and artificial gas. For the purpose in hand, it is not necessary to consider the technical fire hazards of gases, as these are well understood by those who know about the manufacture of artificial gas or the control of natural gas. To those who use these gases for industrial or household purposes, however, a word of warning seems not untimely, as the record shows that greater care is necessary if fires are to be avoided from this source.

Natural and artificial gas are explosive, and the greatest need for care is in avoiding leaks or the accumulation of these gases in low spots or enclosures. Fires result from these gases being ignited by flame or sparks. Open lights, matches used in locating leaks, defective electric wiring, or friction from machinery will ignite them causing fire or explosion. Danger from these gases is present when they come in contact with an ignition medium, and although the cause of ignition and consequent fire is given as gas, it is in reality the open flame or spark, lightning, or static electricity. Caution should be exercised in looking for leaks. (See Table 5-56.)

FIRE PROTECTION

The extinguishment of fire in industrial plants is an essential responsibility of plant management. It will not be a success unless recognized by the executive management as an important permanent addition to the plant operations. Regardless of the size of the plant or establishment, the personnel and workmen should be organized for the purpose of preventing and extinguishing fire. In some plants the plant manager will be the fire-prevention engineer, whose duties are confined to the analysis and correction of fire hazards. The extinguishment and fire fighting will be delegated to a fire chief and private fire brigade. In other plants the analysis and correction of fire hazards as well as the fire fighting are delegated to the fire chief and the plant fire brigade. In still other plants the safety engineer will include in his duties the analysis and correction of fire hazards, and the fire fighting will be delegated to the fire chief and plant fire brigade. In setting up "the defense against fire" within the plant, it is necessary for whoever is responsible for the defense to have a knowledge of those things which comprise the defense. These are

1. A ground plan of the property and all buildings thereon
2. A plan of all available water supplies (public and private), including water mains, reservoirs, sumps, and tanks, with capacities and pressures available at ground level
3. A diagram of all controlling valves, check valves, pumps, hydrants, and hose houses
4. First aid equipment, fire extinguishers
5. Standpipes
6. Yard hydrants and hose streams
7. Automatic sprinkler systems, foam and waterspray or fog
8. Alarm systems

9. **Plant fire brigade**
10. **Attack**
11. **Stock flow method**

Ground Plan. The ground plan should include the boundary lines of the property and plans of all buildings thereon, using the map symbols, as given on previous page, for types of buildings, heights, stairways and elevators, shafts, and window protection.

Plan of Available Water Supplies. The plan of available water supplies should show the water mains by sizes (and open-butt flow tests at ground level). It should also show standpipes and their gauge pressures at top outlets; sprinkler risers and their gauge pressures at top outlets; and reservoirs, sumps, and tanks, with their capacities and pressures at ground level, if elevated.

Diagram of Valves. The diagram of valves should show all controlling valves and check valves (above- and belowground) and post-indicator valves (OS and Y valves on sprinkler system). If single-floor control, it should be so indicated. The diagram should show pumps, indicating the type, capacity, type of power, and location; hydrants, their location, number of outlets, and pressures; and hose houses (if over hydrant) with the quantity of hose in each and their size.

First-aid Equipment.[29] The primary purpose of first-aid equipment is its immediate application to an incipient fire. To accomplish this, it is essential that those who are charged with its application be thoroughly familiar with the characteristics of the portable equipment. It is recommended that all employees and members of the fire brigade be given an opportunity to handle and operate the equipment at drills and at time of recharging so that they will know how they operate, their ingredients, their weight, and the purpose for which they are best suited. This drill will tend to make their attitude one of confidence and familiarity with the instrument.

Fire Extinguishers. The action of portable extinguishing mediums consists in cooling the burning substance to below its ignition temperature, excluding the air supply, or a combination of both, and in excluding arcs in electrical equipment Portable fire extinguishers should be purchased only if they bear the approval of some authoritative testing laboratory such as Underwriters' Laboratories, Inc , or the Factory Mutual Laboratories, not only to ensure the performance reliability and suitability of the device but to ensure safety, as the pressures developed require sufficient strength in the materials used. The quenching, cooling, and blanketing effects are set forth in the plan developed by Underwriters' Laboratories as follows:

Classification of Fires

Class A fires—Fires in ordinary combustible materials, when the quenching and cooling effects of quantities of water or solutions containing large percentages of water are of first importance

Class B fires—Fires in flammable liquids, greases, etc., where a blanketing effect is essential

Class C fires—Fires in electrical equipment, where the use of a nonconducting extinguishing agent is of first importance

Extinguishers are further classified in units of first-aid fire protection, depending on their relative extinguishing capacity under average conditions of use.

As a guide in determining the number of units that should be installed under various conditions, the following recommendations are given:

Class 1—Light-hazard occupancies. Offices, schools, public buildings, etc. Units should be so located that a person will not have to travel more than 100 ft from any point to reach the nearest unit. At least one unit should be required for each 5,000 sq ft of floor area.

Class 2—Ordinary combustible occupancies. Department and dry-goods stores, warehouses, manufacturers, of average hazard. Units should be so located that a person will not have to travel more than 50 ft from any point to reach the nearest unit. At least one unit shall be required for each 2,500 sq ft of floor area.

Class 3—Extra-hazardous occupancies. Woodworkers, paint spraying, dipping, etc. Units shall be so located that a person will not have to travel more than 50 ft from any point to reach the nearest unit. At least one unit shall be required for each 2,500 sq ft of floor area *and any additional units as the severity of the hazard may require.*

Wheeled extinguishers, provided for larger hazards, shall be located within 200 ft of all ordinary hazards or within 75 ft of extra hazards. Classification or designation (in standards) A-2 indicates that the extinguisher is suitable for class A fires and that two extinguishers are required to make a unit.

Fire pails—five 12-qt pails equivalent to one 2½-gal soda-acid extinguisher

Bucket tanks—six 10-qt pails, 40 gal equivalent to one 2½-gal soda-acid

Sand pails—Same as water pails

The manufacturers' instructions as to filling and maintenance should be followed out carefully. All extinguishers should be inspected once a year and tagged.

Use of Extinguishers on Electrical Equipment. Streams directed on a metal plate at 550 volts, alternating current to ground, gave results as shown in Table 5-57.

Table 5-57

	Distance current was conducted
Calcium chloride	6 ft
Soda acid	4½ ft
Foam	5 in.
Water	2 in.
Carbon tetrachloride; carbon dioxide, CO_2; Dry chemical;	Nonconductors at all distances

Streams directed at 550-v switchboard panels having live bus bars and cutouts showed that foam and calcium chloride caused sufficient arcing on the switchboard to blow the fuses.

Table 5-58. Weights of Typical Fire Extinguishers Charged and Ready for Use

Type	*Approx. weight, lb*
1½ gal soda acid, foam or water	20-25
2½ gal soda acid, foam or water	35
2½ gal pump tank	40
5 gal pump tank	65
5 gal foam	70
2½ gal calcium chloride or loaded stream	40–45
1 qt-vaporizing-liquid carbon-tetrachloride	7
1 gal vaporizing-liquid carbon-tetrachloride	25–35
3 gal vaporizing-liquid carbon-tetrachloride	75
7½ lb CO_2	35
20 lb CO_2	55–75
7½ lb dry chemical	40
20 lb dry chemical	55

Soda-acid Extinguisher for Class A Fires. Soda-acid extinguishers are made in two principal sizes—2½ gal liquid capacity and 1¼ or 1½ gal liquid capacity. The materials used are a dry chemical, bicarbonate of soda, designed to be dissolved in water, and a liquid chemical sulfuric acid (H_2SO_4). Reaction of the acid and the bicarbonate of soda produces pressure which expells the liquid from the extinguisher a horizontal distance of 30 to 40 ft at a rate of 2½ gal in 1 min. Protection against freezing consists of a suitable heated cabinet or felt-lined boxing. Antifreezing solutions should not be used in the extinguisher, as they interfere with the operation.

Table 5-59. Antifreezing Solutions, to Make 2½ Gal

Approx. freezing temperature, deg F	Water	Calcium chloride	Specific gravity
10	2 gal, 1 qt	5 lb	1.138
0	2 gal, 1 pt	6¼ lb	1.175
−10	2 gal	7 lb 6 oz	1.205
−20	2 gal	8 lb 6 oz	1.228
−30	2 gal	9 lb 2 oz	1.245
−40	2 gal	10 lb	1.263

Foam Extinguisher for Class A and B Fires. Foam extinguishers are made in two sizes—1½ gal liquid capacity and 2½ gal liquid capacity. The materials used are a dry chemical, bicarbonate of soda, a foam stabilizing agent (soap bark) dissolved in water for the outer compartment, and aluminum sulfate dissolved in water for the inner cylinder. Reaction between the aluminum sulfate and the bicarbonate of soda produces carbon dioxide gas in the form of bubbles with a light precipitate of aluminum hydroxide in the bubble film, which will expel the foam a horizontal distance of 30 to 40 ft at a rate of 2½ gal in 1 min. A 2½-gal extinguisher will produce 18 to 20 gal of foam at ordinary room temperature. Protection against freezing is the same as for soda-acid extinguishers.

Loaded-stream Extinguisher for Class A and B Fires. Loaded-stream extinguishers are made in three sizes—1 gal liquid capacity, 1¾ gal liquid capacity, and 2½ gal liquid capacity. There are also 17- and 33-gal liquid capacity extinguishers in wheeled unit. The material used is a special solution of alkali metal salts, which is a trade secret. *It is essentially an antifreeze solution.* Pressure to expel the liquid is produced by either a CO_2 cartridge or by chemical action. The stream reaches a distance of 30 to 40 ft at a rate of 2½ gal in 1 min. The alkali metal salt solution has an effect on fire that is unlike any other extinguishing agent. On class A fires, the flame is extinguished rather suddenly, and there is a pronounced fireproofing effect in that flash back is materially retarded. The effect on small class B fires has not been explained. There is no smothering vapor to blanket the fire, but there is a chemical action tending to inhibit oxidation. This extinguisher must be recharged annually and after use.

Plain Water Extinguisher for Class A Fires. Plain water extinguishers are made in 2½ gal liquid capacity. The material used is plain water, and a CO_2 cartridge is used to provide the pressure. The cartridge should be weighed and tested for leaks. The stream reaches a distance of 30 to 40 ft at a rate of 2½ gal in 1 min.

Calcium Chloride Extinguisher for Class A Fires. Calcium chloride extinguishers are made in two sizes—2½ gal liquid capacity and 5 gal liquid capacity. Material used is plain water or an antifreezing solution of granulated or flake calcium chloride and water. The pressure to expel the liquid is produced either by a slow-burning fuse cartridge, a CO_2 cartridge, or by chemical action. The stream reaches a distance of 30 to 40 ft at a rate of 2½ gal in 1 min.

Pump Tank Extinguisher for Class A Fires. Pump tank extinguishers are made in two sizes—2½ gal liquid capacity and 5 gal liquid capacity. The material used is the same as in the calcium chloride extinguisher. Pressure to expel liquid is by a hand pump installed in tank.

Vaporizing Liquid Extinguisher for Class B and C Fires Vaporizing liquid extinguishers (carbon tetrachloride base) are made in four sizes—1, 1¼, 1½, and 2 qt liquid capacity. The material used is a specially treated nonconducting liquid having a carbon tetrachloride base, with components added to depress the freezing point to −50°F and to avoid corrosion. The liquid is heavier than air and will not support combustion. Carbon tetrachloride vapor has an anaesthetic effect and if subjected to high temperature decomposes to some extent, forming toxic gases such as hydrochloric acid and phosgene ($CO + CL_2 = COCL_2$). When it is used, caution should be taken to avoid breathing the vapors or gases produced. The stream reaches a distance of 20 to 30 ft at the rate of 1 qt in 1 min The stream of liquid rapidly evaporates to form a smothering vapor. The quantity of vapor from 1 lb of liquid is approximately 2½ cu ft at room temperature. These extinguishers are made in 1-, 2-, and 3-gal capacity for special use, in pump-type and stored-pressure-type extinguishers, using either air or CO_2 gas.

Carbon Dioxide Extinguisher for Class B and C Fires. Carbon dioxide extinguishers are made in six sizes—2, 4, 7½, 10, 15, and 20 lb. The material used is CO_2 under pressure in a liquid condition. The stream reaches a distance of 3 ft at a rate of 2 lb in 11 sec. Carbon dioxide at ordinary temperature and atmospheric pressure is a gas, 1½ times as heavy as air. It is inert and will not support combustion. The pressure in the container is the vapor pressure of CO_2, which varies with the temperature. It is reduced to a liquid by pressure if the temperature is below 88°F, the critical temperature of CO_2. At ordinary room temperature (68°F) the pressure is between 800 and 900 psi. One pound of liquid CO_2 converted to a gas will occupy approximately 8.6 cu ft. Carbon dioxide gas, like any inert gas, will produce suffocation owing to oxygen deficiency. The extinguisher should be weighed annually for leaks. A loss of 10 per cent is normal.

Dry-compound Extinguisher for Class B and C Fires. Dry-compound extinguishers are made in three sizes—7½, 12, and 20 lb. The material used is bicarbonate of soda which has been chemically processed to make it waterproof and free flowing. Pressure is generated by a CO_2 gas cartridge. The stream reaches a distance of 14 ft at a rate of 7½ lb in 17 sec. Dry-compound wheeled engines are available in 150- and 350-lb sizes, with pressure furnished by nitrogen gas. The streams from these reach a distance of 35 ft at a rate of 150 lb in 1 min and 350 lb in 3 min, respectively. Dry-compound extinguishers should be inspected every 6 months.

Fire Pails for Class A Fire. The 12-qt pail is standard.

Sand Pails for Class B Fire. A 12-qt, fine, dry, clean, sand scoop should be provided (see Antifreezing Solutions for unheated areas).

Soda and Sawdust for Class B Fires. Bicarbonate of soda and sawdust in bins with scoop is the usual equipment.

Glass-bulb and Bottle Extinguisher for Class A and B Fires. Carbon tetrachloride is used in bulbs or bottles. This type of extinguisher is used in confined spaces or applied directly on incipient fires (see Vaporizing Liquid Extinguisher for physical properties).[30]

Standpipes. A well-designed, -equipped, and -maintained standpipe system constitutes one of the best means for the extinguishment of fire in buildings as it is the only reliable means of obtaining effective fire streams at the upper stories of high buildings in a short space of time.

Standpipe systems are designed for two types of service—for small hose streams for use of occupants of building and for large hose streams for use of public fire departments or plant brigades.

For small hose streams for use of occupants, 1½-in. unlined linen hose, with ⅜- or ½-in. nozzle, with not more than 100 ft at each outlet should be provided. The hose should be coupled to a control valve, either straightaway or globe and carried in an approved rack. Drip connections should be provided as hose is liable to rot at the coupling, gaskets should also be replaced at intervals. Where the pressure exceeds 50 psi, an adjustable reducing valve should be provided. For large hose streams for public fire department or plant brigade 2½-in. unlined linen hose with 1- or 1⅛-in. nozzle should be used. In large systems, the hose may not be attached, as the fire department may prefer to bring in its own hose. Hose can also be stored at various floor levels for use of public departments. Reducers can be provided if both small and large hose are to be used on the same system. The smaller size hose is sometimes attached to automatic sprinkler systems.

The size of standpipes is governed by the size and number of fire streams needed and by the distance of the outlets from the source of water supply. Standpipes for small hose streams should not be less than 2 in for buildings 55 ft in height; 4 in. for buildings 55 to 75 ft in height, 6 in. for buildings 75 ft or over in height; and 2½ in. for theaters on both sides of stage.

The number of standpipes should be arranged so that all parts of every floor can be reached within 30 ft, from a nozzle attached to 100 ft of hose connected to a standpipe, *e.g.*, an area covered by interlocking circles having a diameter of 130 ft. Outlets for occupant use should be located in floor area. Standpipes should be located in fire-resistive stairways, or near fire escapes or fire towers so as to be available for public fire department's use.

Water Supply for Standpipes. The value of the water supply for standpipes should be considered in the following order: City water-works system, where the domestic pressure is adequate, should be not less than 250 gpm for one riser or 500 gpm for two or more risers. The supply should deliver 1 hr pressure at 40 to 50 lb at topmost 2½-in. outlet, discharging through 50 ft of 2½-in. CRL hose with a 1⅛-in nozzle. Twenty pounds at topmost outlet flowing pressure is the minimum acceptable It is a practice to add 25 lb to pressure requirements for all standpipes.

Where fire pumps are required, for buildings up to 150 ft high, the sizes should be 500 gpm for 4-in. standpipe; 750 gpm for 6-in. standpipe or two 4-in. pipes; and 1,000 gpm for two or more 6 in. pipes.

At least one fire-department connection should be provided for each standpipe.

Water pressure should be maintained at all times in standpipes. If building is unheated, water should be controlled by manually operated remote-control valves or automatic dry valves. Monitor nozzles and hose houses can be placed on roofs.

Yard Hydrants and Hose Houses.[31] Where hose is kept connected to hydrants in hose houses, a fire line can be laid and water turned on in approximately one-half minute, as compared with 2 or 3 min where a hose cart must be run up, the hose coupled to the hydrant, run out, and the nozzle attached, before the water is turned on.

The standard mill-yard hose house embodies the features of protection against the weather and ventilation, the ventilation being secured through slatted floors and shelves and vent spaces under the overhanging roof, so arranged so that rain cannot drive into the building. At least 100 to 150 ft of 2½-in. cotton-rubber-lined hose should be attached to one outlet. One shelf in a standard hose house, will hold 150 to 200 ft of single-jacket cotton-rubber-lined hose, folded forward and back, so placed that it can be readily inspected. To determine the length of hose required in a hose house, a line should be laid in easy curves from the hydrant to the building, through the door, up the stairs, to the top story of the building, and then a stream played from a far window. A hose should also be taken up an extension ladder to the roof, allowing one length (50 ft) on roof. Make sure that hoisting ropes and hose straps are kept in hose house. There should also be sufficient hose available to reach to the far side of a building, remote from the hydrant, and a safe and effective distance from the building. If it is necessary to lock the hose house, a special lock with brittle shackle should be used or a latch placed behind a glass plate which can be broken easily.

Accessory Equipment for Hose Houses. Accessory equipment for hose houses should consist of the following:

Standard play pipe (one for each hydrant outlet) 30 in. long with swivel handles and 1⅛-in. smooth-bore tip
2 play-pipe holders
4 to 6 tabor spanners
1 fire axe weighing 6 lb
1 1¼-in. by 5-ft crowbar
2 hose straps
1 extra hydrant wrench
1 heavy mill lantern kept filled and ready for use
4 to 6 extra washers for hose couplings
1 hand line of ½-in. manila rope, long enough to reach roof of highest building

Public and Private Water Supplies. The following data may be helpful to private plant brigades:

The capacity of any public water system is determined by the total amount of water it must furnish. This is the sum of

1. Water required for domestic or industrial use
2. Water required for fire service

In rural districts the water problem has these phases:

1. The population needs, domestic, near centers
2. The population needs, domestic, away from centers
3. The fire-protection requirements which involve small congested areas spreading fires owing to shingle roofs and brush fires

In cities, the problem has three phases:

1. The population needs, domestic
2. The fire service needs, domestic and industrial
3. The fire service needs, conflagration

The general domestic water consumption will range from 40 to 250 gal per capita, varying with the peaks of daily consumption and seasonal variations, including wastage from underground piping and carelessness in private use.

Fire service or fire flow based upon average conditions found in communities of various sizes is shown in Table 5-60.

A fire requiring 10 streams for 5 hr would use 750,000 gal of water. A standard fire stream is taken at 250 gpm, 50 psi, with 1⅛-in. standard play pipe.

To determine the reliability of the water supply, the following should be taken into consideration.

1. Frequency of and duration of drought
2. Condition of intakes
3. Danger from earthquakes or seismic disturbances
4. Physical injury
5. Reservoirs out of service for cleaning
6. The condition, arrangement, and reliability of individual units of plant equipment, such as pumps, engines, generators, electric motors, fuel supply, and electrical-transmission lines
7. Combustible construction of pumping stations
8. Machine shops connected with maintenance

Table 5-60. Required Fire Flow for Average City, Gpm*

Population	*Fire flow, gpm*
1,000	1,000
2,000	1,500
4,000	2,000
6,000	2,500
10,000	3,000
13,000	3,500
17,000	4,000
22,000	4,500
28,000	5,000
40,000	6,000
60,000	7,000
80,000	8,000
100,000	9,000
125,000	10,000
150,000	11,000
200,000	12,000

NOTE. Over 200,000 population, 12,000 gpm with 2,000 to 8,000 additional for a second fire.

* NBFU.

Spacing of Hydrants. Hydrants and pipes are cheaper than hose in the long run, so frequent hydrant spacing is desirable.

The minimum satisfactory pressure at which water can be supplied for fire pumpers is 20 lb at the hydrant. If supply for automatic sprinklers is taken direct from municipal water mains or yard systems, normal pressure should give 15 lb on top line of sprinklers with 250 to 500 gal flowing. For extra hazards, pressures from 50 to 75 lb are desirable.

Table 5-61

Fire flow required, gpm	Average area per hydrant, sq ft	
	Engine streams	Direct hydrant streams
1,000	120,000	100,000
2,000	110,000	85,000
3,000	100,000	70,000
4,000	90,000	55,000
5,000	85,000	40,000
6,000	80,000	40,000
7,000	70,000	40,000
8,000	60,000	40,000
9,000	55,000	40,000
10,000	48,000	40,000
11,000	43,000	40,000
12,000	40,000	40,000

Piping. Piping should be no less than 6 in. in diameter for fire service. Depth of cover to prevent freezing will vary from 2½ ft in the South to 10 ft in the North.

Hydrants. Hydrants should not be distributed more than 300 or 400 ft from buildings to be protected, as hose lines of 400 or 500 ft are difficult to handle. If hose streams are to be used direct from hydrants, the spacing should be 100 ft less. Hydrants should be placed 50 ft from building to prevent damage from falling walls. *Testing hydrants* for freezing: may be accomplished by sound by striking the hand over open outlet; water or ice shortens the length of sound tube and raises the pitch. The stem should be tried; if frozen solidly, it will not turn. Tapping on hydrant nut may release it if it is not frozen solidly. If a weight is lowered on a string into hydrant, it may strike ice or water, shown if the weight is wet. Steam should be used to thaw out the hydrant.

Valves. Fire-prevention inspectors must be valve-conscious. Many plants have been destroyed, because a valve was closed.

Reservoirs. Reservoirs form a good source of water supply if adequate. A fire flow of 10 hr is adequate for large cities or similar needs. A fire flow of 5 hr is adequate for cities of 2,500 population or with similar needs. Auxiliary sources consist of ponds, swimming pools, cooling tanks, rivers, and streams. Streams of 1,000-gpm flow are acceptable, with suitable approach for fire-engine suction. For a fire pump of 1,000-gpm rating, a tank or reservoir for suction should have a 100,000-gal capacity.

Gravity Tanks. Gravity tanks are usually built of wood or steel and supported on steel towers. If there is exposure within 20 ft of tower, steel should be fireproofed.

All brush should be cleared from vicinity of tower. Steel tanks of 50,000- to 100,000-gal capacity should have four-column support. Steel tanks of 100,000- to 300,000-gal capacity should have six-column support. Steel tanks of over 300,000-gal capacity should have eight-column support.

If the tank is directly connected to fire service and is to supply hose lines from hydrants, a minimum capacity of 30,000 gal with the bottom of tank not less than 75 ft above ground is required. For unsprinklered buildings where hose streams are relied upon for protection, the bottom of the tank should be 40 ft above the roof of the highest building.

Supports for tanks should preferably be in the ground. If supported on buildings, they should be located over noncombustible stairways or an elevator tower. Buildings should be examined by competent engineers to determine their ability to sustain the load including trestle or towers. Drops should be protected from freezing by suitable boxing. Tank lumber can be treated against rot by preservatives such as sodium fluoride, creosote, or zinc chloride. Tanks can be heated by steam from boilers at not less than 10 lb of pressure. Pits containing OSandY gates and checks should be heated to 40°F during freezing weather. Water-level indicators are of the float or mercury-gauge type, but when there is doubt, the tank should be flooded. Flat hoops, subject to rust, on wooden tanks are obsolete (see Hurricanes).

Pressure Tanks. Tank capacity of pressure tanks is the total combined, including water and air, not including dish ends. Tank capacity should be 4,500 gal for light occupancy, but 3,000 gal is acceptable. Capacity should not exceed 9,000 gal. It is preferable to use two 4,500-gal tanks. Tanks should be kept two-thirds full of water, and an air pressure of 75 psi maintained. When the bottom of the tank is located below the highest line of sprinklers, the air pressure should be three times the pressure caused by the column of water in the sprinkler system above the tank bottom, plus the 75 lb. Pressure tanks should be tied into system 40 ft below the bottom of pressure tank and gravity tank to prevent water lock. They should be installed in incombustible buildings, kept painted, and given a hydrostatic test every 2 years.

Air Compressor. An air compressor should be capable of delivering 16 cu ft of free air per minute for tanks of 7,500-gal total capacity; 20 cu ft of free air for larger sizes. Steam or electrically driven compressors should be located in tank houses

Fire Pumps (specified by Underwriters' Laboratories, Inc., or Associated Factory Mutual Laboratories). Fire pumps should be located in rooms or buildings so constructed as to prevent damage from falling walls. floors, or machinery and from smoke, fire, and water which may prevent their operation. Troubles with pumps can be traced to defects in suction lines. Suction pipes should be tight and should be laid to true grade. Air traps should be avoided. The greater the lift, the less the length of the suction should be. Foot valves should be provided for all centrifugal pumps and for rotary and steam pumps having a suction lift of over 10 ft or suction pipe over 100 ft long with any lift. Screens should be provided, where needed, with an approximate area of ten times the area of the suction pipe.

Pump Capacities (feeding Automatic Sprinklers only). For light hazards, the pump capacity should be 250 gpm, for ordinary hazards, 500 gpm; and for heavy hazards, 1,000 gpm. Occupancy, construction, size, and value of property should be considered.

Steam Pumps. Steam pumps should conform to the specifications for Underwriters steam-fire pumps published by the Factory Mutual Laboratories. See also the NBFU Standards.

To test for condition of steam pumps, all valves should be closed, the pop valve should be set at 100, if piston moves, the travel should be measured (140 fpm is usual travel).

Centrifugal Pump. The centrifugal pump is a casing in which a disk or impeller carrying vanes rotates at high speed. By increasing the speed of an impeller, by increasing its diameter, or by arranging two or more impellers in series (multistage), higher pressures may be obtained. The pump can be driven by an electric motor, gasoline engine, or steam turbine, since the speed of the pump and prime mover may be the same, thus permitting direct connection.

Table 5-62. Standard Steam-pump Sizes for 1,000 Gpm

Pump sizes, in.			Ratio	Capacity at 100 lb at pump	Boiler power required, hp steam 150 pres. at pump, lb	Full speed, rpm	Piston travel, fpm
Steam	Water	Stoke					
18	10	12	3:1	1,000 $\frac{999}{1{,}050}$	45	70	140

Pumps are made in six sizes—500, 750, 1,000, 1,500, 2,000, and 2,500 gpm.

Maximum speeds for centrifugal fire pumps are usually 1,800 rpm, but in some cases, speeds are as high as 3,600 rpm. The minimum-size fire pump recognized is 500 gpm for supplying standpipes and sprinklers; 750 gpm, for supplying both sprinklers and standpipes; and 750 gpm, for supplying hydrants.

In light hazards pumps with a capacity of 250-gpm for sprinklers only and pumps of 500-gpm capacity should supply sprinklers and standpipes.

Pumps should be primed by a 250-gal tank or other reliable source.

Rotary Pumps. The rotary pump is simple in construction and inexpensive, but wasteful of power. It is generally of the double-shaft (or twin) type with cams or buckets which intermesh, the pump being direct-connected by a spur gear or gear clutch or by a friction gear. The cams are keyed to the shafts as are the gears. The gears and cams are so fitted that when the gears are properly in mesh, the cams just touch each other. Cams cannot be fitted absolutely tight, and there is an unavoidable slip or passing of water back into the suction. Bronze fittings have eliminated wear and corrosion. The rotary pump takes water under a slight head. Pulsation is reduced by having air chambers attached. Discharge outlets should not be less than 6 in. for 500-gpm pumps; 8 in for 750- to 1,000-gpm pumps; and 10 in. for 15,000-gpm pumps. Stuffing boxes should be checked for leaks. Bearings should be lubricated.

Booster Pump. Booster pumps with a capacity of from 30 to 100 gpm are used in conjunction with a water tank of 80-gal capacity. An 80- or 100-gal tank takes the same space as a 40-gal chemical tank. Rural districts use tanks of 300 gal or larger. Some fire departments carry lines of $1\frac{1}{2}$-in. hose with $\frac{1}{2}$- or $\frac{5}{8}$-in. nozzles connected to large booster tanks for use in dwelling and brush fires. The booster pumps supplied by OCD are centrifugal gasoline-driven pumps on trailers or tied onto front of motor trucks.

Automatic Sprinkler Systems. An automatic sprinkler system is the extension of the public water system or private-supply installations to every part of a building by a network of piping of reducing sizes, with automatic spray valves placed at intervals on this piping system, which, when activated by the convected or radiated heat of a fire, permit water to be sprayed upon a predetermined area. The design of the system is based upon the nature of the occupancy; the possible fire intensity, which includes the character of the raw stock, the process, and the finished product; the area exposed, the internal exposure to fire spread, and the external exposure to fire attack; and the character of the building that houses the occupancy.

Types of systems designed to meet these requirements are automatic wet system, automatic dry system, automatic deluge system, thermostatic preaction system, open sprinkler system, and nonfreezing solution system.

The auxiliary water supplies, which enter the design of the systems, are taken from gravity tanks and pressure tanks and from underground sumps. To augment the water pressure from public mains and private water supplies, the design may include pumps, either steam or electrically driven, of the piston, cam, or vane type, known as positive displacement, rotary, or centrifugal, respectively.

The standard requirement for automatic wet systems is that water shall be delivered to the spray valve or sprinkler head, located on the highest pipe lines, at not less than 15 psi with a flow of not less than 100 gpm per head for all heads in the largest single fire area. These requirements are minimum for ordinary occupancies, but where the heat intensity, owing to character or quantity of the combustible material present, warrants, they are augmented to effect the control of fire.

The design of the system must also take into consideration the type of building construction, particularly the floor spaces, bays, and ceiling contours, vertical and horizontal openings, roof type (peak or saw tooth), skylights (monitor, Texas), and roof structures. The shape of the floor area is also important as this determines the layout of the piping network.

The internal temperatures which result from the heat intensity of the occupancy and all the equipment it entails in the effective control of fire are based upon the speed of operation of the sprinkler head activated by these temperatures. The external temperatures (weather) are important factors in the design, as the freezing of water in any part of the system will impair its effectiveness.

The above requirements may be termed the basic factors of design, and upon these the system is laid out to protect the single structure, series of structures, or multiple fire divisions in a single structure.

The foremost intent of the installation of an automatic sprinkler system, however, is "the extinguishment of fire in its incipient stage," and the design of the system should be such as to accomplish this purpose.

Table 5-63. Sprinkler Pipe Sizes*

Size of pipe, in	Light	Ordinary	Extra hazard
¾	Eliminated		
1	2	2	1
1¼	3	3	2
1½	5	5	5
2	10	10	8
2½	40	20	15
3	No limit	40	27
3½	No limit	65	40
4	No limit	100	55
5	No limit	160	90
6	No limit	250	150
8	No limit		

* NFPA 1940 Standard.

The details of the design of the system must take into account the adequacy and control of water supply; fire areas; test devices for water flow due to fire or leakage; alarms and detectors; air supply for dry-pipe systems; accelerators and exhausters; thermostats for preaction systems; valves, check valves, dry valves, heaters for tanks, meters on public supplies, post-indicator valves for the control of sections; protection against freezing of tank drops; corrosion and pollution, hose attachments, building-construction details; tightness of floors; curtain boards; scuppers; steam pressure for pumps; electrical equipment; supervisory systems such as ADT to call outside aid or fire department; yard hydrant system for outside protection; hose houses; maintenance and supplies, additional heads; and necessary tools to make repairs.

The 1940 standard provides for three classes of occupancy.

A—Light-hazard occupancies. This includes apartment houses, asylums, clubhouses, colleges, churches, dormitories, dwellings, hospitals, hotels, libraries, museums, office buildings, schools, and tenements.

B—Ordinary-hazard occupancies. This includes mercantiles, warehouses, manufacturing, and occupancies not covered by A or C.

Table 5-64

Flowing pressure, psi	*Discharge, gpm*
5	12 80
10	18 10
20	25 80
30	32 80
40	37 20
50	42 20

C—Extra-hazard occupancies. This includes only those buildings or portions of buildings where the hazard is severe as determined by the inspection department having jurisdiction.

It will be seen by the foregoing that in the 1940 standard consideration was given to the theory of heat intensity and quantity of combustible material as determined by the occupancy. In terms of immediate extinguishment, this will call for wider or closer distribution of water but will not affect the quantity of water flowing from the sprinkler head other than the quantity that would flow under a given pressure. The Underwriters' Laboratories' test in 1926 indicated the quantity of water per head as shown in Table 5-64.

Formulas for the discharge from orifices, according to Factory Mutual Laboratories, are as follows:

$$\text{Gpm} = 29.83CD^2\sqrt{P}$$

where C = coefficient of discharge
D = diameter of outlet, in.
P = pitot-tube pressure, psi

Coefficient = 0.90 for smooth and well-rounded outlet
0.80 for square and sharp outlet
0.70 for square outlet and outlet projecting into barrel

For ordinary use $29.7D^2\sqrt{P}$ can be used. For sprinkler heads *only*,

$$\text{Gpm} = 5.6\sqrt{P}.$$

For required quantities on top lines gpm = $\frac{1}{2}P + 15$ lb. Average flow in sprinkler fires = 5,000 gal, which would fill a tank 12 by 12 by 5 ft. Standard sprinkler heads have $\frac{1}{2}$-in. ring nozzles or $\frac{7}{16}$-in tapered nozzle.

Sprinkler Valve or Head. There are approximately six types of sprinkler valves or heads

1. Link and lever
2. Frangible (fragile) bulb, nonsolder
3. Spring, lever, and strut
4. Duckbill
5. Chemical, nonsolder
6. Triangular strut

The frangible (fragile) bulb nonsolder-type head is a quartz bulb nearly filled with a liquid (tetrachloride of carbon) which expands when heated, shattering the bulb and releasing the valve cap The chemical type (Saveall) contained in the strut is a small cylinder filled with a low-fusing chemical This chemical liquefies at the rated temperature and allows the strut to collapse, releasing the valve cap. The pendant is a special type which prevents clogging Sidewall sprinkler heads have flares attached to deflect the water from the wall about 15 ft. They should only be used in special places. Picker-trunk sprinkler heads have a smooth deflector attached to avoid collection of dust Chloride of calcium sprinkler head is a special design for this type of equipment.

These are furnished in various patterns—plain, ornamented, wax-coated, lead-coated, wax- and lead-coated, calcium chloride, lacquer- and wax-coated, upright, pendant, picker trunk, and sidewall. Most of the heads used are of the solder type (a metal strut and fusible solder).

Tests of sprinkler heads should be made at about 15-year intervals. Tests in the field can be made by cutting the solder if fragile or flaky, head should be removed. An extra supply of heads should be kept on hand at all times and kept at a temperature not exceeding 100°F. The operating parts of a sprinkler head should never be painted.

Table 5-65

Max temp. at ceiling, deg F	Type rated	Operating temperature, deg F		Color
		Nonsolder	Solder	
100	Ordinary	135 150	155 165	Bronze
150	Intermediate	175	212	White
225	Hard	250	286	Blue
300	Extra hard	325	360	Red
375	Extra hard	400	360	Green
475	Extra hard	500	300	Orange

Temperature ratings of a sprinkler head approximate the temperature at which the sprinkler head operates in a hot-water bath at a slowly rising temperature.

Where room temperatures exceed 100°F or in any space subject to the heat of the sun's rays, it is better practice to use the next highest test head for margin of safety.

Network or Piping. If reference is made to differentiate a system such as 1-2-3, 1-2-4, or 2-3-5, this refers to the number of sprinkler heads on a given size of pipe (branch lines).

1 head on a ¾-in. pipe or 2 heads on a 1-in. pipe
2 heads on a 1-in. pipe or 3 heads on a 1¼-in. pipe
3 heads on a 1¼-in. pipe or 5 heads on a 1½-in. pipe

The piping increases as it reaches the riser. The pipe sizes have been figured to allow sufficient water to reach the sprinkler head without undue loss by friction. The design of the network of pipes is governed by the floor construction, as all sprinkler heads should be in an upright position wherever possible. The deflector or spray shield should not be more than 10 in. or less than 4 in. from the ceiling or bottom of beams or joists (in fire-resistive construction, 14 in.) (see Fig. 5-7). The sprinkler head should be so placed that all parts of the ceiling are sprayed by the water.

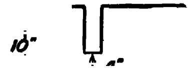

FIG. 5-7. Clearance between sprinkler and ceiling.

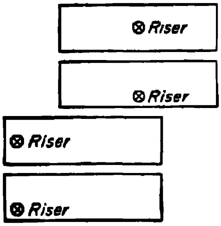

FIG. 5-8. Automatic sprinkler riser positions to accommodate construction types.

The spacing of sprinkler heads is generally staggered so that all intervening spaces are covered. End sprinkler head on alternate lines should not be more than 2 ft from wall; alternate line, 4 ft. Network designs follow four general patterns (see Fig. 5-8).

The center central feed is the most efficient network design as the others favor friction loss.

Table 5-66. Spacing and Area

Cons. of ceiling	Max. sq ft per sprinkler		Max. spacing bet. lines and bays, ft	
	Ord. haz.	Light haz.	Ord. haz.	Light haz.
Fire resistive	100	196	12	14
Mill	100	168	12	14
Semimill	90	144	10	14
Open joist	80	80	8 right angle to joist	8 parallel to joist

Risers. The size of the riser depends upon the number of sprinkler heads on any one floor or section fed by the riser (see Table 5-63). For 400 heads on an 8-in. pipe, it is preferable to use two or more 4- or 6-in. risers than one 8-in. riser where there are more than 250 heads on a floor.

EXAMPLE: Floor or section area is 50 by 100 ft = 5,000 sq ft, divided by 80 sq ft = 63 heads.

$$20 \text{ psi on head-gpm} = \tfrac{1}{2}P + 15 = 25$$
$$25 \times 63 = 1{,}575 \text{ gpm for } 20 \text{ min} = 31{,}500 \text{ gal}$$

All floors or sections should be equipped with scuppers, two to each 250 gal flowing. The water flow from the riser to the network of piping is controlled at each floor or section by OSandY valves (outside screw and yoke). These are sealed open with a dated tag (to prevent tampering). Check valves are placed in the piping to maintain pressures and control from yard main, tanks, etc. PIV (post-indicator valves) are installed to control water supplies to buildings and sections and to cut out valves for repairs. Certain types of systems have a single-control OSandY valve at the base of the riser for a single building or section. This necessitates shutting down the entire water supply to the network in case of fire. The control by floors or single sections shuts off only that area where the fire occurs and is confined, thus making it possible to save water damage and to restore service promptly.

Hydrostatic Test. The entire system when completely installed should be subjected to a hydrostatic test of 200 psi for 2 hr or 50 lb above the normal pressure when the normal pressure is in excess of 150 lb. The general practice is to test at 200 psi plus 50 psi for 2 hr. All tests should be made by the installing company with an inspector (from rating bureau) present, and a written statement should be furnished that the work has been completed and tested in accordance with the approved specifications and plans.

Details of Automatic Sprinkler System. The *base of the riser* where it connects to the main water supply should be carried to a point below the frost line and from this point to the floor of the building. It should be protected against freezing by suitable boxing or brick walls filled with solid earth.

CONTROL VALVES. The control valves should be OSandY, inside buildings, in pits, or aboveground. Underground valves, controlling main lines or sections, should be of the post-indicator type PIV.

CHECK VALVES. Check valves should be of the straightaway pattern, placed in a horizontal position. If double checks are used, they should be arranged so that inspection is made easy.

FITTINGS. Long-turn fittings are preferable. Extra-heavy fittings are required if normal pressure exceeds 175 lb.

HANGERS. For piping, see listing by Underwriters' Laboratories.

CORROSION. Nonferrous metal is used for sprinkler parts, but special coatings are needed when parts are exposed to corrosion, chemicals, or vapors, such as wax, lead, paper, or glass globes.

TEST PIPES. On all 4-in. or over risers, a 2-in test pipe is required which should discharge to the outside of the building. A 1-in. test pipe should be installed on wet systems near the top of the system or riser for use of inspector. A 1-in. test pipe should be installed on dry systems on the end of the most distant branch lines. A test gauge should be installed at the test pipe to note the drop of pressure, if any.

ALARMS. All sprinkler systems should be equipped with alarm devices to notify those responsible for its care and also the authorities, such as fire department or special services These alarms are attached to the system at or near the base of the riser to indicate the slightest flow of water. There are many types of alarms, including the vane or paddle type, with make-and-break electric circuits, vertical checks with electric attachment; retard-chamber types which prevent false alarms, water-flow gongs, and electrical water-flow gongs. All valves, checks, and alarms should be clearly marked.

SUPERVISORY SYSTEMS. Supervisory systems are those which are under supervision of a special service of American District Telegraph which responds when the alarm is given by sending a messenger to the plant and also to the fire department.

PROPRIETARY SYSTEMS. Proprietary systems are those within the plant to notify the employees and local fire defense.

OBSTRUCTION. A clear space of at least 24 in. should be maintained under all sprinklers.

Maintenance. Automatic sprinkler systems should always be maintained at the highest efficiency. A record of 21 years shows unsatisfactory conditions as given in Table 5-67.

Sprinkler Leakage. Sprinkler leakage is accidental leakage or discharge of water from the sprinkler system, which includes piping, heads, tanks, and other water supplies. Systems are rugged and are subjected to heavy pressure. Sprinkler heads will not break unless injured. Fifty per cent of the leakage cases are due to accidents to sprinkler heads.

Freezing. Freezing of sprinklers is generally caused by lack of heat in exposed places such as roofs and skylights and end pipes near windows; concealed spaces; windows left open; incorrect pitch of lines; and poor drainage.

Undesirable Conditions. Some undesirable conditions are change of occupancy, which may call for change of heat temperature rating, lack of heat, improper mechanical conditions with risers not properly supported, and strains due to settling of building or ground.

Table 5-67

	Cases
Water shut off	1,370
Unsprinklered portions	26,669
Defective water supplies	2,607
Freezing	5,049
Dry systems not maintained	2,564
Wrong temperature rating of sprinklers	2,260
Obstruction to distribution	11,001
Alarm valves and gongs out of order	9,197
Gate valves, repair needed	7,805
Gravity tanks, repair needed	4,450
Pressure tanks, repair needed	1,596
Fire pump, repair needed	184
Outside sprinklers with plugged heads	208

Table 5-68. Effects of Sprinklers

Effect	Fires, 1897 to 1939, inc.	
	No.	Per cent
Practically or entirely extinguished	44,256	70
Held in check	16,500	26.1
Total	60,756	96.1
Unsatisfactory	2,490	3.9

Water Supplies. Water supplies are treated under Public and Private Water Supplies (page 248) and consist of fire-department connections, city water, gravity tanks (from 5,000 to 100,000 gal), pressure tanks and fire pumps and underground sumps.

Outside Sprinklers. (See Exposure.) For pipe sizes and supplies see NBFU Standards on Automatic Sprinklers.

Table 5-69. Pipe Sizes for Six Stories (Counting Down)

	Orifice, in.	Riser size, in.	Branch lines, number of heads		
			⅜ in.	5/16 in.	¼ in.
Top line	⅜	1½	6	6	6
5	⅜	2	10	10	10
4	5/16	2½	20	20	20
3	5/16	3	36	36	36
2	¼	3½	55	55	55
1	¼	4	72	72	72

Not more than six heads should be used on a branch line. Cornices should be treated the same as windows. For ridgepoles ⅜-in. orifices, 6 ft apart, should be used.

Deluge System. The purpose of the deluge system is to wet down an entire area all at once by admitting water to open sprinklers. These systems can be operated manually or by thermostatic or rate-of-rise control. Deluge systems are used on extreme hazards, films, lacquer, spray coating, cotton nitrating, and airplane hangars. These systems have from 75 to 150 heads, and the usual requirements are doubled.[32]

Preaction Systems. Preaction systems are designed to eliminate the delay in the discharge of water which occurs in the operation of dry-pipe systems. An air pressure of 1 or 2 lb is maintained on the system. If this pressure is relieved, an alarm is given, and a deluge or hydraulic valve is opened. This also prevents the danger of premature or accidental operation of automatic sprinklers.

Automatic Rate-of-rise Systems. A heat-activated device is fastened to the ceiling and connected by a copper tubing containing air. The impulse caused by increase of air pressure operates an "automatic release." This device gives an alarm, closes fire doors, opens explosion vents, releases water to the sprinkler system, and stops fan motors, etc. The automatic "Supertex" system is a development of the preaction system. It operates on $1\frac{1}{2}$ lb of air.

Dry-pipe Systems. The piping system for dry systems is the same as for wet systems, the difference being that the dry system is filled with air under pressure which is controlled by a dry valve. When the dry valve operates, the system acts like a wet system.

Dry Valves. Dry valves are generally of two types—the differential type and the mechanical type.

The differential type of dry valve has two clappers of unequal size. The tripping point of one clapper to the other is determined by the ratio of area. The ordinary ratio of water to air is 6:1, *e.g.*, water pressure of 50 to 100 lb will take an air pressure of 15 lb. As a factor of safety, 30 to 40 lb of air may be carried.

In the mechanical type of dry valve the clappers may or may not be of the same area. The air clapper holds the water clapper shut by a series of levers and a stress screw. This type is obsolete but will be found in many plants.

Not more than 600 sprinklers should be on a single dry valve. Dry-pipe valves controlling more than 300 sprinklers should be equipped with quick-opening devices. Dry valves should be located in accessible places as near to the sprinkler system they supply as possible and protected from mechanical injury and freezing.

Air Pressure. The automatic sprinkler system should not lose more than 10 lb of air per week. It is permissible to carry 20 lb over the tripping ratio. The air compressor should be able to supply the normal air pressure times 25 per cent in 30 min. Relief valves should be set between compressor and controlling valve (on line) to 5 lb excess over maximum required. Water supply should enter below dry valve. A 2-in test pipe should be located between control valve and dry valve. A 1-in. test pipe should be provided also. All sprinklers should be in an upright position. All piping should be arranged to drain properly and be protected from freezing.

Records show that twice as many sprinklers open on dry systems as wet systems. The fire record shows the following for a 5-year period with a total of 2,130 fires: For 1,961 fires, sprinkler operation was satisfactory (92.1 per cent); for 169 fires, sprinkler operation was unsatisfactory (7.9 per cent). The setting up of the dry valve should be studied in order to understand its technique.

Inspection of Dry System. The main gate should be checked. It should be open and fastened. The air pressure and water pressure should be noted. The 2-in. pipe should be tested, and the air compressor should be checked. The dry valve should be tested for water above the valve (at air test pipe). If water is present, it should be drawn off slowly if quick-opening devices are attached.

Nonfreezing Solutions. Calcium chloride or sodium chloride should be used in cold-storage warehouses as well as glycol and glycerine.

Quick-opening Devices. On systems of over 300 heads, quick-opening devices should be employed.

The accelerator type of quick-opening device operates as follows: When sprinklers open and air pressure drops 1 or 2 lb, the diaphragm becomes unbalanced. This forces open a valve which permits the air to enter the intermediate chamber of the differential valve, and the valve trips.

The exhaustor type of quick-opening device operates as follows: The diaphragm causes a larger valve to open, and the air discharges by a 2-in. outlet to the outer air. The exhaustor takes a little longer time, but the water reaches the sprinklers in about the same time.

Alarms. The alarms on dry systems should be the same as those used on wet systems.

Cost of installation of automatic sprinkler systems can be given only after a complete analysis is made of the plant. For a rough estimate of approximate initial cost, however, the following items can be considered: entire floor-plan area, including basement, attics, and roof structures and all areas in concealed spaces, decks, and tables. This entire square-foot area divided by 80 will indicate the number of heads needed. The price per head area will range from \$20 to \$30, or an average of \$25.

Additional charges for dry-pipe systems may increase the cost 15 to 20 per cent. The city meter charge varies greatly as to whether the public water supply is municipal or private. The cost of gravity tanks, pressure tanks, outside sprinklers, and rate-of-rise systems has to be ascertained. This estimate in no wise fixes the price of the entire installation as this must be given by the installing company.

Special Types of Extinguishing Systems.[33] *Foam Systems.* It has been demonstrated that the extinguishment of fires in tanks of flammable liquids by smothering them through the use of foam on the surface of the liquid can be successfully accomplished. The use of this form of protection is particularly indicated where the usual means of extinguishment involving the use of water may be undesirable. Foam has the quality of flowing over and floating upon most flammable liquids, and it also adheres to most surfaces, thereby protecting them against fire by displacing the oxygen and cutting off the further formation of burnable gases. The foam consists of minute bubbles of carbonic acid gas and has a smothering action on the fire.

The variety of hazards which may be protected by foam extinguishment systems is great, and in applying the rules care should be taken to determine first under which class the hazard to be protected falls, so that the particular rules for that class may be applied. There are two types of foam:

Type 1—Suitable for use on flammable liquids not miscible with water, principally petroleum and its products

Type 2—Suitable for use on flammable liquids that are miscible with water, such as alcohols, esters, and acetones, and may be used on petroleum products

At present there is approved apparatus covering four general methods of applying foam:

1. Self-contained apparatus consisting of certain approved types of containers with devices to operate them automatically, the foam-producing materials being contained within the device.
2. Closed apparatus containing the chemicals necessary for producing foam but having provision for the admission of water to these materials with the necessary automatic or nonautomatic apparatus to produce proper operation.
3. Generators requiring a water supply and into which dry foam-producing chemicals are added, the generators being designed to mix the chemicals and water and produce a discharge of foam solution. There are two types of these generators. One type uses a single foam-producing dry chemical, and the other uses two dry chemicals constituting each of the two principal ingredients, the two solutions formed in the latter type of generator being kept separate until mixed in or beyond the generator.
4. Stored-solution systems. The two foam-producing liquids are stored separately and handled by pump pressure or gravity tanks to provide the necessary mixing and discharge to produce foam. One pound of combined chemicals and 1 gal of water are necessary to produce 1 cu ft of foam. Where two solutions are used, $\frac{1}{2}$ gal of each solution to make 1 gal combined having an expansion of eight at ordinary temperature, may be assumed to produce 1 cu ft of foam.

Water-spray Fog Systems.[34] The value of water applied in finely divided form by means of a special type of spray and so-called "fog nozzles" in extinguishing or controlling certain types of fires has been recognized. There are two methods of applying water spray:

1. By the use of hose lines (see *a* below)
2. By the use of fixed systems of piping (see *b* below)

Extinguishment of fire by the application of water in a finely divided form is probably accomplished by a combination of a smothering effect produced by steam, displacement of air, or a maintained film of water; by cooling; and in the case of some oils, by forming a smothering foam or emulsion over the surface of the burning liquid. Water thus used evaporates (absorbs heat) rapidly and so has a marked cooling effect.

a. For manual use, spray nozzles and play pipes may be used on outside and inside hose lines. When using spray nozzles on hose, a distance of at least 10 ft should be kept from electrically charged apparatus to protect operators.

b. Where fixed-pipe systems are installed, the construction standards for automatic sprinkler systems shall apply. All piping should be galvanized or of noncorrodable material.

Carbon Dioxide (CO_2) *Systems.*[35] The extinguishment of fires through the use of carbon dioxide, producing a smothering effect, can be successfully accomplished where there are flammable liquids in open and enclosed containers, rooms or enclosures containing flammable liquids, ovens, dryers, electrical and other special machinery and apparatus, and processes involving the use of flammable liquids, vapors, or dusts, fur storage, lumber dry kilns, coal bins, loose textile stocks, grain-handling machinery, and in other enclosures containing stocks through which gas may permeate and where protection by water or other means may be ineffective or undesirable; also in vaults, library stacks, organs, and other such places where fires may be extinguished by carbon dioxide gas with less loss than if water is used.

HIGH-PRESSURE SYSTEMS. Carbon dioxide is applied from cylinders in which it is stored at a pressure of about 850 psi at 70°F. It is required that the quantity of carbon dioxide in the cylinders be determined either by weighing or by other means at least once a year.

LOW-PRESSURE SYSTEMS. Carbon dioxide gas may be stored in tanks in liquid form in any capacity. Low-pressure tanks are kept refrigerated so that gas pressure may not exceed the designed working pressure of the vessel (usually around 325 psi). So far as safety to life is concerned, the gas, if not breathed in excessive amounts, is not dangerous, but in quantities it is suffocating.

Alarm Systems.[36] The primary intent of all alarm systems is to notify someone that a fire has broken out. This can be done by audible alarm or by direct connection to public fire-fighting forces. All alarm systems must work 24 hr a day. Therefore, care and maintenance must be maintained every hour of the day and night. Alarm systems have entered the broad field and are used as detecting devices on all types of machinery operated automatically to maintain water levels, steam pressures, atmospheric conditions, gate valves, and fire doors to ensure their immediate operation Some type of fire-alarm system should be installed in every plant because the immediate detection of a fire is the most important factor in its extinguishment.

Clock and Dial System. The watchman carries a clock which contains a paper dial. Keys are placed at predetermined locations throughout the plant (usually by the rating bureau), and the watchman on his hourly rounds "punches the clock" with the key, which makes a perforation in the dial. The dial is printed as an hour and minute graph, and the perforations complete the graph as to the watchman's rounds.

Key and Dial System. The paper dial is set up in a central clock in the office or any suitable location. The watchman carries the key and sends an impulse from the boxes or stations placed throughout the plant. The mechanism of the clock makes a perforation on the dial, which also acts as a graph.

Magneto and Dial System. The magneto and dial system is the same as the key and dial with one difference. The watchman rotates the magneto at each station to send the impulse to the clock.

Water-flow Type of System. The water-flow type of system is an electrical alarm activated by the slightest movement of water in pipes on flaps, vanes, or wheels, which close a circuit and thus send in an alarm.

Rate-of-rise System (air expansion by heat). The rate-of-rise system is operated by the expansion of air in small copper tubing run on ceilings strategically. This expanded air exerts an impulse on a selenoid cell, which in turn either opens or closes a circuit to give an alarm or activates a diaphragm for the same purpose. This system can be extended to operate fire doors, etc.

Thermostat System (metal expansion). The thermostat system is made up of a circuit in which is inserted a broken coil or ring. This coil when heated closes the gap and thereby closes the circuit to send in an alarm. There is also a system that uses the properties of two metals, bismuth and antimony, for making an electrical contact when heated (Ruchel rate of rise).

Supervisory or Central-station Protective Signaling System. The supervisory or central-station protective signaling system is an automatic electrically operated system, using detecting devices. It operates on the principle of rendering a service in addition to transmitting alarms. It checks the watchman on his rounds and maintains runner or armed-guard service which can be sent to the plant in case of trouble.

Proprietary Systems. Proprietary systems are operated on the same principle as that used in the electrical circuits but are confined to the plant and give only an audible local alarm.

Auxiliary Alarm Systems. Auxiliary alarm systems have circuit-closing switches throughout the plant tied into the municipal circuit and are of the shunt or series types. The shunt type is connected to the main circuit and is equipped with a tripping magnet which shunts the current until one of the circuits is closed. The series type has a separate source of current which operates an electric relay controlling the current to the tripping magnet, which is separate from the main circuit. When a switch is closed, the tripping magnet is energized and operates the municipal fire-alarm box. The shunt type is acceptable to most fire departments. The automatic McCullougher circuit utilizes a ground return for the current by inserting a code wheel, which makes and breaks a connection between the line and the ground.

Plant Fire Brigade. Regardless of the size of the plant or establishment, the personnel and workmen should be organized for the purpose of preventing and extinguishing fires. A plant fire brigade, to be a success, must be recognized by the management as an important permanent addition to the plant operation. The fire brigade should be organized under a constitution and by-laws and hold regular meetings for discussion and drill. Each officer should be provided with a badge denoting rank, and incentives should be given for membership and distinction and privileges awarded. The chief of the brigade should be selected for his ability to lead, analyze, and plan; he should be responsible and report to the highest executive in the plant.

The master mechanic makes a good fire chief if he has the ability. The chief must have full charge at a fire unless superseded by an officer in charge of the public fire departments. The assistant chief should have qualifications similar to those of the chief. Captains should be selected from heads of departments. The plant engineer and electrician should be members of the brigade. The watchman should be brought into contact with the brigade to become acquainted with the proper procedure in case of fire. The strength of a company should be 10 men, but the division of units may call for a smaller number. To be efficient a fire brigade should observe three essentials: rigid discipline, provision and maintenance of necessary apparatus, and adequate training under discipline with the apparatus. The plant fire brigade should invite the public fire department to visit and inspect the plant and should cooperate with it. The entire strength of the brigade, amount of equipment, and frequency of fire drills will depend upon the size of the plant and the nature of the hazards involved. Fire drills should be held at least twice a month, and the location of the drills changed so that the men can become familiar with all parts and conditions of the plant.

Drills should consist of making hose connections with hydrants and standpipes, laying hose, coupling and uncoupling, carrying hose up ladders, over roofs, etc., and in holding play pipe because of kickback. When plant is in proximity to natural water supply which is available for fire use, landings should be maintained for pumping engines to take suction. Roads should be kept clear, and if snow impedes access, hydrants should be marked with suitable signs. Crossings at railroads and tracks should be kept free. In sprinklered plants, officers should delegate men in case of fire to make sure the sprinkler valves are open, to see if sprinklers are operating, and that the fire pump is started. Use of hose streams should not endanger the supply of water to the sprinkler system. No one should close a sprinkler valve unless ordered to do so by the fire chief. After the fire all used sprinkler heads should be replaced, valves should be checked to see that none is closed, and the system restored as quickly as possible.

Watchman.[37] An alert, intelligent watchman should be employed. He should know the plant thoroughly, should know how to send in an alarm, and how to shut off water in case of sprinkler leakage. His rounds should be made on time, but time should be allowed to make a thorough inspection of premises as he proceeds.

Stock-flow Method. The stock-flow method is the proper approach to the study of fire prevention in the industrial plant. A diagram of the plant operations and processes, including raw stock (storage), stock flow, machinery and mechanical conversions, finishing processes and finished stock (handling and storage) should be made and studied to ascertain

1. Concentration of critical material
2. Concentration of values
3. Susceptibility of materials (raw, in process, and finished) to water and smoke damage and flaming and the degree of burnability
4. Operational processes of a single machine or group concentration that may develop a fire hazard
5. The area that may be affected by a single fire, including horizontal and vertical area
6. The rapidity of spread of fire due to the flaming nature of the material
7. The possible damage to equipment and stock and the time replacement of such equipment and stock
8. The value of fire barriers or cutoffs to confine a fire to a given area, both horizontal and vertical
9. The standard treatment for mitigating or removing possibilities of fire in any process or machine operation
10. The exposure of hazardous operations to high values, critical material, and equipment

Fire Attack. A map should be made of the entire plant and surrounding exposures. A good-sized map can be made on a scale of 50 ft to 1 in. The map or plan should be divided into squares of 50 sq ft and again into squares of 200 sq ft. The stock flow, concentration of values, hazards, susceptibility of stock and equipment to water and smoke, gases and acids, and discoloration and contamination should be studied as well as floor openings and cutoffs. It should be remembered that fire and smoke go upward, and water goes downward. The necessary first-aid equipment should be provided; precautions to be taken and the necessary action to be taken should be posted. Workmen and employees should be instructed to notify plant fire chief at once, no matter how small the fire. The public fire department should be called at once.

Self-inspection Blank. The following blank should be used as a constant check on the plant, and this report should be perused by the plant manager every month. The inspection should be made by a competent man who is familiar with the details of the blank and who can interpret the defects in an understandable manner.

SUGGESTED FORM
OF
SELF-INSPECTION BLANK
FOR
INDUSTRIAL PLANTS

Prepared by the National Board of Fire Underwriters, 85 John Street, New York City 7, as a Daily Report for Plant Owners to Have Printed in Quantity for Their Individual Use.

NOTE: The following general rules should be observed by the foreman or other trusted employee selected to make these reports.

Give attention to *every* question on this blank. If the question does not apply to this plant, draw a line through the space left for the answer. In this way you can be sure that you have not overlooked anything.

Some questions are to be answered by Yes or No, but others must be answered more fully.

When you find some defect, explain its cause and the steps that you are taking to correct it in the space headed Corrections and Remarks, on the last page of the blank. In doing this, *give the number of the question.*

If it ever becomes necessary to shut off the water from the sprinkler system, notify the office of the plant *at once* (even in advance, if possible).

This is important to enable us to notify the insurance companies or association.

If there is anything that you do not understand, consult with the manager at once.

Turn in the report blanks promptly to the manager of this plant.

Remember that these inspections are very important. The safety of this plant from fire is largely up to *you.*

GENERAL CONDITIONS

Cleanliness and Order

1. Was your inspection complete, covering all parts of the premises, including looking under benches, into closets, behind radiators, elevator pits, etc?........

2. Where did you find dirt or litter?

3. Were all clothes lockers clean and in good repair?..............................

4. Where did you find oily waste or any other greasy material outside of approved waste cans?..............................

5. Are any waste cans not emptied daily after closing hours?..............................

6. Is there any failure thoroughly to clean up shipping and packing rooms at closing time?..............................

7. Is there more packing material brought in than is needed for one day's use?..............................

8. What rooms or departments were not as clean as they should be?..............

9. Was yard free from combustible material?..............................

10. Was basement clean?....................

Maintenance

11. Is there any part of the plant which the watchman fails to visit?............

12. Are any watch-clock records unsatisfactory?..............................

13. Where were machinery, belts, or shafting in bad condition?........................

14. Where were bearings dirty or poorly oiled?..............................

15. Where did you find broken window panes, plastering, partitions, flooring, or other defects?..............................

16. Were any aisles obstructed in stockroom?..............................

17. Where do piles of stock or other obstructions interfere with entering any part of building?..............................

HAZARDS

Heating

18. Where was woodwork or other combustible material too near to smokestacks, flues, furnaces, boilers, steampipes, etc.? ....

....

19. Where was anything placed to dry on boiler or steampipes? ....

20. Was fuel supply safely arranged?

21. Can heated irons be set upon combustible material? ....

Lighting and Electrical Equipment

22. Where were there any open flame lights near combustible material? ....

23. Where were there any broken fixtures or loosened wires? ....

24. Where were ordinary electric cords looped over nails or found in contact with anything? ....

25. Where were any fuses replaced by wire or otherwise defective? ....

26. Where did any panel boards or switch and fuse cabinets need cleaning?

27. Where did any motors need cleaning, outside or inside? ....

28. Where was there insufficient oil in any motor bearings? ....

29. In what manner was there any violation of our rules for storing or handling oils, gasoline, or other inflammable liquids? ....

30. Did you find dry room disorderly or with dirty steampipes? ....

31. Where were any fan bearings inaccessible or poorly oiled?

32. Where were any screens or dampers in air ducts out of order?

33. Where did you find any other than safety matches? ....

....

34. Where did you find any violation of our rules on smoking? ....

PROTECTION

Fire Doors, Traps, Shutters, and Escapes

35. Where were fire doors wedged open, obstructed, or out of order? ....

....

36. Where were the automatic attachments of fire doors out of order? ....

37. Where were traps or doors on openings through floors out of order? ....

38. Are they ever left open when not in use? ....

39. Are fire doors or shutters ever left open at night or on Sundays or holidays? ....

40. Where were fire escapes obstructed, broken, or out of order? ....

....

Fire Apparatus

(Note: Each hose house, watchman station, room, or department should be known by a separate number. If you find *any* defect in any items, place the station number opposite the item. This will aid in keeping records. At each of these points there should be a card stating the quantity of the various kinds of apparatus which are required at that point.)

Inside

41. At what points are there *less* than the required number of

- *a. Full* water casks ....
- *b. Full* fire pails ....
- *c. Full* sand pails ....
- *d.* Feet of hose ....
- *e.* Nozzles ....
- *f.* Spanners ....
- *g.* Chemical extinguishers ....

(*Should be recharged at least once a year*)

- *h.* Ladders ....

Outside

42. Where were post-indicator valves poorly oiled? ....

43. Where did indicator valves fail to show open? ....

44. Which yard hydrants are hard to operate? ....

(*Do not open or test hydrants in the wintertime*)

....

45. Which ones do not drain properly? ....

....

46. Which ones have you found obstructed with snow or ice? ....

47. Which ones are otherwise obstructed or hard to reach? ....

48. Where have you found that hose, nozzles, or spanners were missing or not ready for use? ....

....

Fire Pumps

(Note: Pumps must be started at least once a week, discharging water through relief valve, in order to make certain that they are in working order. They must be given a *thorough test* with rated number of hose streams every spring and fall.)

49 Give make, style, and size of all fire pumps in the plant

	Make	*Style and size*
A		
B		
C		

50 Give results of any tests made since last report

	A	B	C
a Time required to obtain water?			
b What pressure was maintained			
c Was action smooth?			
d Is there an automatic regulator?			
e Was priming tank full?			
f Was priming gate valve closed?			
g Were steam drips open?			
h Did steam trap operate			
i Was there enough oil			
j Was suction clear of leaves or other obstruction			
k Was pump reservoir full			
l Were valves in steam connection from boilers to pump wide open?			
m How many rpm at 100 lb water pressure with all outlets closed			

For electric pumps add	A	B	C
o Has current been interrupted since last report			
p What is condition of contact points on switches circuit breakers controllers etc			

Gravity Supply from Tanks and Reservoirs

51 Give location and capacity of each tank or reservoir

	Location	*Capacity gal*
A		
B		
C		

	A	B	C
52 What was water level			
53 Was water frozen?			
54 Was ladder out of order?			
55 Were hoops and support defective?			
56 Was telltale out of order?			

For pressure tanks add	A	B	C
57 What was air pressure and was water level correct?			
58 What was tank room temperature?			

City Water Connection

59 Was valve (on our premises) in connection to city water main wide open?

60 What was pressure on gauge? lb

61 Has there been any interruption of city supply since last report?

62 Give results of any tests since last report

a Number of hose streams
b Diameter of nozzles in
c Pressure at nozzles lb

Sprinkler Supply Valves

(Note All gate valves must be secured open with leather straps or other approved method fastened with sealed or riveted padlocks the keys being held by responsible persons In inspection each valve must be given one full turn to make sure that it is wide open and in working order Drip valves must be strapped shut in similar manner Valves under approved supervisory system however need not be secured)

Mark every sprinkler supply valve plainly with a number This will aid in keeping record

63 Give the number of any valves found closed

64 Give the number of any valves found not strapped

65 Give the number of any drip valves found open

66 Give the number of any valves to which access was obstructed

Dry Valves

(Note Dry valves should be tested for water column and condition of spring at least once each 3 months they should be tripped at least once a year)

	Location		*Location*

71. How was valve tested?				
72. Did any bells fails to ring?				
73. Was valve left in order?				

Automatic Sprinklers

74. Where is stock piled within 24 in. of sprinkler heads?

75. Have any sprinklers operated since last inspection?

76. Where are any sprinklers coated or corroded?

77. Where are any sprinklers obstructed by partitions, joists, etc?

78. Where are any sprinklers bent?

79. Where are any sprinklers leaking?

80. Where are any sprinklers exposed to freezing?

81. Where are any sprinklers missing?

82. Where are any sprinklers disconnected?

83. How many sprinkler heads are kept in reserve?

CORRECTIONS AND REMARKS

(NOTE: Wherever defects are found, steps must be taken *at once* to have them corrected. If the corrections have been made when this report is turned in, *this fact* must be stated below. If the correction has not yet been made, an *explanation* must be given below. Always refer to the question by number. *For example*, "*15—The broken windows in the shipping room were caused by boys throwing stones. I have reported the matter to the police and have had the broken panes replaced.*")
I have made a careful inspection and to the best of my knowledge and belief the foregoing statement are all correct.

FUNDAMENTALS OF GOOD PLANT MAINTENANCE

BY HENRY W. SHOCKLEY

Maintenance Consultant, E. I. du Pont de Nemours & Company, Inc.

Maintenance of a modern industrial plant, precedented on low cost and continuous operation, cannot tolerate a status where emergencies and excessive repairs are a regular condition. Instead, it must function according to definite rules of orderly procedure and be subjected continuously to scientific study and change in order to meet continuous changing conditions in industry. Simultaneously, as the methods of manufacturing the product are being continuously investigated for improvement of process, manufacture, etc., to meet the ever-increasing effect of competition, so plant maintenance must be continuously investigated for better materials, improved designs, better equipment, tools, facilities, etc.

Over the past quarter of a century, there have been almost complete changes in the design of industrial plants, the handling and transportation of product, the use of automotive equipment, the divisions of labor, etc., owing in no small part to the effects of mass production in which large volumes and low costs are predominant. In the future these will be further emphasized to an even greater extent owing to the necessity of expanding the fields of industry to meet the needs of greater employment, increased wages, and higher standards of living.

In addition, another change has been added which may have an even greater effect on maintenance. This condition is one in which the individual operator is becoming more interested in the automatic operation of manufacturing equipment, where physical effort is less strenuous, and where the machine performs the major part of the work. This change will require equipment that

1. Is more automatic in operation.
2. Is more complicated in design.
3. Requires every safety feature.
4. Introduces the use of all measuring devices; both mechanical and electrical.

These changes will require closer attention by specially trained mechanics and engineering supervision. They will also necessitate the development of training programs covering the requirements for the special skills needed. The application and maintenance costs should be the basis for a continuous program of advanced development in equipment design and better materials of construction.

This enlargement in scope of a maintenance department indicates that the maintenance engineer can no longer be satisfied in maintaining a plant but must have the additional capacity and knowledge to use those factors which will prevent repairs or interference with operations and the best engineering methods available to improve the conditions of operation, equipment, or plant. This does not mean that the maintenance department will assume the responsibilities of those services now segregated under experiment and development. These, while more essential than ever to a plant today, are separate because of the type of problem and time required for investigation which makes it feasible for them to be segregated unto themselves. However, sufficient engineering knowledge and skill should be available in a maintenance department to recognize and understand the principles of engineering in their application to plant improvement. This requires the creating and availability of basic records and control to point out poor conditions and assist in the study of operating and maintenance costs, as well as the experience in and knowledge of the use of actual skills, tools, facilities, and equipment properly to maintain a plant.

To meet these conditions successfully it will be necessary that the maintenance organization and methods employed be equivalent in both quantity and quality to the size of plant and type of equipment. Otherwise, results will be unsatisfactory and maintenance costs will be excessive. It should be understood that a low maintenance cost may be the difference between an operating profit or loss, particularly since maintenance costs have increased to such a great extent during the past few years, with a greater proportion in labor costs than in material.

The essential need for any plant for best maintenance control is a plan to meet all these conditions. The application and use of such a plan is covered in this treatise.

The plan revolves around the following six major controls, *viz:*

1. Organization—supervisory and wage roll
2. Work and labor control
3. Training
4. Preventive maintenance
5. Corrective maintenance
6. Cost controls

It will be quite obvious as these various controls and subheadings under each are explained that this is a far-reaching plan; that results will be obtained based on effort expended; and that it may be necessary to change methods, viewpoints, and procedures to gain best results. It is believed that the plan is founded on a sound basis of facts; that there are sufficient checks and balances to offset variations in plant conditions; and that it will not only establish a standard of maintenance at all times but will furnish all necessary information to determine where improvements or changes should be made. The plan is described according to the six major controls.

ORGANIZATION (SUPERVISORY)

The importance of the proper organization structure to meet the conditions outlined in this plan cannot be overemphasized. Not only must there be supervision to carry out the duties and responsibilities for all services involving the proper maintenance of a plant at all levels of production and with a minimum of down time of operating equipment, but also the supervisory personnel itself must measure up to corresponding conditions of selectivity. Too often the selection has been based on general and not specific requirements or has been to meet the personnel available in the plant.

In many instances also the actual duties and responsibilities of a maintenance organization are not definitely defined or understood with the result that supervision is not applying itself to necessary requirements. This results in overlapping of duties, failure to understand conditions, and consequent poor results. Many times the knowledge of their responsibilities and a training program covering them would assist materially in improving present personnel, but without both knowledge and training only mediocre results can be expected.

Typical functional organization charts for both large and small industrial plants are shown in Figs. 6-1 and 6-2. In addition, Fig. 6-3 shows the responsibilities of the various types of supervision including clerical assistance. In establishing general standards of selection covering the various types of supervision and clerks, the recommendations would be as follows:

1. All engineers:
   a. Graduate engineers or equivalent
   b. From 5 to 10 years of plant experience
   c. Adapted to the responsibilities as shown in Fig 6-3
2. Foremen and clerks:
   a. Foremen and clerks to have at least a high-school education or equivalent
   b. Foremen to have learned a trade or its equivalent
   c. Foremen to have had from 5 to 10 years of practical experience in their trade or the plant

The organization charts (Figs. 6-1 and 6-2) indicate that maintenance of a plant should be considered under three headings, each of which determines the kind of organization required.

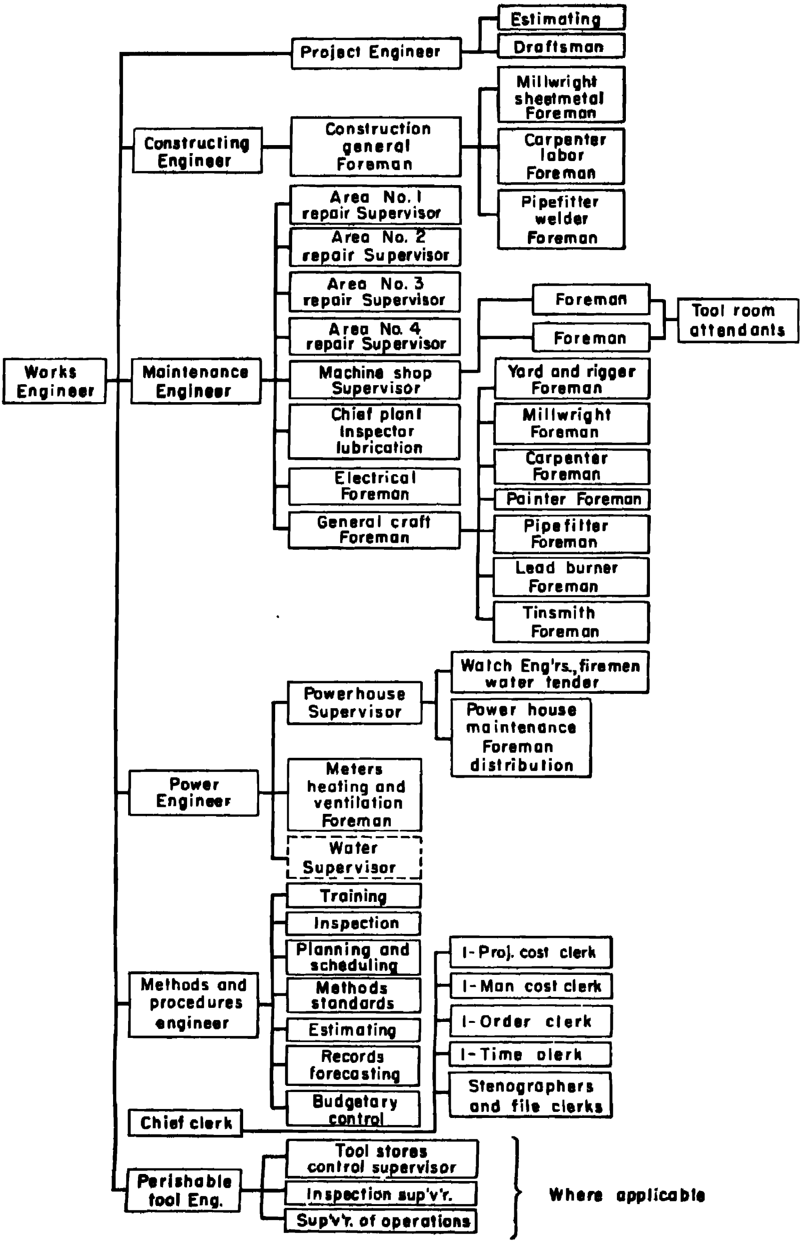

Fig. 6-1. Typical functional organization chart, power and mechanical department (department personnel above 200).

1. Shop and craft work, or common facilities
2. Work special to the particular area
3. Minor construction, which may affect both 1 and 2

In all plants the amount and kind of work done over a period of time indicates that which is common to an area or department and that which represents the use of common facilities both as to personnel and equipment requirements. It is therefore very necessary that an analysis of actual work requirements be known before the proper type of organization can be established and the foreman-mechanic ratio be determined correctly.

Although proof is not too definite, experience has indicated that the foreman-mechanic ratio can be 1:15 for outside crafts and up to 1:25 for shops or more centrally controlled groups. The more definite the responsibilities and duties of supervision are, the better this ratio can be measured. Experience also indicates that emergencies and confusion are evident where responsibilities and duties are not known.

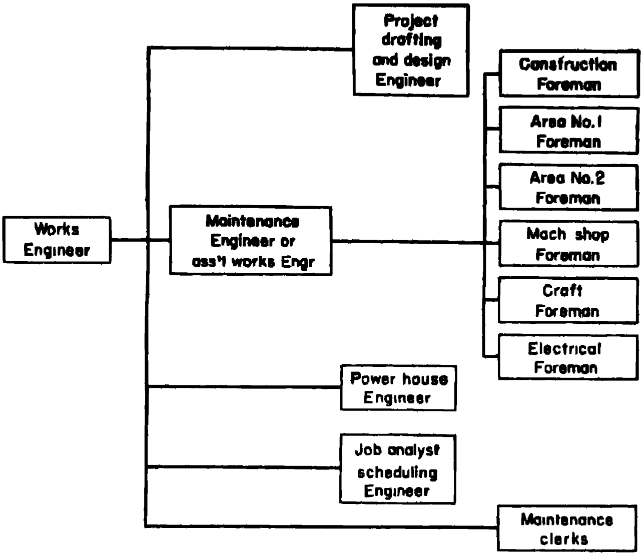

Fig. 6-2. Typical functional organization chart, power and mechanical department (department personnel above 150).

ORGANIZATION (WAGE ROLL)

Just as the administrative and supervisory functions of a works engineering organization must be definite and understood, so also must the work and crew requirements of all crafts and groups be definitely established as to skills, experience, tool requirements, etc., in order that they may do their work safely and effectively. This is also necessary for job-evaluation purposes or for determining wage scales to meet job requirements.

The general requirements common to all maintenance crafts and groups are shown in Fig. 6-4, and the specific job requirements for one craft, millwrighting, are shown in Fig. 6-5.

In order to meet plant requirements, it is necessary that the general requirements be understood and carried out 100 per cent by each craft or group according to its class and that 75 per cent of the job requirements be met in order to meet the rate of the particular class.

In addition, the requirements represent a standard for measuring personnel and in assisting them to do a better job.

Fig 6-3

PROPOSED CLASSIFICATION OF CRAFTS—GENERAL REQUIREMENTS

Although not a requirement, it is very desirable that class 1 and 2 craftsmen be capable of doing an acceptable job in a lower classification in some other closely related craft. Class 3 men of less experience will probably not have sufficient skill in other crafts, although such ability will make them more desirable employees.

To advance to a higher classification, a man must have worked sufficiently long under proper supervision at the advanced classification to prove his capability.

Craftsmen of all classes must have sufficient knowledge to use information given in standard reference and handbooks of their trade. Craftsmen of all classes should cooperate with the foreman in the education of apprentices.

Throughout the various classifications, Supervision will be referred to as Close, Average, and Minimum. The definitions of each are as follows:

Close Supervision	Average Supervision	Minimum Supervision
Close supervision means that the job must not only be planned and scheduled properly, but it must be analyzed in more detail relative to tools and materials required; described fully; and the person executing the job be contacted frequently and given detailed instructions.	*Average supervision* means that the job must be planned and scheduled properly to eliminate lost time in its execution, and contacting between jobs, but that the patrol of the job is infrequent and fewer instructions are required.	*Minimum supervision* means after the job has been properly planned and scheduled that a minimum of contact and instructions are required.

The following general requirements must be met by workmen of all crafts:

Class 1 Craftsmen	Class 2 Craftsmen	Class 3 Craftsmen
1. Class 1 refers to the highest trained man in the craft who shall have had the proper training and experience in his craft according to plant requirements. The time required to meet such requirements will be specified by the plant.	1. Class 2 refers to men who are so trained in their craft that they are able to do as good a job as a class 1 man in certain types of work but will require more supervision and instruction.	1. Class 3 refers to men who have just completed their trade or those in the probationary period, who lack experience, skill, and seasoning. They require closer supervision and cannot be expected to accept responsibility.
2. He must be able to work from any print or clear sketch and be able to take his own field measurements and make a readable sketch or diagram when necessary.	2. He must be able to work from most prints but will require some aid on the difficult ones. He should be able to take his own field measurements when necessary and to make a readable sketch or diagram.	2. He will not be expected to work from drawings, take field measurements, or make sketches unaided, although ability to do so will make him a more valuable employee.
3. He must be able to work effectively from verbal instructions, drawing on knowledge accumulated during his broad experience for determining proper procedures for economical execution of the work.	3. He must be able to work effectively from verbal instructions; however, more detailed instructions will be necessary.	3. He should be expected to work from verbal orders only if given explicit instructions covering all details.
4. He must be reliable, resourceful, conscientious, and steadfast; be able to gain and hold the confidence of his fellow workers; and be capable of directing the work of other men in number according to plant policy. However, the number of men directed should be definitely stated.	4. Same as class 1, but he should be capable of directing the work of mechanics of lower classification or helpers according to policy of the plant.	4. He will not be expected to direct the work of others in any type of work under his classification.
5. He must know and practice all plant safety and housekeeping rules.	5. He must know and practice all plant safety and housekeeping rules.	5. He must know and practice all plant safety and housekeeping rules.

Fig. 6-4.

WORK AND CREW CLASSIFICATION
MILLWRIGHTS

Class 1 Millwrights	Class 2 Millwrights	Class 3 Millwrights
1. To be able to read and interpret mechanical drawings of standard machines or machinery on the plant and make intelligent sketches of the machine parts.	1. To be able to read and interpret mechanical drawings of standard machines or machinery on the plant and make simple sketches or layouts of mechanical parts.	1. To be able to read, follow, and perform work from simple drawings.
2. To check working load on various ropes, chains, and cables with the aid of handbooks. To have a working knowledge of materials which will stand up under the chemical conditions on the plant.	2. To be able to check strength of materials with the aid of a handbook, under close supervision, and to have general knowledge of materials that are standard for use on various machines.	2. Same as class 1 and 2, but under close supervision of foreman or senior craftsman.
3. To do all common methods of rigging or handling of heavy machines and materials in a safe and economical way.	3. To do all common methods of rigging and handling of heavy machines and materials in a safe and economical way under average supervision.	3. To do elementary rigging where no unusual problems are involved.
4. To be able to dismantle and assemble any standard machines and powerhouse equipment except turbine generators requiring outside supervision.	4. To take apart, put together, install, or replace any parts on common machines.	4. To dismantle or assemble any mechanical equipment either under close supervision or assisting a mechanic in a higher classification.
5. To recognize by feel, sight, or hearing, mechanical faults in machines in common use on the plant and repair same. This to be acquired by long and varied experience in the trade and on the plant.	5. To recognize by feel, sight, or hearing mechanical faults in machines in common use on the plant and make general repairs.	5. To have the mechanical ability to recognize common faults on common machines and make simple repairs.
6. To be able to run equipment in his own shop and simple machine-shop equipment, so as to be able to get out simple repair parts without help when necessary.	6. To be able to run drill presses, hacksaws, bolt machines, and simple machines which are in his craft shop.	6. To be able to run equipment in his own shop under supervision.
7. Ability to use the tools of his craft such as calipers, feelers, micrometers, etc., in order to secure tolerances of 0.001 in. on equipment where required, in order to give accurate dimensions and check finished machine work before installation. Also, to be familiar with all tolerances of running, shrink or press fits on shafts, bushings, keys.	7. Ability to use the tools of his craft, such as calipers, feelers, micrometers, etc., necessary to complete repairs on machines in order to secure tolerances of 0.005 in. on equipment where required.	7. To be able to use the tools of his craft, such as calipers, feelers, micrometers, etc., under average supervision.
8. To be able to use a complete set of millwright tools.	8. To be able to use the tools that will allow him to perform the above duties with minimum amount of trouble and expedite the job assigned to him with average supervision.	8. To be able to use such tools that will enable him to step into the next higher classification when the opportunity presents itself.
9. Be able to ascertain difference between materials and their application as related to plant operation.	9. Be able to ascertain difference between such common materials as cast iron, cast steel, steel, tool steel, ordinary babbitt, high-speed babbitt, and their applications. Have the ability to reline bearings.	9. Should be able to ascertain difference between common materials of his craft, such as cast iron, steel, babbitt, etc.

FIG. 6-5.

The training of mechanics relative to both their general and job requirements is essential for a proper understanding of what their responsibilities should be in relation to their jobs, particularly as a majority of mechanics in many plants have not had the benefits of an apprenticeship training program.

It is also believed that a definite scheduled program for training both supervisory and wage-roll personnel will have added advantages in directing their thinking and giving such personnel a status it has not previously had.

Of equal importance is the availability of locker space, showers, washrooms, etc., for the employees, close to their work stations in order to reduce the possibility of colds due to overheating, lack of clothing, etc. It must be understood that personnel is the most important factor in the proper functioning of an industrial plant.

WORK AND LABOR CONTROL

There are a number of maintenance services under work and labor control, each of which affects the maintenance of a plant to a large degree, both in work requirements and in having a minimum of personnel available to meet them. Each has a definite relationship to the other.

Repair-order Control. The first or key service is that of repair-order control, which is the means whereby every type of maintenance job done, whether minor or major in scope, is definitely covered by a standard written form which shows that the work is needed, is adequately described, is properly approved, is issued by proper authority, and provides a record of all this information.

The purpose of a repair order is to enable a maintenance foreman to analyze and schedule his work; to provide a means of scrutinizing jobs as to cost, necessity, size, etc., both before and after they are done; to assist the operating supervision in determining the necessity of the job; and to give maintenance supervision the means to estimate and schedule the job according to best plant requirements.

Reference to Fig. 6-3 indicates that repair-order control and time distribution are direct responsibilities of both general area and craft foremen, as this type of supervision is in direct contact with the work itself and the method of doing it.

It is also very important that operating supervision understand the work requirements, particularly their effect on operating schedules, facilities, etc. Because of their familiarity with process conditions, they are also in an excellent position to know the necessity for the expenditure.

Figure 6-6 shows the front of a normal order form, which describes the work to be performed, assignment, cost preparation and distribution, signatures, etc.

Figure 6-7 shows the back of this form, allowing space for additional instructions, materials required, special tools, number of men, safety precautions, etc.

Figure 6-8 shows a patrol-order form used for small nonrepetitive jobs up to 4 man-hours of labor and a maximum of $10 in material.

Repair-order control is a control of work requirements. It therefore becomes necessary that similar control be exercised over personnel requirements to do this work plus some measurement of the rate of receipt and completion of work

Control of Maintenance Labor Requirements. Control of maintenance labor requirements is a method used by maintenance supervision to compare estimated hours of work load with actual man-hours available.

The purpose of this control is to maintain minimum personnel requirements covering crafts, shops, areas, or minor construction groups according to optimum conditions of maintenance work and to meet production requirements.

Figure 6-9 shows a labor control or backlog chart covering all maintenance forces whether shop or craft, area, or minor construction groups. They are also segregated according to individual foremen and areas.

The required man-hours of work are estimated by the various foremen responsible according to repair or patrol orders received, and these are compared with man-hours available on a weekly basis. The result is known as "backlog of work." Periodic checks are made for accuracy of estimating and to assist each foreman in improving his estimating effectiveness by comparing actual hours of jobs completed with estimated hours before completion. This is termed the "correction factor."

FIG 6-7 Normal repair-order form, back side, job analysis

Experience has indicated that this procedure gives the following results:

1. It establishes minimum personnel requirements based on available work to be done in order to meet production schedules
2. It determines the rate of increase or decrease for any craft or group in volume of work over a period of time
3. It establishes a means for supervision to measure its own performance

Job Analysis and Scheduling. The third item under work and labor control is job analysis and scheduling of maintenance work. In order to utilize these controls to their best advantage, a method of assisting the foremen is first introduced. This is known as a "scheduling rack."

FIG. 6-9. Backlog chart, control of maintenance labor requirements.

Figure 6-10 shows a scheduling rack. It consists of six pigeonholes each 6 by 6 by 12 in., each marked as follows: jobs to be analyzed, jobs analyzed; jobs to be inspected; jobs waiting on material; jobs waiting on shutdown; jobs over 1 week old. This rack eliminates lost time in handling all repair orders, permits good housekeeping, and reduces clerical effort on the foreman's part in handling this work.

Jobs waiting on material and jobs over 1 week old will be discussed below. The others will follow under Maintenance Job Analysis, Scheduling Maintenance Work, and Inspection.

Jobs Waiting on Material. When a job is analyzed by the foreman, the material requirements are established. The type or kind of material is determined by the foreman as stores stock or special. If special, it must be purchased from outside vendors, which delays the execution of the work until the material is available in the plant. If the material is part of stores stock, it is assumed that the work can be done as soon as it can be scheduled.

Jobs over One Week Old. A certain backlog is necessary to plan and schedule maintenance work properly. Too great a backlog may result in emergencies, loss of production, down time, etc., while too small a backlog may result in lost time, poor scheduling, etc. Experience indicates that over 2 weeks' backlog in shops, exclusive of construction, results in the first condition given above, while less than 2 weeks in crafts results in the second condition. Segregation of jobs over 1 week old allows a means for closer checking of work and makes it available for scheduling.

Maintenance Job Analysis. Maintenance job analysis is the analysis of each maintenance job as to craft, material, tools, and methods and the preparation of a workable estimate of time and man-power requirements.

1 Jobs to be analyzed	2 Jobs analyzed	3 Jobs to be inspected
4 Jobs waiting on material	5 Jobs waiting on shutdown	6 Jobs over one week old

FIG. 6-10. Foreman's scheduling rack for repair orders.

The purpose of job analysis is to train maintenance supervision in the various factors that affect proper job execution, to have available for personnel doing the work the means of working effectively, and to have available for computing backlog the estimated man-hours for completion of all approved jobs.

A maintenance foreman receiving a normal repair order (Fig. 6-6) visits the location of the proposed work. He analyzes the job as to man-hours required by his own craft or group and enters this on the face of the order, noting also the work to be done by the other crafts and groups, to each of which he issues a cross order. In addition, he notes on the back of normal repair order (Fig. 6-7) the following: any additional descriptions that will assist the person or persons doing the job; the general materials necessary; tools, either regular or special, that are not a part of a standard tool kit; and any safety precautions to be taken. If the material required to do his part of the job is not stores stock, it is his responsibility to see that it is ordered. Cross orders are treated in the same way as normal orders by the foremen receiving them. Patrol orders, because of the type of work involved, require little analysis by the foreman. The job is also estimated at the time it is analyzed.

In discussing job analysis, one adverse argument is the inability to determine the extent or need of repair without a certain amount of inspection or disassembly. This is definitely recognized and only emphasizes the need for analysis to determine this condition and make ready for it and the necessity of being sure that the repair order describes the real repair as a basis for effective execution and proper record for corrective maintenance.

It also seems obvious that this is a method whereby a foreman should investigate each job to determine the above conditions if he is interested in securing effective work and lower costs. The use of the scheduling rack and the knowledge of job analysis enable the foreman to schedule his maintenance work in a formal manner, but it is also essential that materials be available before any work is formally scheduled

One of the most recurrent criticisms of job analysis in its relation to scheduling and patrolling of work by the maintenance foreman is the time it requires Even though actual study has indicated that this criticism is fictitious, it persists To assist the foreman in a better understanding of what job analysis means in the proper completion of work and in knowing those factors that enter into a thorough analysis, job-training programs have been established, which cover all the tools, procedures, or services that are needed to do a good maintenance job

Scheduling Maintenance Work. Scheduling maintenance work consists in fitting analyzed jobs into a daily planning and scheduling sheet (Fig 6-11) according to operating conditions, production schedules, personnel, and availability of materials.

ACTUAL TIME

CAUSE OF CHANGE

Fig 6-11 Foreman's daily planning and scheduling sheet

The purpose of scheduling is to have ready for personnel in each craft or group sufficient jobs to cover a day's work, arranged according to priority and analyzed as to labor, material, tools, etc, required and so arranged that on the completion of one job another is available for every person in the craft or group

The scheduling of maintenance work is done by the maintenance foreman assisted by a repair-order-control and scheduling clerk Analyzed jobs are scheduled according to the personnel available and are recorded on a daily planning and scheduling sheet (Fig 6-11) made out in duplicate These sheets are prepared for the following day's work by a fixed time of the previous afternoon They are then approved by the general foreman A red line is drawn under the last job recorded Any job added to this sheet after general approval becomes an emergency job and is investigated as to cause by the planning and scheduling engineer, whose duties in this respect are shown in Fig 6-3

The schedule sheet is valuable because it is

1 A formal record of actual use of maintenance labor

2. A tool to train maintenance supervision in the proper planning of work
3. A record of real emergency conditions
4. A summation of the day's activities for each foreman

On the basis that each man under each foreman has sufficient duly analyzed jobs, the effectiveness of scheduling will be measured by the number of emergency jobs.

An emergency job is one which has not been scheduled but which must be taken care of during the day the schedule sheet is in effect. In order to place the responsibility for such jobs, a list of emergency classifications has been determined (see Fig. 6-12). At the end of each week typewritten copies of investigation sheets covering all emergency jobs and their classifications are submitted to plant management and to operating supervisors in whose areas the jobs occurred. The investigation of these emergency jobs and the recording of results (Fig. 6-12*a*) for corrective purposes are functions of the planning and scheduling engineer working in conjunction with the area engineer and craft or area foreman, as indicated by Fig. 6-3. To enable these records to represent the truest picture, they are approved by the maintenance engineer before distribution. These records should be discussed with the area engineers and operating supervisors, and a definite decision should be made concerning what means are to be taken to prevent recurrence. Such records are very valuable in giving both operations and maintenance a picture of why jobs cannot be planned, what causes the emergency condition, and what means must be taken to prevent a recurrence if down time is to be eliminated and poor maintenance conditions corrected.

Fig. 6-12.

To reduce maintenance costs by investigating repair or replacement conditions as they occur, whether emergency or not, and by such measures training the foreman relative to the importance of this phase of his responsibility, certain repair orders designated by the maintenance engineer are also being investigated in the same manner as emergency jobs. Selection of such work is usually based on repetitive repair conditions as shown by equipment records.

Forecasting or Longer Term Scheduling. The coordination of plant maintenance and minor construction work with production and other factors requires specific planning. One method just described was daily planning and scheduling. However, there are many jobs requiring more than a day's duration or more than one craft to complete. This method of planning and scheduling is termed "weekly forecasting."

According to this method, man-power requirements by craft or major maintenance and minor construction jobs are detailed into a single master schedule (see Fig. 6-12*b*).

Fig. 6-12b.

Tentative labor assignments are detailed for each individual craft or other groups in terms of man-days for each day of the 1-week schedule period. Minor and routine maintenance work is excluded in order to simplify this schedule. Labor assignments, as represented by the master schedule, are proportioned on the basis of the total labor supply in relation to the anticipated requirements of minor, routine, emergency maintenance, and minor construction work.

Correlation and supervision of the weekly schedule is a function of the planning and scheduling engineer or similarly qualified individual.

The weekly master schedule serves maintenance and minor construction foremen as a firm starting point for establishing daily work schedules. It permits coordination among various crafts, tie-ins with production shutdowns, and less frequent changes in the daily work requirements.

TRAINING

A training program is introduced for all foremen covering the use of the various procedures that affect the work.

Referring to Fig. 6-3, it is noted that job training (supervisory) is a responsibility of all engineers except the project engineer; job training (wage roll) is a responsibility of all foremen; and the planning and scheduling engineer is responsible for both. His responsibility, however, is only to assist in the preparation of training programs and instruct where assistance to supervision is necessary.

Training is usually divided into two parts—orientation and job training. In the former all subjects such as company history, policies, various company plans, etc., are included, while job training refers to procedures or methods that affect the actual maintenance work of the plant.

Training in its broadest sense can be used in various ways and is continuously used by good supervision in teaching those under them a better understanding of their jobs. By this method the basic responsibilities and duties can be both understood and taught in an informal way if all members of an organization are to accept the responsibility of their jobs to their fullest extent.

The persons fundamentally responsible for training programs are the works engineer and the planning and scheduling engineer, the former to be assured of their being used and the latter for their establishment and application. The latter responsibility also applies to all engineers and foremen. It is therefore essential that the planning and scheduling engineer be trained to assist organization in applying the procedures most effectively that will result in the best execution of maintenance and minor construction work.

Maintenance Job Standardization. Maintenance job standardization is the arrangement of the component parts of the job and the selection of correct materials, tools, equipment, supplies, and labor to determine the one best method of performance at any particular time.

The purpose of maintenance job or work standardization is to break down a job into its elemental operations in order to determine the possibilities of improvement relative to use, design, methods, etc., and to utilize the information secured in establishing a standard of performance for practical use.

Jobs must be studied by engineers who understand how such an analysis need be made. A flow chart should be made up of the elemental operations, and this should be studied from the standpoint of use of the equipment, the cause of the repair, the best method to be used, the tools required, etc. A revised chart covering all improvements should be made and discussed with both operating and maintenance supervision to secure the benefits of their experience. Any development work required as a result of this study should be turned over to the experimental or development groups referred to previously. After all corrections or improvements have been made, the process chart is issued as a standard operation sheet covering that maintenance job.

Once job standardization is accomplished, very little job analysis is necessary.

Job standardization assists the maintenance foreman in reducing analysis time since it outlines the one best way of doing the work. In addition, the investigation of job costs and their repetition determines their priority in being standardized. A job-standardization program results in a continuous review of all maintenance work for cost reduction and definitely opens the way for corrective maintenance and the use of both maintenance and development engineers in its activities.

Planning and Scheduling Engineer. The responsibilities of the planning and scheduling engineer are to institute, coordinate, and follow up methods required by a works-engineering organization for optimum conditions of performance and cost and to assist in the training of personnel in the application and use of maintenance procedures such as

1. Repair-order procedure
2. Planning and scheduling
3. Equipment-cost-card procedure
4. Job standardization
5. Budgetary control
6. Organization training
7. Preventive maintenance
8. Corrective maintenance

One of the persons to be trained by the planning and scheduling engineer is the repair-order-control and scheduling clerk in the clerical duties related to

1. Repair-order control, control of maintenance labor requirements, scheduling, maintenance-cost control, maintenance-inspection control, costing, etc., segregating from maintenance and construction supervision the following clerical duties:
   - *a.* Coding and writing repair orders
   - *b.* Mechanics of scheduling by the use of racks, job cards, time clocks, schedule sheets
   - *c.* Posting accurate records of job time to scheduling sheets
   - *d.* Accumulating and maintaining records and backlog charts, cost cards, etc.

Inventory Control of Materials. One of the sources of irritation in the successful planning of maintenance work is the unavailability of materials. This is due to some extent to the necessity of keeping capital investment for such materials to a reasonable figure and having available the many grades or sizes of maintenance materials and spare parts, etc , used in the maintenance of a plant. To this might be added the additional problem of storage space.

Experience over a period of years has indicated that two factors affect the availability of materials more than any others. They are

1. Lack of adequate records
2. Abnormal removals from maintenance stores

Figure 6-13 shows an inventory-control card, which contains all the information necessary for the proper control of any maintenance material, spare part, etc. If the maintenance department places the full responsibility on the stores department for receipt and disbursement of maintenance materials, spare parts, supplies, etc., and assists them in eliminating from stores accounts all slow-moving parts, the material problem will be greatly improved.

Closely related to this is the use of both central-stores and department-stores stock. If materials are not easily available, it is obvious that in plants covering large areas, or even in separate buildings, certain time will be lost in the handling and transportation of such materials. If it has been found to be advantageous to segregate labor by areas or buildings, the same reasoning also should be applied to materials, but such materials should be common to that area and properly controlled for stores purposes. The maintenance department can appreciably help in this particular phase of material control if it assists in both having and keeping these material records up to date.

Closely allied to the successful scheduling of maintenance work are shops, mechanical tools, and facilities. All these represent capital investment which should be made available only as found necessary. Studies should be made of the work and the use of mechanical facilities to the extent possible for greatest economies.

Such a study usually must extend over a considerable period of time as it involves both area- and central-shop requirements, as well as repetitive and nonrepetitive work. The increase in labor-material ratios as applied to maintenance costs over

Fig. 6-13.

the past years from an average of 50:50 to approximately 75:25 clearly indicates that a study of these services is necessary in most plants.

Prefabrication also fits into the shops and tool picture. It is obvious that disassembly, fabrication, and reassembly can be done with greater effectiveness in a location where proper equipment and facilities are available. Such conditions are possible to a greater extent either in a central shop or area shop arranged for such work than in the field. It is not only more convenient, but it is safer.

The use of job analysis and job standardization represents a degree of analysis where definite indications should be evident as to the possible extent of prefabrication. Repetition of work and studies in handling and transportation will contribute information that will aid in determining to what extent prefabrication can be used.

Shop layout must also be considered, particularly because of the need for available floor space in order to utilize this service to do the job properly; to have room to place and fabricate parts; and to have handling facilities such as cranes, monorails, chain falls, etc., to reduce fatigue and expedite work. Power-driven hand and machine tools are available in practically every line of craftwork, and each one has its place in cost reduction. The same applies to cutting tools, dies, fixtures, etc.

PREVENTIVE MAINTENANCE

Preventive maintenance consists in establishing the means to reduce maintenance costs through a knowledge of the necessity of repair. Therefore, the real instrument to meet this condition is inspection.

Maintenance inspection is a procedure for determining the necessity for either major or minor repairs. Its purpose is to prevent, from any cause, unscheduled interruptions to operating equipment and undue deterioration to buildings and facilities.

An inspection procedure operates in two ways:

1. Visual or working inspection, or observing equipment in operation to determine potential breakdowns and making adjustments or small repairs
2. Shutdown inspection, or determining the wear and general condition when equipment is not operating

In addition, inspection is necessary for all parts of an industrial plant such as buildings, roofs, lines, etc. This might also be called visual inspection, although it may be done at less frequent intervals. In establishing an inspection procedure, all buildings, equipment, etc., should be listed and analyzed to determine whether they should be inspected on a visual or shutdown basis.

An inspection system must be applied in as simple a way as possible, with the duties of individuals definitely delegated and results maintained if it is to be of value and succeed in its purpose. Therefore, it should be an integral part of actual repair to as large an extent as possible.

The organization of a maintenance department was described as consisting of craft and shop groups and area groups. If there were to be a segregation of these groups as to inspection, based on the kind of work done and the size of the job as well, we would say that the work of the crafts and shops dealt more with shutdown inspection, while that of the area groups dealt with visual or working inspection.

It is therefore necessary that the extent of the use and kind of inspection be based on an actual study of work conditions.

Assuming that all maintenance work is done either by patrol (Fig. 6-8), or normal repair orders (Figs. 6-6 and 6-7), it is obvious that the work covered by each of these must be analyzed over a definite period of time to determine the kind of work involved, amount of each kind, frequency, and individual times required. After this has been done, it becomes a matter of establishing a standard task with definite work and personnel requirements covering all work of a visual-inspection nature. Infrequent small jobs must still be covered by written patrol orders.

The size and frequency of overhaul of the larger jobs will establish their frequency for shutdown inspection. This frequency is very vital to the success of an inspection system, since too long an interval will not describe potential breakdowns in time to apply preventive maintenance, and too short a period results in excessive inspection cost and reduces equipment operating hours

Additional frequency-determining factors for shutdown inspection are

1 Operating time
2 Individual equipment conditions, such as
   a Speed
   b Complexity
   c. Materials of construction
   d Materials processed
   e Surrounding conditions
3 Importance to plant operations

Another important method of determining frequency of inspection consists in dividing annual maintenance costs by investment, *i e*, if the estimated inspection

NOV
DEC

FIG 6-14 Plant equipment inspection schedule.

frequency is high, the maintenance to investment ratio will usually be found to be high, and vice versa

This means that, if maintenance costs are not kept by equipment, which will be explained under Corrective Maintenance, this information will not be available for establishing inspection frequencies based on work done

Inspection Schedules. After all inspection frequencies have been determined, a schedule (see Fig 6-14) is established covering all equipment in this category (The same can be done for buildings, facilities, etc) The equipment is not scheduled any closer than a week, since arrangements must be made with the operating department to take the equipment out of service at a time convenient to production schedules Space is also allotted on this sheet to show the actual date on which the inspection is completed, since this serves as a follow-up and information for future scheduling

In addition to the inspection schedule, there should also be a record of the condition of each piece of equipment when inspection was made This record will also serve as a basis for repair as well as a continuous master record of the condition of that piece of equipment Such a maintenance inspection operation sheet is shown in Fig 6-15, which is laid out to fit in with the ideas of job standardization as to the proper arrangement of the component parts of the job and the selection of correct materials, tools, etc

CORRECTIVE MAINTENANCE

There are five requisites to a corrective maintenance program, *viz*:

1. A Real Desire for Improvement. Too often responsible personnel in a plant tends to become close-minded relative to possible improvements because of a lack of facts or figures to indicate the condition. In order to overcome this last condition, the engineer must accumulate as many measuring factors as is possible to indicate the need for improvement. For instance, the maintenance cost as per cent of investment of a total plant may seem to be quite reasonable, whereas a breakdown by individual or groups of similar equipment may be quite the reverse. Also the total maintenance labor-material ratio might not be indicative of any unusual condition, whereas a similar breakdown by individual equipment might show some very outstanding discrepancies. The collection of such informative data will very definitely hasten a desire for improvement.

2. Engineering Assistance. A review of Fig. 6-3 indicates that while constructive criticism can be given by supervision of the engineering department toward any corrective maintenance program, supervision is not in a position to make actual studies either of jobs or of accumulated information. These are functions of the planning and scheduling or methods engineer.

3. A Practical Inspection Program (discussed under Preventive Maintenance).

4. Job-standardization Program (page 284).

5. An Equipment-cost-card Procedure (see below).

To state that 5 is superfluous is to deny facts that indicate the tremendous possibilities to plant improvement through the use of an equipment-cost-card procedure as well as an active support of 2, 3, and 4. Under Cost Controls will be shown charts of the results of maintenance conditions in two plants where one was receiving active support of improvement programs and the other was not.

Equipment-cost Cards. An equipment-cost-card procedure is a systematic posting of all completed maintenance work according to individual building or equipment.

EQUIPMENT-COST CARD

		Brought forward							

Sheet No ______

Equipment No ______

FIG. 6-16.

The purpose is to provide a system of records of plant maintenance and construction work by buildings, equipment, facilities, etc., and to have available a means of easier analysis of jobs for both preventive and corrective maintenance.

The equipment-cost card (Fig. 6-16) provides for the posting of the following information:

1. Repair-order number and date
2. Description of work done and material used according to key method
3. Labor and material costs by direct and indirect
4. A periodic summary of data as a basis for maintenance improvement

Equipment cards should cover

1. Individual buildings
2. Groups of similar equipment
3. Utilities such as the main air, steam, and water lines, roads, outside tanks, etc.
4. Blanket orders as blanket equipment number
5. Burden codes such as shops, supplies, hospital, fire protection, etc., as burden equipment numbers

Postings are made of completed normal orders. Patrol orders are posted only as a summation of monthly costs according to equipment numbers.

In this section reference has been made a number of times to a blanket repair order. This type of order covers a series of regular repetitive scheduled jobs. While it very definitely can be misused and can become a dumping ground for miscellaneous charges, if used correctly it very definitely has a place in a maintenance program. In the equipment-cost-card procedure blanket orders become blanket equipment numbers. It is very necessary that all maintenance costs be covered by the equipment-cost-card procedure.

Some criticisms concerning the use of the equipment-cost cards for keeping maintenance costs are

1. It requires the numbering of all equipment, buildings, etc., and represent additional codes to the plant.
2. It requires clerical assistance to maintain
3. It requires clerical assistance to publish a report semiannually.
4. In some cases the information is not used after collected.

Answers to these criticisms are as follows:

1. Equipment-cost cards do require the numbering of all plant equipment, buildings, etc., but in most cases they must be numbered for inventory purposes anyway. The equipment numbers also serve as departmental codes for cost purposes, and no additional coding is required.

2. They do require clerical assistance to maintain, but (*a*) the repair orders represent the actual records of work done, and this method of recording tends to reduce engineering experience required for analyzing purposes, thus reducing the clerical effort to a minimum. In addition, the need for better description as required for the equipment posting tends to necessitate better analysis of the repair orders by the foreman. Simplicity of posting is secured by the use of the key method which records on the equipment-cost card only the equipment number, part repaired, and total labor and material costs and is usually limited to one line. The equipment-cost card does not take the place of the standard operation sheet used for job standardization or shutdown inspection, as this would only clutter up the card with information that has already been established elsewhere.

(*b*) They give a summary of results over a sufficient period of time to determine trends and allow these results to be analyzed for corrective purposes.

3. As stated previously, it is necessary to want improvement to have it. If a plant or maintenance organization is not interested either in improvement or correct frequencies of inspection for preventive maintenance, it is useless to keep these records.

COST CONTROLS

The objective of the cost-control plan is low maintenance cost, but it is a result rather than a cause, and it is essential that all factors discussed herein be complied with if these costs are to be attained.

Maintenance costs cannot be measured as a lump sum or in relation to the product or products as a whole. Maintenance costs are not that simple to interpret but are representative of various plant conditions which must be understood if these costs are to be of value in indicating actual conditions. The plan's approach to this problem of cost interpretation is to segregate maintenance costs into three classes, which are described as follows:

Cost Classification—Direct, Indirect, and General. Cost classification is a method of segregating maintenance labor and material costs according to three classes of maintenance known as direct, indirect and general.

Direct Maintenance. Direct maintenance covers repairs to operating equipment or auxiliary equipment attached to it. It also includes miscellaneous repairs such as oiling machinery, packing pumps, inspections, etc. Direct maintenance should be proportional to production.

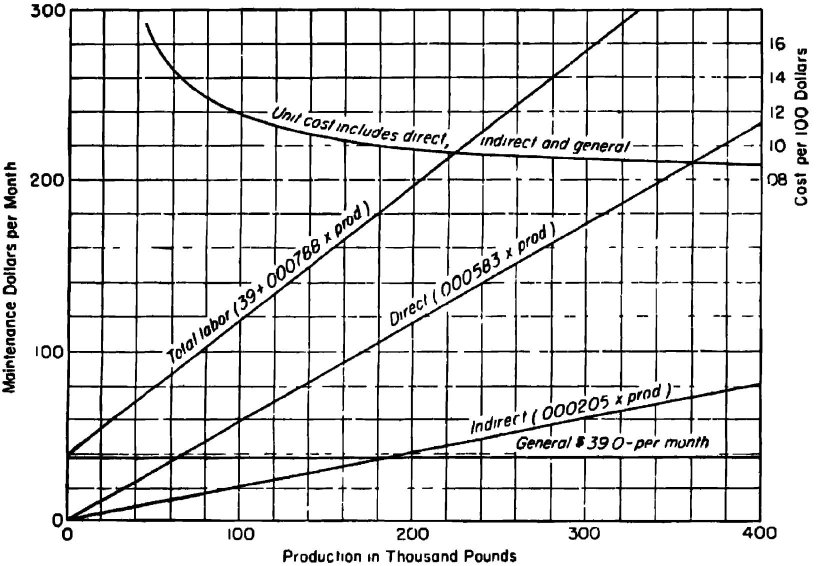

Fig. 6-17. A chart for establishing monthly budgets based on direct, indirect, and general maintenance costs.

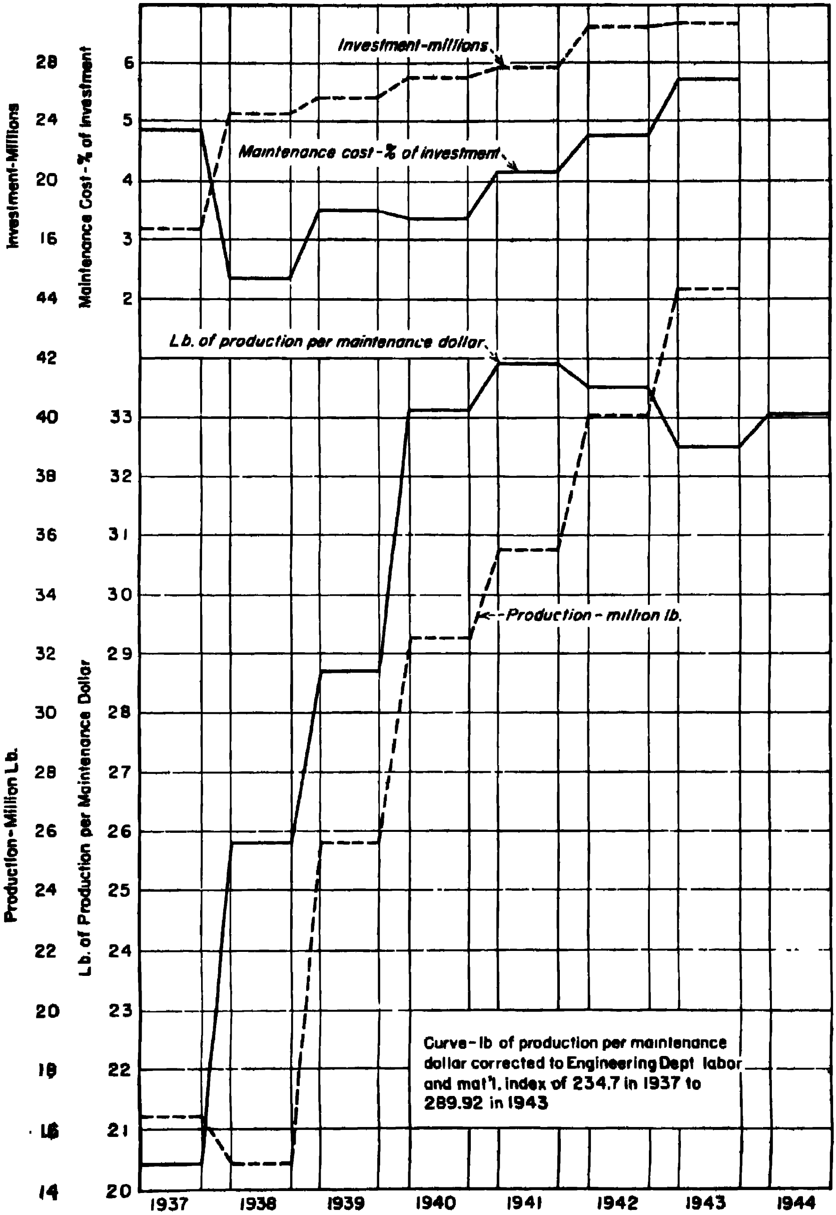
Indirect Maintenance. Indirect maintenance covers repairs or replacement of parts, such parts being not entirely worn out, replacing them with parts of improved design, additions (when not capitalized), replacements (when they reflect changes in design), materials and methods only, rearrangements, and service to operations.

General Maintenance. General maintenance covers repairs to buildings, outside lines, storage tanks, roads, main power, steam, air, or process lines, and structural support of buildings, but not that supporting equipment. General maintenance covers any type of repair that does not vary with production.

The purpose of this classification is to segregate the various classes of maintenance as to responsibility, conditions, etc., in order that cause can be investigated and improvements made accordingly; to emphasize what work is or is not affected by production; to establish a control of indirect work and determine its relationship to direct and general classes in similar plants.

In charging all maintenance costs in a lump sum, the variables due to production, development changes, service conditions, etc., are lost sight of, as well as those conditions in which production has little effect such as weather, service, burden, etc. By dividing maintenance costs according to the three classes, a means is provided



Curve-lb of production per maintenance dollar corrected to Engineering Dept labor and mat'l. index of 234.7 in 1937 to 289.92 in 1943

FIG. 6-18. A chart for measuring annual maintenance effectiveness; indicates progress.

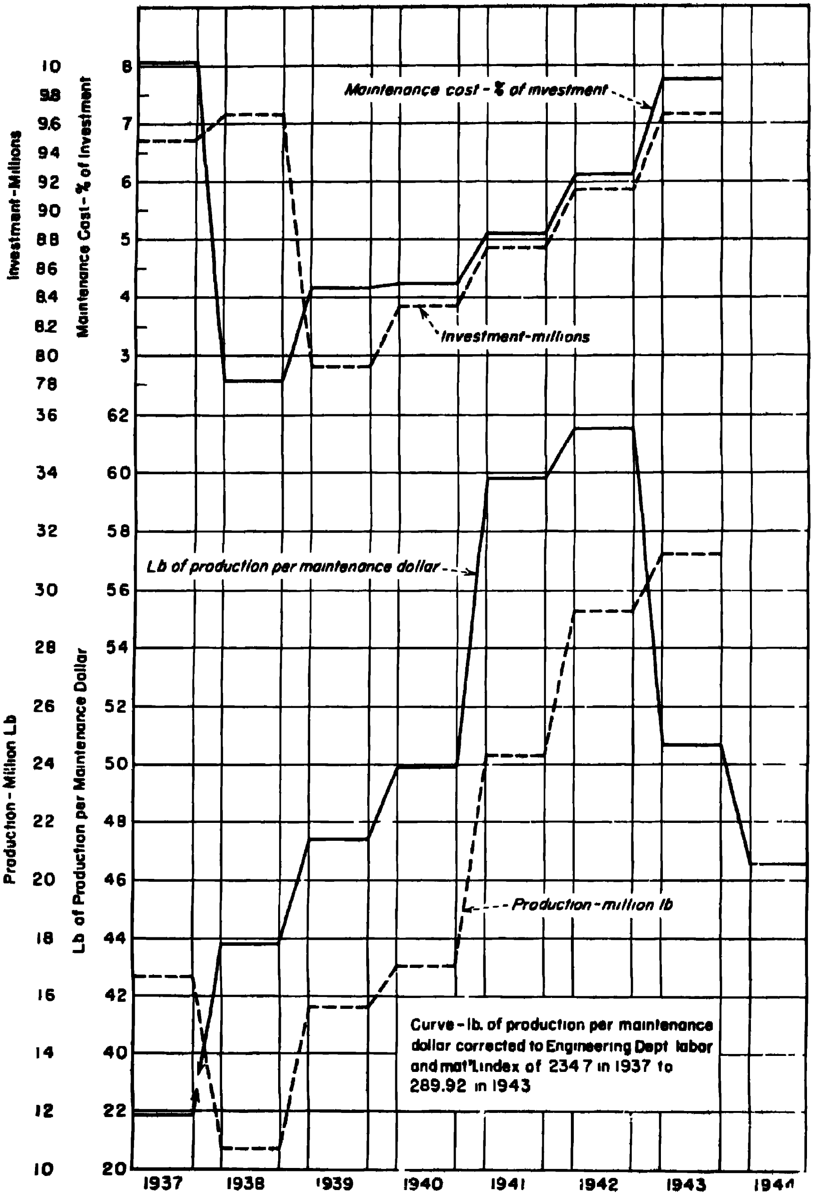


FIG. 6-19. A chart for measuring annual maintenance effectiveness; indicates retrogression.

for definitely segregating the work that is a direct function of a maintenance organization and that which must be justified by the other departments.

Budgets. A monthly budget chart established according to the three classes of maintenance discussed is shown in Fig. 6-17. Figures making up such a chart must be worked up carefully covering a number of years for any particular plant in order to reflect an average condition of maintenance. The chart also must represent maintenance conditions at various levels of production which is so necessary in determining budget figures.

7. Organization chart

FIG. 6-20.

On the basis that budgets are made to indicate possible costs, that meeting budgets is only balanced spending, and that improvements will be reflected in the use of budgets, it is obvious that the same rules must be applied to this manner of measuring costs as to any other.

Charts. A method of measuring maintenance results at two plants is shown in Figs. 6-18 and 6-19. The bases of measurement are

1. Maintenance cost as per cent of investment
2. Pounds of production per maintenance dollar

In order to have conditions comparable, all maintenance costs are corrected to an index figure (1) as shown on the lower part of the chart. Maintenance cost as per cent of investment reflects actual costs.

To show improvement it is necessary that the heavy line in the lower part of the chart indicating pounds of production per maintenance dollar continue its upward path with the production or dotted line. Conversely, a trend in the opposite direction indicates lack of improvement.

Maintenance cost as per cent of investment shown on the upper part of the chart by the heavy line indicates a method of measuring results over a period of time and also indicates whether maintenance improvement has been secured by expenditure of capital dollars. This will also be reflected if the maintenance department makes improvements through the application of methods and better procedures without additional capital expenditure.

It was previously stated that charts would be shown, one of which represented a plant where improvement was about continuous, while the other showed a definite backward trend. Figure 6-18 is an example of the first case, while Fig. 6-19 represents the second case.

Monthly Report. Another measure of results is the maintenance monthly report. A proposed form to be used covering the result of the use of some of the procedures outlined in this section is shown in Fig. 6-20. It is believed that not only this report, but all the other measures outlined, are essential for good maintenance.

The results to be gained by using the basic principles outlined in this plan can be summed up as follows: The plan constitutes

1. A method to maintain a plant in good operating condition at a minimum of cost
2. A means to correct and improve
3. A basis for selecting a high type of maintenance supervising personnel

Maintenance Measurement (Actual Time Values). All the foregoing is measurement, and it is believed necessary before actual time measurement is of any real value. In establishing time measurement standards, experience has indicated that their failure in most cases has been due to one or more of the following:

1. Lack of job standardization, or establishing the one best method
2. Insufficient knowledge and training of personnel in establishing the standards
3. Lack of consideration and understanding of the importance of maintaining the standards up to date, taking into consideration both process and technological changes

Although time measurement can be successfully applied to maintenance and/or any other factor of production, it should not be effected until the above or some similar plan has been applied, since only confusion and adverse reaction will occur.

INDUSTRIAL WATER PURIFICATION AND TREATMENT

BY D. C. CARMICHAEL

Chemical Engineer, E. I. du Pont de Nemours & Co.

Water is a fundamental requirement for every industrial plant. It supplies feed water for all steam-power plants; cooling water for internal-combustion engines and steam condensers; means of washing, preparing, and distributing the pulp for paper manufacture; washing requirements for textile mills, dyeing establishments, and laundries; and enters in some manner into all major industries.

The fitness of the water supply for the respective industries has frequently been a determining factor in the location of manufacturing industries, especially in case of textile and dyeing industries. With the industrial development of our country, we have long since passed through the period when the character of the water was a determining factor in the location of an industry. With the advancement made in the art of water purification, it is only the exceptional water supply which cannot be treated or purified to meet the requirements of any of our major industries.

The substances in water that is objectionable for use in various industries are chiefly the mineral solids or gases. The bacteriological growths in water supplies, which must be so carefully controlled in the large municipal plants where water is prepared for drinking purposes or food products, are not commonly of much significance for most of the industrial requirements. This, however, does not always apply, since bacteria in water supplies frequently are the cause of slime deposits objectionable in the paper industry as well as in other processes where water is used for cooling.

It therefore becomes necessary to determine all the various constituents in the water that may be objectionable to any particular process requirement before the best method of water purification can be determined. When the process requirements are understood and the constituents of the water are known, a practical treatment with the necessary equipment can nearly always be prescribed. For procedure on analysis of water, the American Public Health Association's "Standard Methods for the Examination of Water and Sewage" is a standard reference. Table 7-1 is a conversion chart frequently used in water analyses.

NATURAL WATERS AND THEIR IMPURITIES

Water is a tasteless, colorless, and odorless liquid. It is a chemical compound which is expressed by the formula H_2O, indicating the combination of two volumes of hydrogen and one volume of oxygen. Chemically pure water is an extremely rare article and difficult to obtain since it is an almost universal solvent, and practically all substances are soluble in it to some degree. Because of this property, water is readily contaminated by substances with which it comes in contact.

Table 7-2 gives a list of the constituents present at times in some waters and which may be objectionable when present.

Generally speaking, the preparation of water for industrial purposes is accomplished by the utilization of equipment for performing the services of

1. Sedimentation
2. Filtration
3. Softening
4. Deaeration

SEDIMENTATION

Sedimentation, filtration, softening, and deaeration may be used either alone or in combination, depending upon the condition of the raw water. In industrial plants,

where the quality of the water is not an important factor, sedimentation alone may satisfy all requirements Many plants install impounding reservoirs for preliminary settling basins since they serve not only for removing part of the turbidity but also as collecting basins for recovered cooling water Not infrequently, a spray cooling system can be installed at one end of the impounded reservoir for lowering the temperature of recovered water An impounding reservoir is especially suitable where the original source of water is a river from which pumping can be carried on during the off-peak electric load

Table 7-2. Common Impurities in Water

Constituent	Chemical formula	Principal source of contaminating substance	Treatment for removal from water
Suspended solids		Surface drainage trade waste	Plain subsidence coagulation filtration evaporators
Silica	SiO_2	Mineral deposits	Plain subsidence coagulation, filtration
Calcium carbonate	$CaCO_3$	Mineral deposits	Softening by chemical, by base exchange materials
Calcium bicarbonate	$Ca(HCO_3)_2$	Mineral deposits	Softening by heaters by chemical or by base exchange materials
Calcium sulfate	$CaSO_4$	Mineral deposits	Softening by chemical by base exchange materials
Calcium chloride	$CaCl$	Mineral deposits	Softening by chemical by base exchange materials
Magnesium carbonate	$MgCO_3$	Mineral deposits	Softening by chemical by base exchange materials
Magnesium bicarbonate	$Mg(HCO_3)$	Mineral deposits	Softening by chemical by base exchange materials
Magnesium chloride	$MgCl_2$	Mineral deposits	Softening by chemical by base exchange materials
Free acids	HCl H_2SO_4	Mine drainage trade waste	Neutralizing acid followed at times by softening
Sodium chloride	$NaCl$	Sewage trade waste mineral deposits	Evaporator
Sodium carbonate	Na_2CO_3	Mineral deposits	By acid exchange material
Sodium bicarbonate	$NaHCO_3$	Mineral deposits	By acid exchange material
Carbonic acid	H_2CO_3	Absorption from the atmosphere mineral deposits decomposition of organic matter	Deaerator
Oxygen	O_2	Absorption from the atmosphere	Deaerator
Grease and oil		Trade waste	Coagulation filter
Organic matter and sewage		Domestic and trade wastes	Coagulation filter

The determining factors in favor of preliminary settling basins are

1 Reduction in the cost of coagulation and filtration resulting from a smaller amount of chemicals required for these purposes

2 Better clarification in coagulation and secondary basins, resulting in reduced load on filters

3 Increased length of runs between cleaning of filters, with reduction in wash water

Chemical Coagulation with Sedimentation. Sedimentation in its simplest form consists of passing the raw water through specially designed horizontal basins at comparatively low velocities so that the solids are precipitated of themselves or by the aid of a coagulant In cases where waters are extremely high in turbidity, *e g*, Mississippi River water, sedimentation may be divided into two stages (1) plain subsidence, in which a greater portion of the suspended matter is allowed to settle without the aid of artificial means, (2) sedimentation with the aid of a coagulant

In most cases, coagulation is coupled with the process of sedimentation, and the most common chemical used as a coagulant is alum or aluminum sulfate.

Sedimentation-basin Design. Present-day design of sedimentation basins calls for equipment for the proper mixing of the coagulant with the water before it enters the sedimentation basin. The apparatus may vary in design, but the sole purpose is to ensure the uniform distribution of the chemical with the water. After the mixture of the coagulant with the water is made, it travels horizontally through the basin at a velocity usually not exceeding 9 to 12 in. per min. The basins are usually rectangular with a total depth not exceeding 14 to 16 ft.

The retention period may vary from 1 to 4 hr, depending upon the condition of the raw water or the degree of sedimentation desired. Frequently, the flow through the sedimentation basin is interrupted by baffles to ensure freedom from short-circuiting and maximum precipitation in the time available. The basins are constructed so that the precipitated matter, after accumulating over a length of time, can be washed to waste through a drain. This requires taking the basin out of service, and, where justified, designs can be provided for continuous collecting of the sludge at one end of the basin and intermittent removal by manual or automatically controlled blowoff.

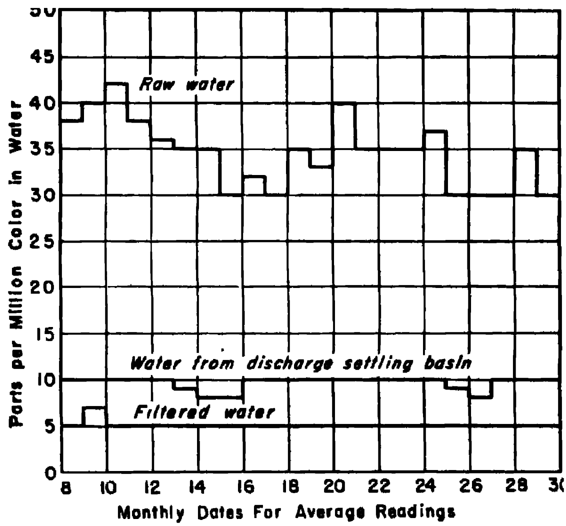

Fig. 7-1. Color content of water in various steps of removal in sedimentation basin.

Color Removal. In addition to the requirements for highly turbid water, sedimentation is necessary for the removal of coloring matter. Coloring matter is prevalent in woodland areas, particularly in swamp districts such as portions of Florida, Wisconsin, and New York State. The color in these waters varies from that which cannot be detected by the eye to that which resembles weak tea. The color is detrimental to many industrial purposes such as papermaking and textiles. While these waters are usually very soft and quite free of suspended matter, removal of the coloring matter presents a problem different from the removal of suspended matter. Aluminum sulfate customarily is used as the coagulant, and in some cases chlorinated copperas has come into use as a highly efficient coagulant for the removal of color. Figures 7-1 and 7-2 show the color content of water in various steps of removal in a sedimentation basin and the effectiveness of chlorinated copperas as compared to alum in removal of color. The chlorine and copperas (ferrous sulfate) form the chlorinated copperas but are fed as separate chemicals.

The removal of color by means of a coagulant is not a chemical process as is the case with suspended matter where the precipitated coagulant, spongelike in nature, mechanically gathers together the finely divided suspended matter. In the case of coloring matter, the reaction is chemical, and the coagulant actually reacts with the coloring matter to form a substance known as a "lake." This substance is more delicate in structure than the aluminum hydrate formed in the coagulation of suspended matter in the absence of color. The delicacy of this precipitate brings about a problem in filtration that is not found where suspended matter only is to be removed.

Iron Removal. Sedimentation has been referred to in connection with the preparation of surface waters. However, it is frequently necessary in the preparation of well waters containing iron. There are certain districts in Illinois, New Jersey, Florida, and the Western states where well waters are known to contain iron having the property of precipitating a brown iron-rust-like sludge after standing. This sludge was originally in solution in the form of ferrous carbonate, and upon becoming exposed to the air it precipitates as ferrous hydrate.

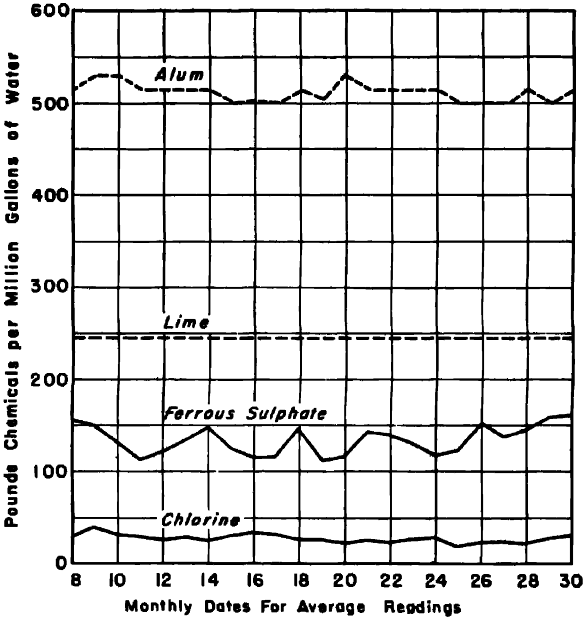

FIG. 7-2. Effectiveness of alum vs. chlorinated copperas in removal of color.

For industries where clear water is essential, it is necessary first to remove the iron from solution before it can be used. The process involves aeration and, usually, sedimentation. Sedimentation, however, is abbreviated compared to that required for the removal of suspended matter and color, and, where the amount of iron is high, less than an hour is required. It is customary in the removal of iron to add either a coagulant or caustic soda in order to bring about better flocculation and precipitation of the iron particles. By a combination of aeration, sedimentation, and filtration, the iron content of the water may be reduced to within limits of 0.2 ppm and in certain cases to 0.01 ppm.

Chemical Control. In the use of coagulants in the process of sedimentation, it is highly desirable to predetermine the most efficient dosages. These coagulants are temperamental and, under slightly varying conditions, may not behave as expected. It is therefore necessary to maintain within delicate limits a certain condition of acidity or alkalinity in the water in order to ensure the most efficient point of coagulation. This point is usually referred to as the "optimum point" and is determined in the laboratory by very delicate indicators for excess alkalinity and acidity as pH or hydrogen-ion values. When the determination is made in the laboratory, it is important to maintain the operating conditions exactly as the laboratory experiments dictate. In many cases, instruments are used where the coagulant is fed not so much in accordance with the flow of raw water as on the basis of the pH or hydrogen-ion value.

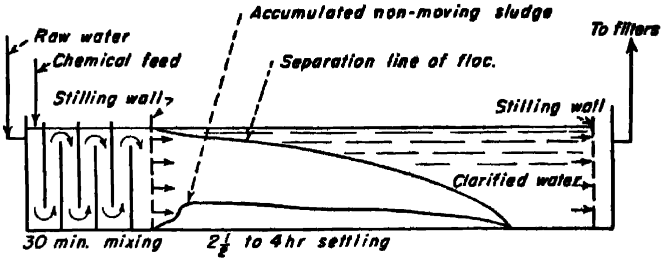

FIG. 7-3. Graphic illustration showing settling in standard mixing chamber and settling basin.

Mechanical Settling. Recent developments in water-purification plants have shown mechanical settling to be superior in many cases to the usual rectangular horizontal basin not only in first cost but also in operating and chemical costs. Mechanical settling, frequently referred to as "rapid sedimentation," is offered by a number of companies, among which are Dorr Company, International Filter Company, and the Permutit Company.

The advantage of mechanical settling over the plain settling basin is that retention time required during mixing and settling is less when compared to the time required in the conventional baffled mixing chamber and settling basin. The required time is 35 to 60 min in the case of mechanical settling and $2\frac{1}{2}$ to 4 hr in the plain settling basin. Mechanical settling by the use of certain principles utilizes sedimentation capacity more efficiently then heretofore. By recycling sludge at high concentrations, coagulation is accelerated, thus reducing the time requirements for mixing. The comparison between the standard mixing and settling basin and two systems of rapid sedimentation is shown graphically in Figs. 7-3, 7-4, and 7-5.

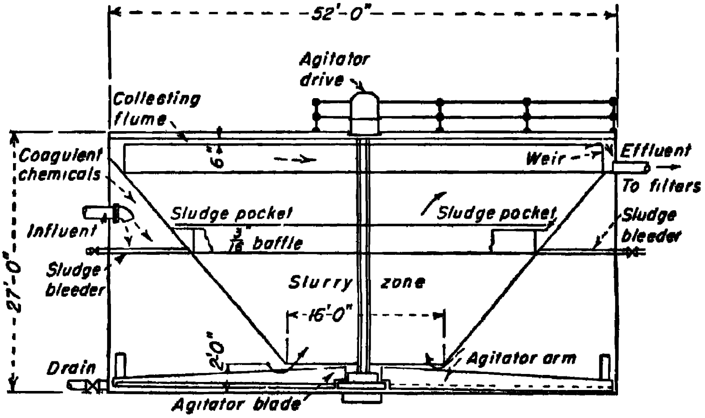

FIG. 7-4. Graphic illustration showing settling in Spaulding precipitator. (*The Permutit Co.*)

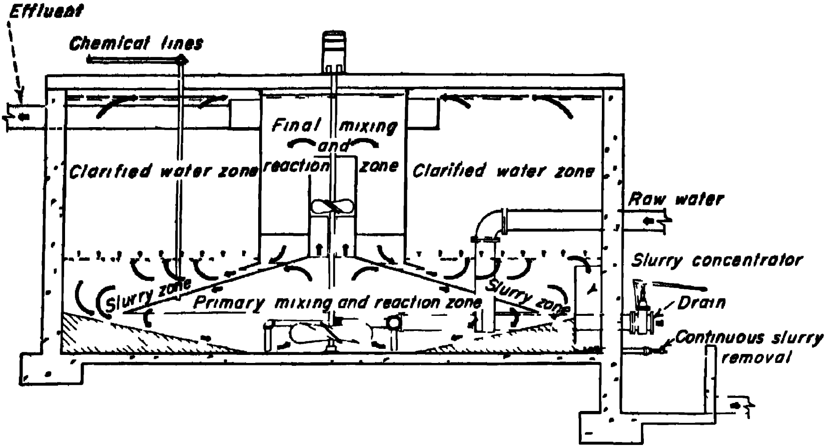

FIG. 7-5. Graphic illustration showing settling in accelator softener. (*Infilco Incorporated.*)

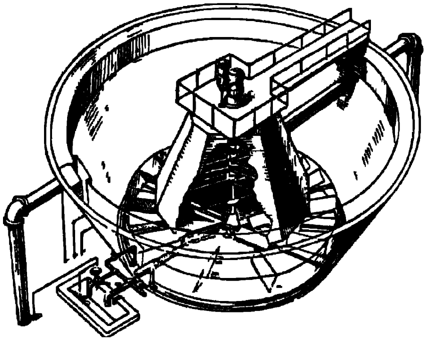

FIG. 7-6. Arrangement of vertical Spaulding precipitator. (*The Permutit Co.*)

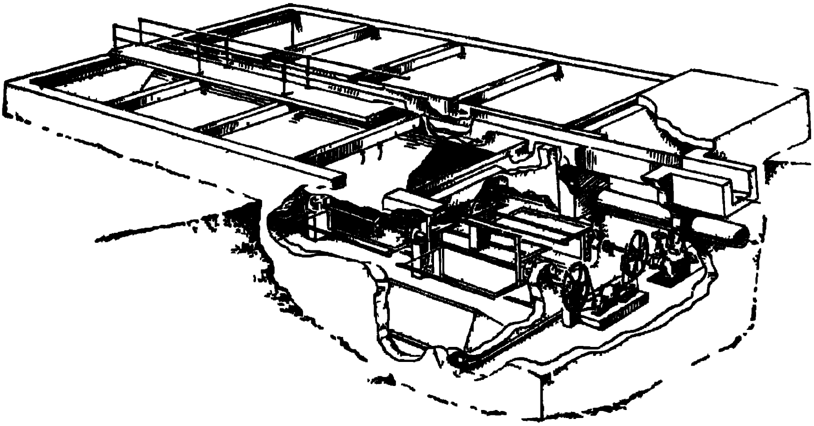

FIG. 7-7. Arrangement of horizontal Spaulding precipitator. (*The Permutit Co.*)

The operation of the standard mixing chamber and sedimentation system as shown in Fig. 7-3 indicates that clarification is accomplished by the precipitation of the individual particles of floc in free settling.

In rapid sedimentation (Figs. 7-4 and 7-5) coagulation is seeded and accelerated by the presence of highly concentrated sludge. No such seeding effect is obtainable in the standard mixing chamber. Settling occurs somewhat in the manner of filtration. The coagulated water is passed upward through a bed of suspended sludge, and the particles of floc are filtered out by the sludge bed. Advantage is taken of the rapid settling rate of the concentrated sludge—hence the high capacities of the rapid sedimentation systems. The sludge level is maintained by continuous or intermittent blowing down, and, where desired, this operation is automatically performed through an electric-program-clock control.

Figure 7-6 is a cutaway view of a vertical Spaulding precipitator, and Fig. 7-7 is a horizontal Spaulding precipitator. The latter design can be employed in converting plain settling basins to mechanical settling.

FILTRATION

The clarification of water by filtration is accomplished by passing the water through a sand bed consisting of grains suitably graded in size, preceded (if required) by coagulation and sometimes by sedimentation. Generally speaking, it is not safe to filter a surface stream without previously passing it through a sedimentation basin. Filtration is essentially a screening and frictional-resistance process. Suspended matter that is too large to pass through the interstices between the sand grains is strained out and retained on the surface of the filter bed, and smaller particles are retained by the bed through frictional resistance. Of the remaining particles, too fine to be removed by straining or frictional resistance, some are colloidal and can be removed after proper coagulation. However, it is well to remember that most filtration processes are preceded by coagulation, with or without sedimentation, in order to make the filtration process more efficient. When water flows through a filter, coagulated solids are retained on the surface of the filter bed, where they in no way interfere with perfect filtration but, on the contrary, cause increased frictional

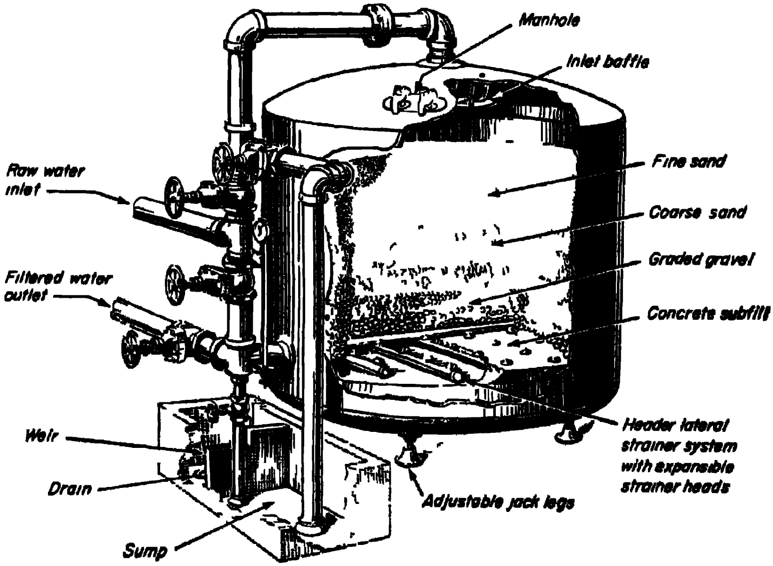

Fig. 7-8. Vertical pressure filter. (*The Permutit Co.*)

resistance and afford a finer screening than when the filter is first placed in service. In fact, a filter is at its best just as its capacity begins to decrease.

When the solids on the surface of the bed accumulate to such an extent that the

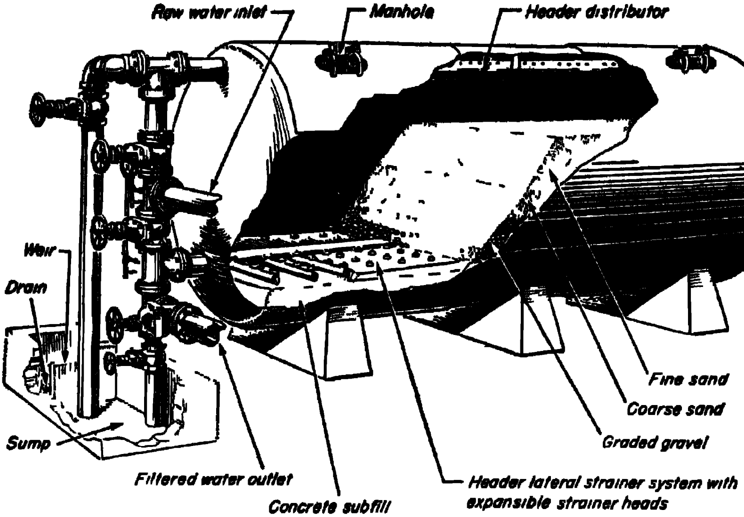

Fig 7-9 Horizontal pressure filter. (*The Permutit Co*)

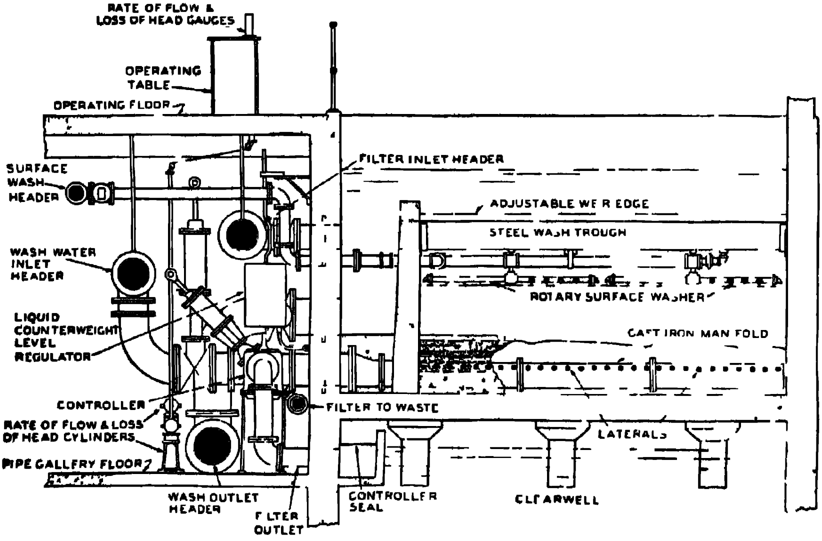

Fig 7-10. Cross section of concrete gravity filter (*The Permutit Co*)

frictional resistance through the bed becomes excessive (say, 5 lb per sq in.), it is generally found desirable to remove the retained solids by backwashing.

Backwashing. In backwashing a filter, the water is passed through the bed in a reversed direction at a rate four to seven times the filtration rate, causing boiling of the sand and carry-off of the suspended matter. In some cases the suspended matter is packed so densely that its removal becomes more easy when backwashing with water is preceded by air agitation. The air bubbling up through the sand bed breaks through the matted surface, which allows easier backwashing with water.

Types of Filters. Filters are of two general designs—the pressure and the open gravity type. For large installations, *e.g.*, textile-plant supplies or municipalities, the gravity type of filter is simpler than a large number of pressure-type filters. The pressure type of filter consists of a tank of either vertical or horizontal construction. Within the tank are placed the essential parts of the filter, such as the inlet manifold, the sand and gravel bed, and the strainer mechanism for collecting the filtered water.

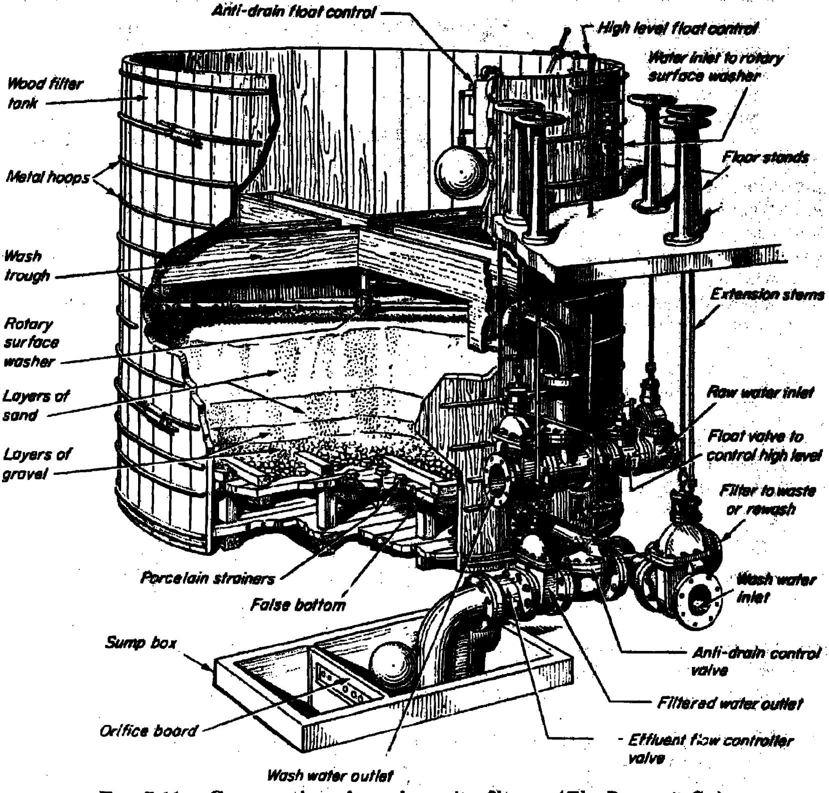

FIG. 7-11. Cross section of wood gravity filter. (*The Permutit Co.*)

The gravity filter covers a greater area than is possible with the pressure type of filter, which is usually rectangular and operated by means of hydraulic valves. One gravity filter may have as much filtering capacity as a dozen pressure filters. It is therefore obvious that for large capacities the control of the gravity installations is very much simplified, whereas for small installations, under certain conditions, the pressure filter offers an advantage. Figures 7-8 and 7-9 show vertical and horizontal pressure filters, and Figs. 7-10 and 7-11 show concrete and wood gravity filters.

The chief distinction between pressure filters and gravity filters is that the former have a closed container designed to withstand the working pressure so that, ordinarily, the use of pressure filters does not require additional pumping. Gravity filters have open containers which make necessary additional pumping unless the water can flow by gravity from a settling basin to the filter, in which case the service pump picks up the filtered water from a clear-well chamber and pumps it to the storage tank or to the various points of use. If it is necessary to pump the water to a filter, it is generally advisable to install a pressure filter, for under these conditions the use of a gravity filter would make it necessary to pump the water twice.

The capacity of a filter is dependent upon the character of the water to be filtered and, in general, lies between 2 and 4 gpm for each square foot of filter-bed area. The more suspended solids in the water, the lower should be the rate of filtration.

Although we consider filtration as meaning a straining action through sand and gravel, recent developments have shown that activated-carbon filters are very efficient in the removal of odors and taste. While this may not be classed strictly as a filtration problem, the units are usually designed along the same lines as filters, including water passage. Therefore, it is pertinent to place this type of equipment in the filter classification.

For the destruction of odor and taste, numerous methods have been employed, such as aeration, excessive chlorination, and introduction of permanganate of potassium.

Where excessive quantities of chlorine are introduced to bring about the destruction of contaminating material, which causes bad taste, the quantity of chlorine is so high that in itself it is objectionable. The removal of this excess chlorine is brought about very efficiently by the passage of the water through a bed of activated carbon. The carbon, of course, acts in an entirely different manner from filtering material, it being an absorbent rather than a strainer, and in the case of chlorine it is believed that the action of chlorine on carbon is purely chemical rather than mechanical. The absorption of other gases, however, may be mechanical, and after the activated carbon becomes saturated, it is necessary to renew the bed.

SOFTENING

In the industrial plant the type of equipment to install presents a problem in itself, depending on the requirements. The industrial softening plant may be divided into several different phases:

1. For industrial processes such as in textile mills
2. For cooling purposes such as engine jackets, spray ponds, etc.
3. For boiler-feed purposes

Textile Mills

In the preparation of water for textile mills, it is essential and highly desirable to remove, as completely as possible, the calcium and magnesium salts. In most textile operations a tremendous amount of soap is used. This soap precipitates any calcium and magnesium and forms a curd which is likely to adhere to the strands of threads and reflect on the quality of the material produced. The absence of calcium and magnesium in such waters not only brings about a better product but also, at the same time, decreases the soap bill considerably. For this purpose, large quantities of cold water are necessary, and the most efficient method of softening under these conditions is the zeolite system. There are many installations now in use where enormous quantities of water are softened by this process.

The most important application of the zeolite softening systems is found in the preparation of industrial waters used in processes where soft water is required, although such systems are used for boiler feed. However, in the selection of a softener for cold industrial water, reduction of hardness and cost of treatment are the main factors to be taken into consideration.

Zeolite Softener. Zeolite softening in its simplest form consists of a tank containing grains of fine bimetal silicate which has the unique property of removing calcium and magnesium from the water. The grains of silicate differ in chemical composition, method of preparation, and amount of softening that may be accomplished by a given volume of the material. The chemical principles involved and the degree of softening obtainable are much the same in all cases. For waters of low hardness it is sometimes desirable to use a natural zeolite of an exchange value of approximately 2,700 grains per cubic foot. For waters very high in hardness and where it is desirable to use small containers, a zeolite of higher exchange value, approximately 7,500 grains per cubic foot, may be used. The degree of softening accomplished by either mineral is essentially the same.

The exchange value of the zeolite and the depth of bed determine the capacity obtainable with any given diameter of container. For convenience, the exchange value of a zeolite is generally based on the cubic foot as a unit. The pound is not so good a unit because the same zeolite may not always contain the same amount of moisture.

The exchange value of a zeolite is measured by the amount of hardness that it will remove between successive regenerations with salt while delivering water of zero hardness by the soap test. This is dependent to some extent upon the rate at which the water is passed through the zeolite bed, although, generally speaking, the rate is not a limiting factor but ordinarily can exceed the actual requirements without lowering the exchange value.

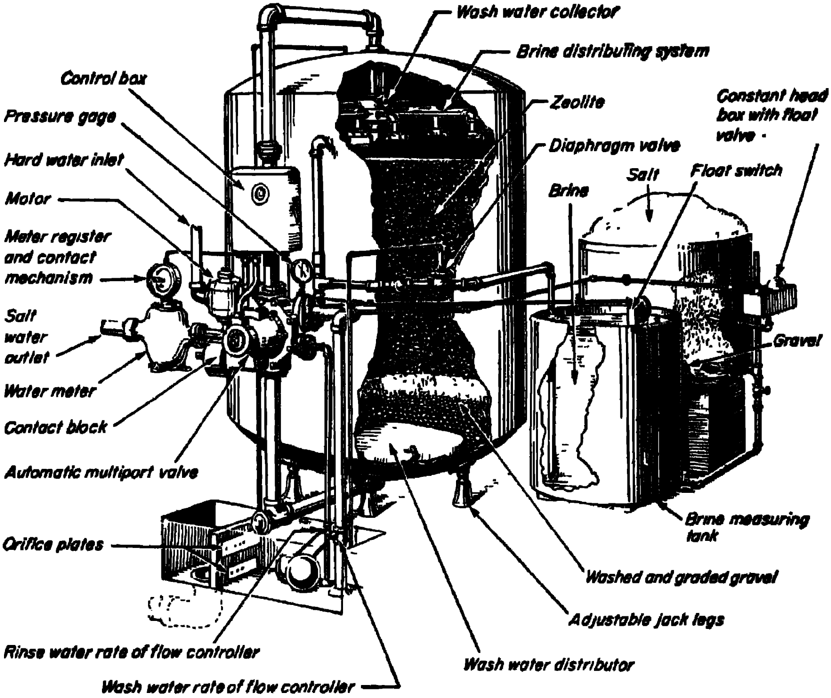

Fig. 7-12. Fully automatic zeolite softener. (*The Permutit Co.*)

Zeolite removes hardness from water much as a sponge absorbs water. Until the pores of the sponge become filled no water will pass through it, but once the pores of the sponge are satisfied any additional water delivered to the sponge passes through or displaces an equal amount of water previously absorbed by the sponge.

Zeolite softeners are offered by a number of companies, among which are Infilco, Cochrane, and Permutit.

A typical automatic zeolite water softener is shown in Fig. 7-12.

Regeneration of Zeolites and Salt Requirements. In passing water through a bed of sodium zeolite, the calcium and magnesium dissolved in the water are absorbed by the zeolite, which gives up a corresponding amount of sodium. After a definite amount of water has passed through the zeolite, so much of the sodium of the bed has been replaced by calcium and magnesium that the zeolite loses its exchange power, and the water is no longer softened. It then becomes necessary to regenerate the bed, *i.e.*, to replace the calcium and magnesium in the zeolite by sodium. This is done by irrigating the zeolite with a strong brine (sodium chloride) solution. A reverse reaction then takes place in that the calcium and magnesium are exchanged for sodium. Whether calcium and magnesium go from the water to the zeolite or from the zeolite to the water depends on the relative proportions of sodium or of calcium and magnesium in the water and in the filter bed. The reaction is, however, so complete that water passing through a regenerated bed of zeolite shows zero hardness as measured by the soap test. As soon as the water leaving the bed contains sufficient hardness to be detected by the soap test, the bed should be regenerated.

The amount of salt required for regeneration is 3½ grains of salt for every grain of hardness in terms of calcium carbonate removed, which is equivalent to ½ lb salt per thousand gallons of water per degree of hardness. To illustrate: if a zeolite softener has the capacity for softening 20,000 gal of 10-deg-hardness water between regenerations, each regeneration will require 100 lb salt.

Since a saturated salt solution contains a definite amount of salt, varying but slightly for ordinary differences in room temperature, and as the water becomes saturated with salt as it passes through the salt in the brine tank, it is necessary only to feed a predetermined depth of salt solution at each regeneration.

Cooling Supplies

The zeolite softener has other applications besides the preparation of process water, such as preparation of water for cooling purposes in the jackets of diesel engines, in the softening of make-up water for cooling ponds, and in the preparation of water for boiler feed and evaporators. In the preparation of water for these latter services, other factors must be taken into consideration besides the degree of softening, for such water, either as leakage or as make-up, finds its way to the boiler, and its preparation must be considered in the same light as would be the preparation of boiler-feed water. The cooling tower and spray pond concentrates water in much the same manner as does a boiler, and wherever condensers are in use with a high-carbonate water, deposits are experienced that greatly interfere with the vacuum to be obtained in the condenser, and, consequently, the operating efficiency of turbo-generator units.

In the treatment of this water the complete softening of the water is not so essential as is the preparation of water for use in textile mills. It is necessary only to reduce the carbonate content to a point sufficiently low so that it does not cause deposits in condensing equipment. For this purpose a number of methods have been proposed. One, as mentioned above, is treatment with a zeolite water softener where the entire hardness must be removed. The second method consists of treating the water with a cold-process water softener, using lime and soda ash as the treating agents. In most cases, however, lime alone is all that is required. This is usually accompanied by a coagulant such as aluminum sulfate, ferrous sulfate, or possibly sodium aluminate. The precipitation of the carbonate hardness to several grains per gallon is all that is required for ample protection. In some cases soda-ash treatment is added to the lime treatment for the precipitation of the permanent hardness, in which case a portion of the water may be used for boiler feed.

Boiler-feed Water

Perhaps the most intricate problem in the selection of water-treating apparatus is in the preparation of water for boiler-feed purposes, where consideration must be taken not only of the degree of softening that may be obtained but of many other factors as well. For the softening of boiler-feed water there is a rather wide selection of treatments and combination of treatments that may be used. These treatments may be divided into two general classes—internal and external. The internal treatments include compounds, soda-ash treatments, colloidal treatments, and various other chemicals that are placed on the market under a definite trade name.

The second method includes lime and soda softeners, cold and hot process, lime and barium softeners, and zeolite softeners.

Internal Treatment. The application of internal treatment without knowledge of the condition of the boiler water, such as the use of a boiler compound, is gambling on whether or not the right dosage is applied. Usually there will be a certain amount of success achieved with this method, depending upon how nearly correct the proper treatment was guessed. Table 7-3, taken from the "Prime Movers Committee Report of the National Electric Light Association," reports 19 boiler compounds of varying compositions. The relative price of soda ash, on the basis of water-softening ability, shows a wide fluctuation as compared to soda ash when purchased on the open market. It is therefore clear why boiler compounds have fallen into disrepute and why a fair success can be achieved with internal treatment by using commercial chemicals such as soda ash, caustic soda, or any of the sodium phosphates.

Internal treatment of water has a certain field, and in some cases, satisfactory results can be obtained. In localities of soft water, where the degree of hardness is low, internal treatment is quite satisfactory. It must be remembered that with internal treatment there is no removal of solids from the raw water supply, and if internal treatment is used on very hard waters where the make-up is high, it is usually followed by a condition of priming or scale formation which requires softening equipment external to the boiler for its correction.

Table 7-3. Boiler Compounds

Boiler compound number	Soda content based on soda ash, per cent	Pounds compound equal to 100 lb soda ash	Costs compared
1	14 0	700	$ 70 00
2	26 6	368	36 80
3	38 8	253	25.30
4	5 4	1,810	181.00
5	26 1	375	37.50
6	35 5	277	27.70

External Treatment. The external softening of water for boiler-feed use may be accomplished in a number of different ways, among the most common being

1. Intermittent—using lime and soda ash
2. Continuous softening—either cold or hot process, using lime and soda ash and/or sodium phosphate
3. Zeolite

Intermittent Softeners. Intermittent softeners are operated on the fill-and-draw plan, the system consisting of two or more tanks, one supplying soft water which has been previously treated, while the others are being filled and treated with the softening reagents. The units are operated generally on a definite cycle, which consists of filling the tank with raw water, adding the entire amounts of chemical in proportion to the amount of carbonate and noncarbonate hardness present in the water, agitating the water to ensure thorough admixture and permitting the insoluble salts to precipitate while the water remains quiet. After a sufficient time has elapsed for subsidence of the precipitate, the soft water is drawn from the tank. The same procedure is followed with the other tank or tanks.

The disadvantage of this method of softening is the rate of reaction. Also the settling of the precipitates is much slower in cold water than in warm or hot water, and degree of hardness removal is limited.

Continuous Softeners. Continuous softening, as the term indicates, softens the water while it flows through the apparatus. The essential features of this type of softener are as follows:

1. The mixing device for the preparation of the chemical
2. The chemical-dosing apparatus for proportioning the chemicals used
3. The reaction or mixing chamber

4. The settling compartment
5. The filter

The disadvantages of cold continuous-process softening are much the same as those of the intermittent process, although the space requirements per unit volume of water are much less with the continuous process.

Hot-process Chemical Softeners. Hot-process chemical softeners are essentially the same as cold softeners of the continuous type but are distinct from other precipitation softeners in that the softening process takes place in a hot solution. The apparatus is a combination of an open feed-water heater and softener in which the scale-forming solids are removed in part by the effect of heat and as the result of chemical reaction.

The speed of chemical reactions is more rapid in hot than in cold solution, and the insoluble compounds formed settle more rapidly and are more completely removed than in cold water. The rate of chemical reaction is shown graphically in Fig. 7-13.

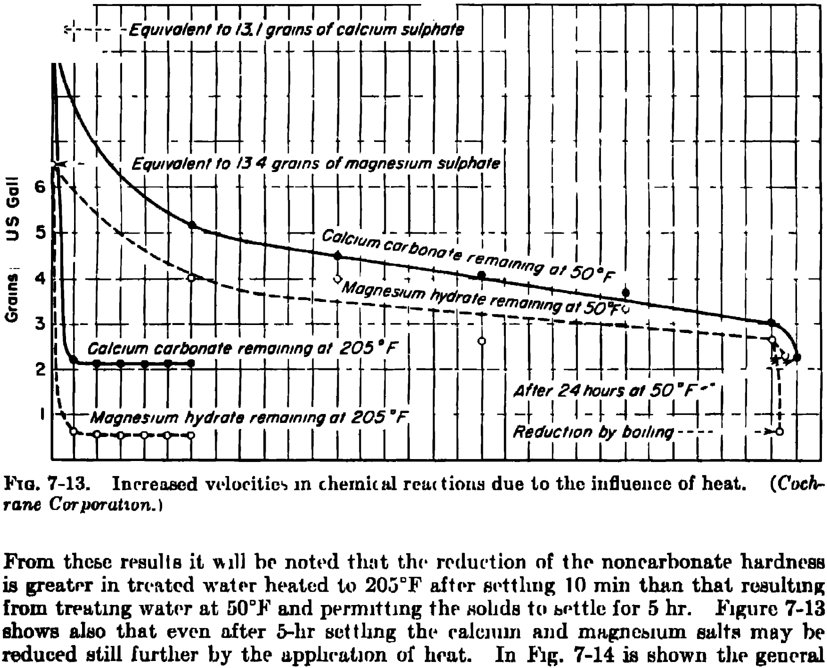

FIG. 7-13. Increased velocities in chemical reactions due to the influence of heat. (*Cochrane Corporation.*)

From these results it will be noted that the reduction of the noncarbonate hardness is greater in treated water heated to 205°F after settling 10 min than that resulting from treating water at 50°F and permitting the solids to settle for 5 hr. Figure 7-13 shows also that even after 5-hr settling the calcium and magnesium salts may be reduced still further by the application of heat. In Fig. 7-14 is shown the general arrangement of a hot-process softener which has been used to treat a large number of feed-water supplies.

A number of hot-process softeners have been placed upon the market within the past few years. They differ from one another primarily in the construction details and in respect to the method of heating the water. Exhaust or live steam may be used, and while exhaust steam is used in most installations the heaters are designed to function under a few pounds of back pressure.

Zeolite. The zeolite softener offers one of the simplest methods for removing hardness from a water supply. Until within the past few years this method of softening was not well adapted for treating all types of water for boiler-feed purposes as none of the solids were removed from the water but were converted to the corresponding soluble sodium salts. The hypothetical reactions which take place in softening water by zeolites may be expressed as follows:

Na_2 zeolite Sodium zeolite	+	$CaCO_3$ Calcium carbonate	Na_2CO_3 Sodium carbonate	+	Ca zeolite Calcium zeolite	(1)
Na_2 zeolite Sodium zeolite	+	$Ca(HCO_3)_2$ Calcium bicarbonate	$NaHCO_3$ Sodium bicarbonate	+	Ca zeolite Calcium zeolite	(2)
Na_2 zeolite Sodium zeolite	+	$CaSO_4$ Calcium sulfate	Na_2SO_4 Sodium sulfate	+	Ca zeolite Calcium zeolite	(3)
Na_2 zeolite Sodium zeolite	+	$Mg(HCO_3)_2$ Magnesium bicarbonate	$NaHCO_3$ Sodium bicarbonate	+	Mg zeolite Magnesium zeolite	(4)
Na_2 zeolite Sodium zeolite	+	$MgSO_4$ Magnesium sulfate	Na_2SO_4 Sodium sulfate	+	Mg zeolite Magnesium zeolite	(5)

Thus it may be seen that all the carbonates and bicarbonates are converted to soluble solids while with the hot-process softener these materials are largely precipitated as was shown in Fig 7-13 If water containing 10 grains per gallon of calcium

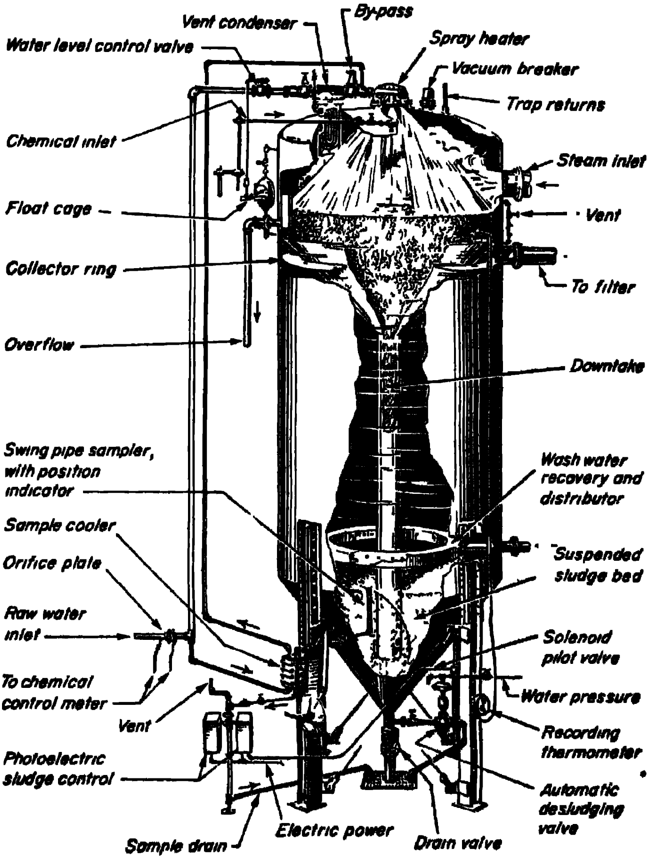

Fig. 7-14. Hot-process chemical softener (*The Permutit Co.*)

carbonate is passed through a zeolite softener, it would be converted to 10.6 grains per gallon of sodium carbonate.

The merit of the zeolite process lies in the fact that the sodium salts do not precipitate to form a scale as would the calcium and magnesium salts. Because of this conversion or exchange process the zeolite softener is not satisfactory for the preparation of all water for boiler feed. Thus the selection of the softening process depends upon the constituents of the raw water.

Degree of Remnant Hardness. The degree of hardness of the treated water is important up to a certain point because it is desirable to keep the boiler water fairly free of suspended matter due to the concentration and consequent precipitation of the hardness remaining in the water after treatment. With any system of precipitating hardness by chemical treatment, such as the cold or hot process, the reduction in hardness depends upon the excess of chemicals used. With a hot-process softener, for example, the use of 1½ grains per gallon excess of sodium carbonate reduced the hardness to 1½ grains per gallon. By increasing the excess of chemical by 1.0 grain, the hardness is reduced by ½ grain. With a cold-process softener, the hardness is not removed so completely, for heat is an accelerator of chemical reactions. While in cold water the hardness is not so completely removed as in hot water, the rule of excess chemical still holds.

With the zeolite, or exchange, type of softener, the reduction in hardness depends upon a number of factors, such as the amount of hardness initially present in the water and the amount of sodium salts initially present.

The hardness of the effluent water may be greater where the raw water is high in sodium salts or hardness than with low-sodium salts or hardness.

Carbonaceous Zeolites. Within the past few years new types of zeolite have become available, among which the most common is carbonaceous zeolite. This material is blackish in color and of granular form, the size of which is so regulated that it will pass a 10-mesh sieve and have definite limits in the amount that will pass a 50- and 60-mesh sieve.

Carbonaceous zeolites can be prepared by any one of a number of treatments of carbonaceous materials such as coal, lignite, or wood. The raw material properly graded is treated for extended periods with any one of a variety of chemicals such as fuming sulfuric acid, sulfur trioxide, chlorosulfonic acid, or zinc chloride, after which it is washed, stabilized, and finally screened to the desired size. Whether or not the raw material has any exchange power, this chemical treatment imparts to it a substantially increased ion-exchange power. In view of this exchange power, this material is classed as a zeolite and, because of its carbonaceous origin, as carbonaceous zeolite.

Carbonaceous zeolite functions in the normal sodium zeolite cycle when it is regenerated with sodium chloride in the usual manner. Because of its unusual resistance to acids, it can also be regenerated with acid solutions such as sulfuric or hydrochloric, in which case it operates in what is termed the hydrogen zeolite cycle, the hydrogen of the acid entering the zeolite and being later replaced by the cations calcium, magnesium, or sodium present in the water to be treated. In addition, the material possesses high operating-exchange value in the order of 5,000 to 12,000 grains of cations (expressed as $CaCO_3$) removed between regenerations per cubic foot of zeolite.

Regeneration. Carbonaceous zeolites when functioning in the sodium (Na_2Z) cycle operate on the same principle as the ordinary sodium zeolite.

For Na_2Z softening

$$(\text{Ca and Mg) salts} + Na_2Z = (\text{Ca and Mg})Z + \text{Na salts}$$

For Na_2Z regeneration

$$(Ca + Mg)Z + 2NaCl = Na_2Z + (\text{Ca and Mg) chlorides}$$

In the hydrogen cycle (H_2Z) the reactions and results differ, as may be noted in the following reaction. Since the cations Ca, Mg, and Na occur in water principally as bicarbonates, sulfates, and chlorides, the various reactions that take place in the hydrogen zeolite cycle are as follows:

For H_2Z softening

$$\left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}(HCO_3)_2 + H_2Z = \left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}Z + 2H_2CO_3$$

$$\left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}SO_4 + H_2Z = \left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}Z + H_2SO_4$$

$$\left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}Cl_2 + H_2Z = \left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}Z + 2HCl$$

For H_2Z regeneration

$$\left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}Z + H_2SO_4 = H_2Z + \left\{\begin{matrix}Ca\\Mg\\Na_2\end{matrix}\right\}SO_4$$

From the above reaction it is noted that in the H_2Z cycle all bicarbonates are converted to H_2CO_3 which decomposes into water and carbon dioxide, thereby reducing the dissolved solids to the extent of the bicarbonate or temporary hardness in water. Where carbonaceous zeolite is used for softening on the hydrogen cycle, the resultant sulfuric or hydrochloric acid is neutralized by mixing water that is treated by the sodium cycle which operates in parallel with the H_2Z units or by the addition of suitable alkali such as caustic soda, soda ash, or phosphates.

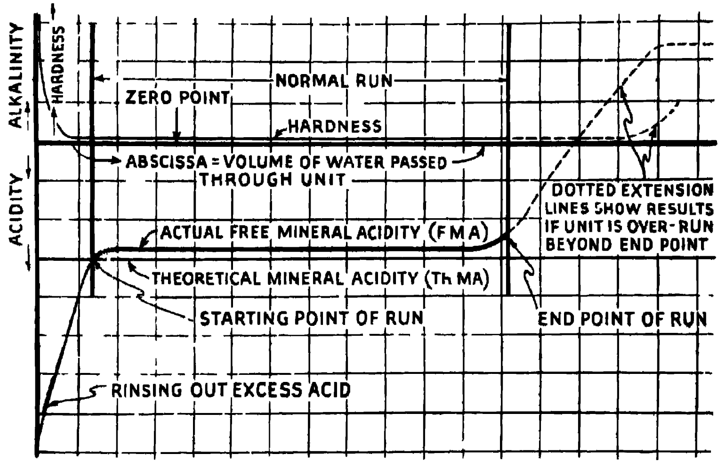

FIG. 7-15. Characteristic curve for carbonaceous-zeolite effluent. (*The Permutit Co.*)

Advantages of Carbonaceous Zeolites. The application of hydrogen zeolite requires study of each water supply to determine the most suitable and economic setup, whether the use of water is for process or boiler feed.

The use of hydrogen zeolite is the only known method, other than distillation, for removing sodium bicarbonate from solution. It likewise will remove hardness to zero and simultaneously reduces alkalinity to any desired value. This is shown in Fig. 7-15. Carbonaceous zeolite has a wide tolerance for acid water and will withstand the attack of acid for long periods.

A typical arrangement of a carbonaceous-zeolite unit operating on the H_2Z cycle is shown in Fig. 7-16.

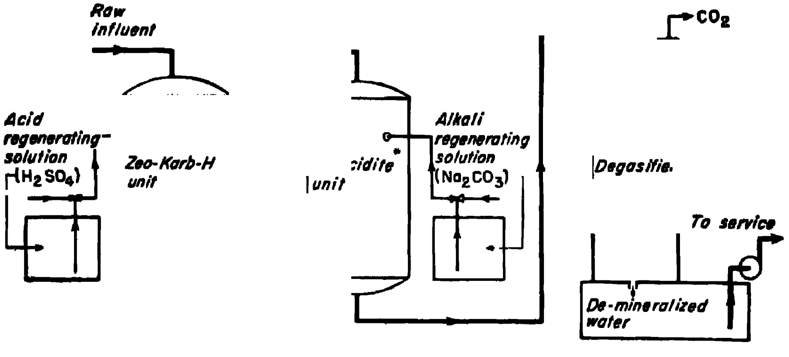
Demineralizing Process for Reducing Dissolved Solids in Water

Many industrial processes require water that is free from the various mineral salts ordinarily present in all natural supplies. This is the case in the processing or manufacture of certain cellulose products, plastics, fine chemicals, pharmaceuticals, photographic materials, and many other materials. In some cases, water free from mineral salts is required throughout all the wet processing. In other cases, it is required only for the final washing, purification, solution, or dilution of the product.



Step No. I
Replacement of metallic cations by hydrogen (H ion) converts salts present in raw water into corresponding acids, viz. HCl, H_2SO_4, and H_2CO_3

Step No. 2
Removal of acids formed in Step No. I. The HCl and H_2SO_4 are absorbed in the De-Acidite unit and the H_2CO_3 and CO_2, this CO_2 escaping to the atmosphere in the degasifier.

FIG. 7-17. Flow diagram of demineralizing process. (*The Permutit Co.*)

Until recently, distillation was the only known process for producing water of such a character. Distillation is effective but expensive. Distilled water costs from 60 cents to $8 per 1,000 gal, depending on the number of evaporator effects.

A simple and relatively inexpensive method known as "demineralization" is rapidly obtaining commercial significance. This is a method whereby the dissolved solids content of water may be reduced by chemical means rather than distillation. In this process, the clear, raw water is demineralized at ordinary temperatures by passing it in succession through two tanks of granular ion exchangers. The process is very similar in principle to zeolite softening and differs only in the chemicals required and the character of the exchange materials. This process is not applicable to highly saline waters such as sea water.

Operation of Demineralizing System. The removal of dissolved solids is accomplished in two steps. First, the cations such as calcium, magnesium, sodium, and potassium are exchanged for hydrogen ions by passing the water through a carbonaceous-zeolite unit operating on the hydrogen cycle. The reactions are those shown on page 316. This leaves the water acid to the extent that anions such as chloride, sulfate, and nitrate are present in the raw water. The second step which takes place in the anion-exchange unit removes the acid in the water from the cation unit.

The chemicals required for regeneration of the exchange materials are sulfuric acid for the cation-exchange unit and sodium carbonate for the anion-exchange unit.

Figure 7-17 is a flow diagram of the demineralization process.

Treatment Costs—Demineralization Process. The operating cost per 1,000 gal for demineralization will depend on the dissolved solids in the raw water and the market price of sulfuric acid and soda ash. Typical costs for various waters are shown in Table 7-4.

Table 7-4. Costs of Water

Water analysis	A	B	C	D	E	F	G
Hardness as ppm $CaCO_3$	43	61	116	120	212	261	302
Alkalinity as ppm $CaCO_3$	34	24	58	93	140	188	227
Sulfates as ppm SO_4	19	26	70	38	80	60	60
Chlorides as ppm Cl	4	8	2	33	24	10	25

AERATORS AND DEGASIFIERS

Aerators and degasifiers are used for the following purposes:

1. Removal of carbon dioxide and increase of pH value
2. Removal of hydrogen sulfide
3. Reduction of taste and odor
4. Oxidation of ferrous iron
5. Oxidation of manganous manganese

In the removal of carbon dioxide, the action is purely physical The introduced air dissolves in the water and, by reducing the partial pressure of the carbon dioxide, forces the gas out of solution

The removal of hydrogen sulfide by aeration is mostly mechanical as, at the temperatures involved, the oxidation of the hydrogen sulfide is so slow as to be almost negligible

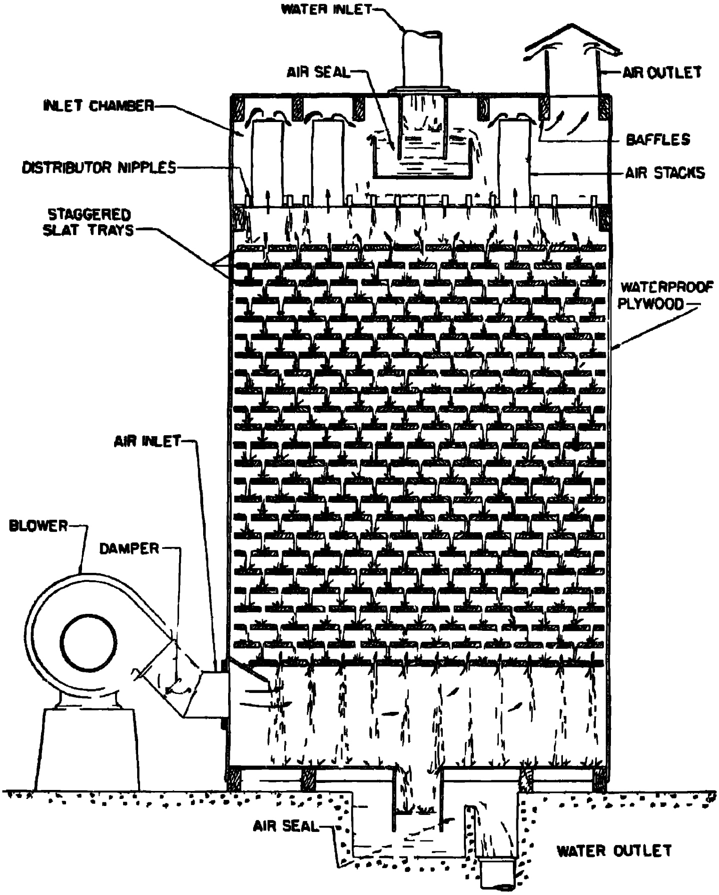

FIG 7-18 Section through degasifier (*The Permutit Co*)

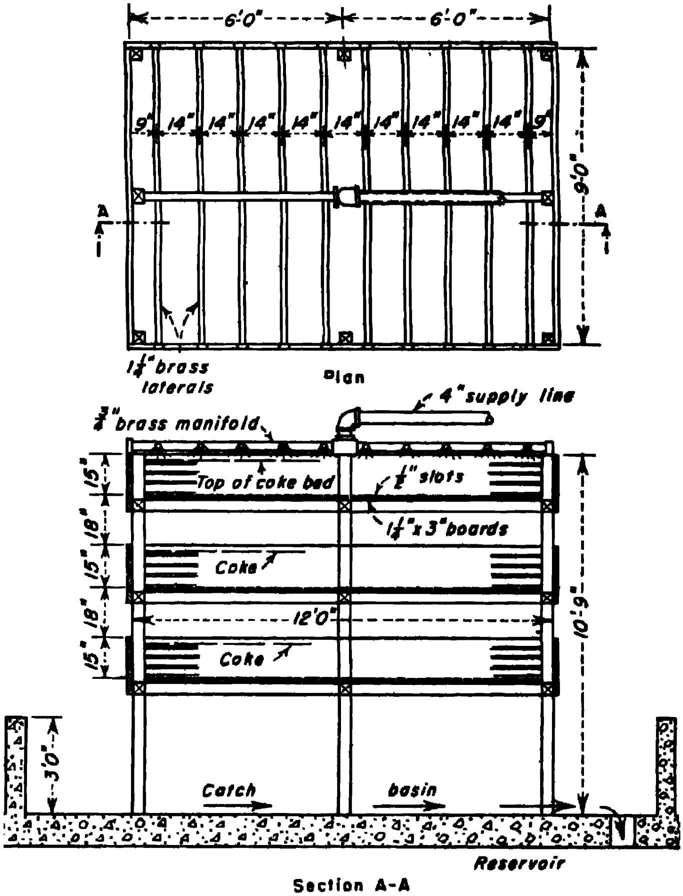
The reduction of taste and odor by aeration is largely mechanical as the objectionable gaseous or volatile bodies are removed in a manner similar to the removal of carbon dioxide, although part of this action may be attributable to oxidation

The oxidation of iron and manganese from soluble ferrous and manganous compounds to practically insoluble higher hydrated oxides is entirely chemical

In aeration, contact of water with air can be accomplished either by (1) introducing the air into the water or (2) introducing the water into the air

Introducing Air into Water. *Open-tank Aeration* Air may be introduced into water by blowing it through water contained in an open tank or by blowing the air into water under pressure in a closed tank which may or may not be vented Blowing the air through water in an open tank may be effected by air grids or porous plates, the source of the air being a blower or compressor. This method is quite often employed where acid is being fed to the water, in which case the air serves the double purpose of mixing the acid with the water and removing the carbon dioxide formed by the reaction.

Pressure Aeration. Pressure aeration is sometimes employed for iron removal where the amount of air to be introduced is not large and where double pumping is undesirable. As the solubility of air in water is directly proportional to the pressure,



Plan

Section A-A

FIG. 7-19. Coke aerator.

saturation of the water with air is often undesirable, since, when pressure is released as at a faucet or valve, a considerable volume of air is evolved from the solution and causes objectionable spattering. This can be avoided either by limiting the quantity of air introduced into all the water or by saturating with air only a portion of the water which is later mixed with the remaining quantity.

Introducing Water into Air. The second method of aeration whereby water is introduced into the air is the method most widely employed. Various devices of various efficiencies have been used to accomplish this. The most satisfactory device is the degasifier (see Fig. 7-18) in which the water rains down over a series of slot trays through a controlled countercurrent of air. The least efficient device is one in which a short, thick stream of water flows through the atmosphere. Other devices range between these extremes.

Coke-tray Aerators. There are two basic designs of equipment for the coke-tray method of aeration—the cylindrical type and the square or rectangular type. Both of these types are louvered structures containing three or four coke trays with air spaces between them. Figure 7-19 is a 300-gpm coke aerator. The entering raw water flows into a distributing tray which causes the water to flow evenly over the entire area and then permits it to drop through an air space to the surface of the first layer of coke. The water percolates through the porous coke and then drops from the bottom of this first tray through an air space to the surface of the second tray. This operation is repeated through the series of trays, and from the bottom of the last tray in the series the water rains down through an air space into a catch basin. Catch basins vary in size depending largely upon the composition of the water and the purpose for which it is being aerated.

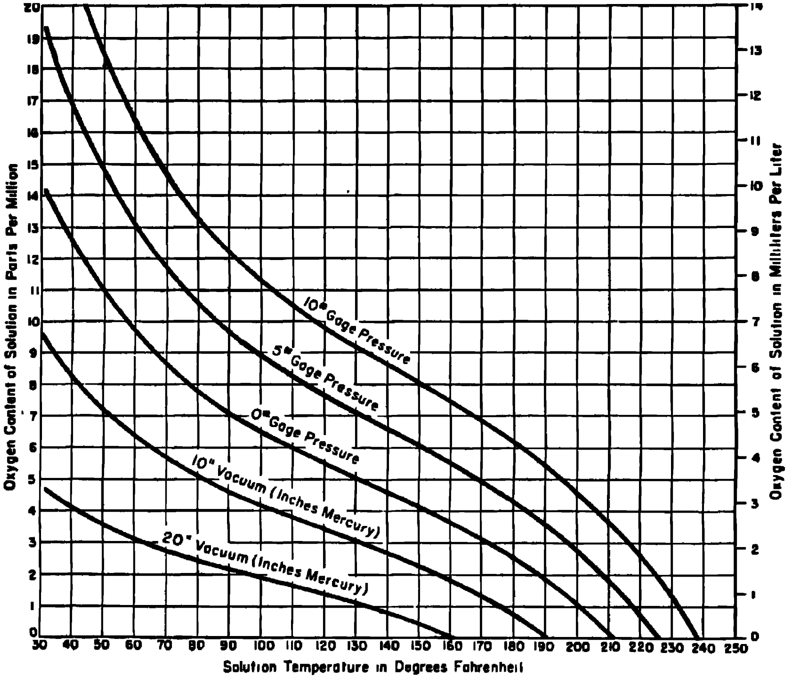


Fig. 7-20. Solubility of oxygen in distilled water.

Spray Aerators. Spray aeration is more frequently used in municipal water-works practice than in industrial-water treatment for removal of carbon dioxide and hydrogen sulfide and reduction of taste and odor. A closed-tank aerator similar to that shown in Fig. 7-18 is more applicable to industrial practice where ground area is limited or where location indoors is desired.

A spray aerator is similar in design to a spray pond, *i.e.*, the water is broken into fine droplets as the water discharges from the spray head and comes in contact with the atmosphere. The loading and space requirements per spray head depend upon the angle of the cone and volume of water handled, the required satisfactory operating conditions being specified by the spray-head manufacturer. A collecting basin is necessary where water is first aerated and then treated with coagulating chemicals, which makes for increased cost over that required with a closed-tank aerator.

Either system of aeration will, for all practical purposes, saturate the water with oxygen at the existing temperature, but in most cases the closed-tank aerator will show the lower first cost.

Corrosion. The utilization of large quantities of raw water in process cooling systems such as through condensers and heat exchangers has brought about a demand for cold-water deaeration to arrest corrosion of these equipments without waste of heat. In many process industries the heat pickup through such equipment by the cooling water is taken to the power plant where this water is a source of make-up. It is found, however, that with the ordinary water supplies, corrosion does occur, and in order to protect these units, cold-water deaeration has become quite prominent the past several years.

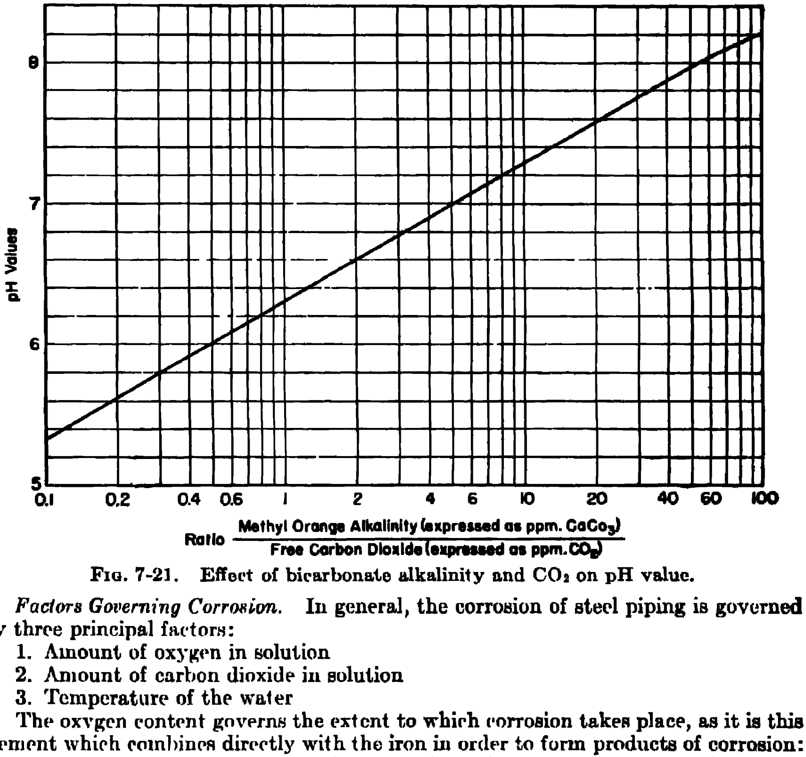

FIG. 7-21. Effect of bicarbonate alkalinity and CO_2 on pH value.

Factors Governing Corrosion. In general, the corrosion of steel piping is governed by three principal factors:

1. Amount of oxygen in solution
2. Amount of carbon dioxide in solution
3. Temperature of the water

The oxygen content governs the extent to which corrosion takes place, as it is this element which combines directly with the iron in order to form products of corrosion: iron rust, such as ferrous oxide, FeO; magnetic oxide, Fe_3O_4; or ferric oxide, Fe_2O_3, the type of product depending upon the concentration of oxygen present at the time rusting takes place.

The solubility of oxygen in distilled water at various temperatures and pressures is shown in Fig. 7-20.

Carbon dioxide in conjunction with the natural alkalinity of the water governs the pH value, which is a means of expressing the active acidity or alkalinity of the water. Figure 7-21 shows the effect of bicarbonate alkalinity and CO_2 on pH value, and Table 7-7 shows the relation of hydrogen-ion concentration and pH value.

The pH value influences the rate at which corrosion proceeds; the lower the pH value, the more acid the water and the greater the intensity of the corrosion; conversely, with higher pH values the corrosion activity becomes less, and in some cases where the temperature is not increased appreciably, corrosion can be arrested merely by adding alkali and raising the pH value.

The temperature of the water is governed by the process requirements and is fixed by the design of heat exchangers and the rate of heat transfer. It therefore becomes impractical to attempt to govern the rate of corrosion by control of the temperature, although it is well known that the corrosion of steel increases rapidly with increase in water temperature when the water contains quantities of oxygen and carbon dioxide in solution.

Table 7-7. Relation of Hydrogen-ion Concentration and pH Value

Hydrogen-ion concentration, per l (1)	Column 1 expressed as a fraction (2)	Reciprocal of Col. 2 (3)	Log of Col. 3 (4)	pH (5)	Acidity or alkalinity of solution relative to a neutral solution (6)

Cold-water Deaerators. Cold-water deaerators are used to remove oxygen and carbon dioxide from solution and obtain a noncorrosive water, where it is desirable to accomplish this without chemicals and with a minimum amount of mechanical equipment.

The art of deaerating cold water is not new, as one of the first installations was placed in service on a large scale in 1917 for checking corrosion of a 30-in. steel pipe 350 miles long from Mundaring to Coolgardie in Western Australia. This installation was capable of deaerating 6 million gal of water per day and consisted of two units, each capable of treating 3 million gal of water in 24 hr. The water was deaerated by spraying it in a vacuum chamber.

Powell and Burns report on the effectiveness of a vacuum deaerator of the tray type in checking corrosion of a 9-mile pipe line conveying Mississippi River water to the Freeport Sulphur Company mining operations 50 miles south of New Orleans, at Grand Ecaille. This installation brought about 95 per cent reduction in the oxygen, the residual oxygen being 0.33 ppm. In order to have assurance that corrosion would be arrested, the residual oxygen was absorbed chemically by the proportioned introduction of sodium sulfite. It is interesting to note that this installation was very successful, whereas chemical means tried previously were not effective and were likewise costly.

General Design of Equipment. Cold-water deaerators, where heat is not applied, require

1. Maintenance of a pressure within the unit corresponding to the boiling point of the water under treatment
2. Means for dividing the water into small and minute particles in order to expose surface and to facilitate the escape of gases from solution while the optimum atmospheric conditions are maintained within the unit
3. Means for withdrawing the gases from the container after liberation and the maintenance of a constant vacuum condition

While the Coolgardie and Freeport installations were successful in achieving their objectives, the design of such equipment has advanced considerably, and it is now possible to reduce oxygen and carbon dioxide down to a fraction of a part per million, eliminating the necessity of supplementary chemical treatment for absorbing the last traces of oxygen.

In general, the equipment is arranged so that water is introduced into the vacuum chamber through a spray pipe from which it is discharged in fine particles over a column of staggered trays, generally constructed of wood. The water cascades down these trays which serve the purpose of distributing the water and breaking it into fine particles or films, permitting easy escape of the gases.

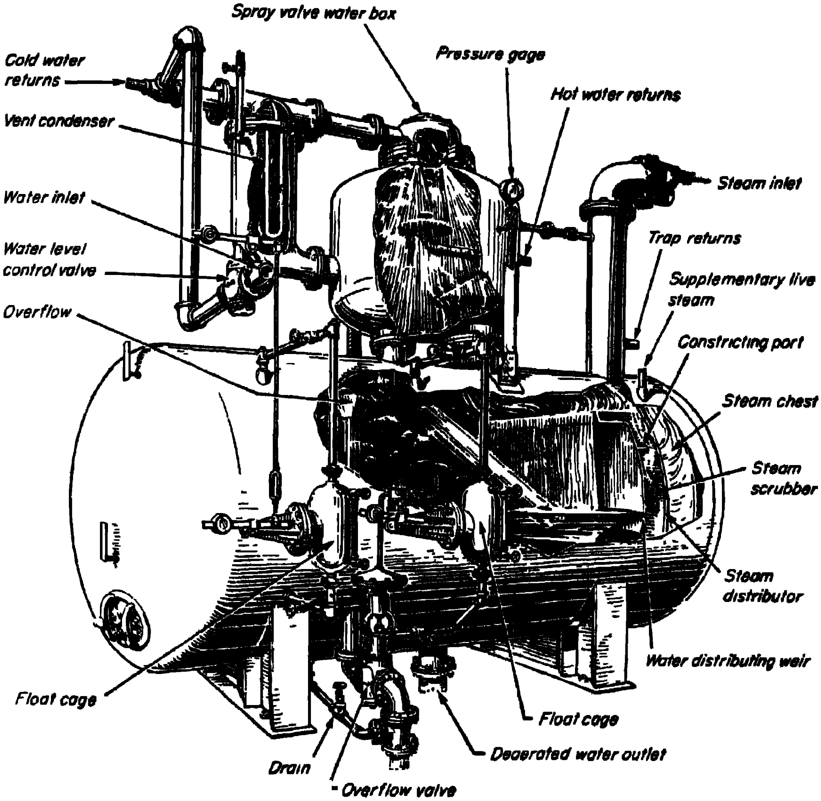

Fig. 7-22. Atomizing deaerating heater. (*The Permutit Co.*)

The noncondensable gases and a portion of the water vapor are withdrawn from the deaerator by means of vacuum-producing equipment which may take the form of steam-jet ejectors or mechanically operated vacuum pumps.

Hot-water Deaerators. In the deaeration of water for boiler-feed purposes or other uses, where hot water of a noncorrosive nature is desired, removal of oxygen and carbon dioxide is accomplished by heating the water to the boiling temperature corresponding to the pressure acting upon it. Various deaeration means for carrying out this heating and removal of the dissolved gases are employed, of which there are three basic methods, *viz.*, reboiling, flowing over trays or pans, and atomization.

In the reboiler deaerator, dissolved gases are removed by causing steam to bubble through the water, this steam being generated either by a closed heater element located in the storage space of the deaerator or by blowing the steam into the water through a multitude of small orifices.

In the second type of deaerator, the tray or pan type, the water is spread out over baffles or trays in thin films in such a manner as to provide intimate contact of the steam with the water, through agitation, and a definite path for the steam so as to remove the gases from the apparatus as rapidly as they are removed from the water.

The third type of deaerator utilizes the principle of atomization. The water is first sprayed into a steam atmosphere where it is heated to within two to three degrees of the steam temperature. This hot and partly deaerated water is then delivered into a high-velocity steam jet created by the flow of the incoming steam through a spring-loaded nozzle.

Figure 7-22 shows a deaerator of the atomizing type.

Scale-forming Waters. Water as used for cooling purposes may be classed as aggressive or nonaggressive in respect to the action on ferrous pipe Very few supplies are neutral, *i.e.*, neither corrosive nor scale forming Table 7-8 gives three water supplies used for cooling: source *A*, which is corrosive to steel, and *B* and *C*, which formed a coating of calcium carbonate in the lines.

Table 7-8. Sources of Water for Cooling

Source	A	B	C
Total solids	48	344	400
Suspended solids	2	9	0
Silica	2	20	10
Sulfates as SO_4	3	24	50
Chlorides as Cl	8	24	40
Carbon dioxide	27	29	30
Calcium as Ca	2		65
Magnesium as Mg	2	.	24
Iron and alumina	1	2	
Soap hardness as $CaCO_3$	12	256	240
Methyl orange alkalinity as $CaCO_3$	5	220	290
pH value	5.9	7.2	7.2

NOTE: All quantities as part per million except pH value.

Problems arise with either type of supply, corrosion with accompanying tuberculation increases the friction drop resulting in greater pumping costs and increased maintenance. A scale-forming water likewise causes greater pumping costs and stoppage of heat-transfer equipment, thus increasing maintenance.

Corrosion Prevention by Chemical Treatment. Deaeration of cold water in many cases cannot be justified, and it is necessary to resort to chemical treatments for decreasing corrosion. Among the most common of these treatments are sodium silicate, calcium hydrate-lime, and chromate compounds.

Sodium Silicate—Calcium Hydrate. With the use of sodium silicate or calcium hydrate, the effectiveness depends upon the promotion of inorganic protective films. Such films may consist of extraneous materials derived from salts dissolved in the water, such as carbonate or silicate of lime, or may be composed of an oxide produced by the attack upon the metal itself. In both cases the efficiency depends on their density and the bond they make with the metal. In this type of chemical treatment the film is derived either from the natural constituents of the water itself, the added chemicals merely changing the equilibriums so as to bring about deposition, or it is furnished by the chemicals as in the case of the silicate. Methods of treatment of this type have been successful in large-scale operations, such as city water supplies. For small-scale applications, however, they are less adaptable because the dosage and even the possibility of any benefits depend upon the composition of the local water and thus often present problems that demand local study and control. Too often, both in investigation and application, the uncompromising fact that water is anything but the same material anywhere has been forgotten. This simple fact cannot be given too much emphasis. The results of research or experience in corrosion by natural water are rarely of general application because they usually have to do with a particular water supply. Water from another source, or even the same water at another time, may not fit into the developed picture.

Chromate Compound In the second type of chemical treatment, in which the protective film is an oxide of the metal itself, the chemical character of the water also plays a part, but one more easily compensated for. The phenomenon in this type is essentially that of passivity. In true passivity, the oxide film is invisible. In fact, it is interesting to note that, as it has been pointed out, invisibility is a measure of effectiveness. To become thick enough to be visible a film must grow, and that means that some attack must occur through it. Furthermore, a thick film is likely to crack. The classical case of passivity is the effect produced on iron by immersion in concentrated nitric acid. The effect is not permanent when the environment is changed.

Fortunately, the soluble chromates are highly effective passivating agents which are not corrosive and consequently can be kept permanently in contact with the surfaces to be protected without danger to the equipment.

Chromates contain chromate anhydride (CrO_3) which becomes converted into inert chromic oxide (Cr_2O_3) by giving up half of its oxygen. It is thus a strong oxidizer. In this respect it resembles other passivating agents, producing a film of oxide of iron. But, again in common with other oxidants, it is also a cathodic depolarizer, thereby tending to promote corrosion as does dissolved oxygen. This latter tendency, however, is successfully combated by the character of its anodic action. The effectiveness of the protective oxide film there produced appears to be due not only to the simple production of a film of iron oxide but also to the remarkable density of the film arising from the effusion in it of a portion of chromic oxide produced by the primary anodic reaction and from the effect of the alkali produced in the immediate proximity by the cathodic action. This last promotes immediate dense precipitation on the anode of the solution which is first formed there, whereas in ordinary corrosion, this solution must diffuse for some distance before a sufficient amount of alkali is encountered to precipitate it, with a result of loss and nonprotective product. Of these factors, the inclusion of chromic oxide is probably the most important as the other actions are also common to other oxidizing agents which have no, or less, protective effect.

The dosage of chromate is important. Its effective action logically depends on its presence at the seat of the reaction in sufficient concentration to play the role just described. It has been indicated that where there is local stagnation of the water, pitting is probable. Where chromate is used it must be present in the circulating water in sufficient concentration to maintain its protective reactions in such places by sufficiently rapid diffusion. If the concentration is too low, the diffusion may be too slow, in which event pitting may actually be promoted by the chromate because of its depolarizing action in surrounding nonstagnant cathodic areas and its effect in increasing the electrolytic conductivity of the water.

Dosage, therefore, is largely dependent on the physical conditions of the equipment as it affects the development of stagnant points. Reentrant corners, crevices, and cracks are largely a matter of design. More important for equipment already in the field are existing rust, loose scale, and tubercles which act as traps for water, thus promoting pitting. When these are present it is dangerous to depend upon increased chromate dosage to offset their effect. They should be removed.

POWER-PLANT THERMODYNAMICS

BY H. L. SOLBERG

Head, School of Mechanical Engineering, Purdue University

AND C. L. BROWN

Assistant Professor in Mechanical Engineering, Purdue University

DEFINITIONS

Thermodynamics. Thermodynamics is the science of heat energy and its transformations. The thermodynamics of power plants is concerned with the study of heat energy derived from burning fuel and the conversion of this energy into mechanical or electrical work.

Energy. Energy has been defined as the capacity for doing work. Fuel has chemical energy which is released by burning and converted to heat energy. Part of this heat energy may be converted into mechanical work in accordance with the laws of thermodynamics. Before these laws may be considered, it is necessary to define certain physical quantities. Some of these are familiar, but in order to avoid possible confusion, all will be defined and the customary units will be specified.

Pressure. Pressure (p) is measured in pounds per square inch (psi) and may be expressed as gauge pressure (psig) or absolute pressure (psia). An ordinary pressure gauge measures pressures above atmospheric, and to get absolute pressure, the pressure of the atmosphere as measured by a barometer must be added to the gauge reading. Since atmospheric pressure is generally read in inches of mercury, this must be converted to psi by multiplying by the factor 0.491.

EXAMPLE 1: Find the absolute pressure of steam in a boiler if the gauge reads 250 psig and the barometric pressure is 28.5 in. of mercury.

SOLUTION:

$$p = 250 + (28.5 \times 0.491) = 264 \text{ psia}$$

Pressures below atmospheric pressure such as are found in condensers are usually measured in inches of mercury vacuum. The absolute pressure in the condenser may be found by subtracting the vacuum reading from the atmospheric pressure.

EXAMPLE 2: Find the absolute pressure in a condenser in which there is a 28-in. vacuum when the atmospheric pressure is 29.5 in. Hg.

SOLUTION:

$$p = 29.5 - 28 = 1.5 \text{ in. Hg abs}$$
$$p = 1.5 \times 0.491 = 0.74 \text{ psia}$$

Temperature. Temperature (t) is measured in the English system of units in degrees Fahrenheit. Sometimes it is necessary to use absolute temperature (T, degrees Rankine) which is measured above absolute zero, the lowest temperature which can exist. Absolute zero is about −460°F so that, if the temperature is known in degrees Fahrenheit, the absolute temperature is $T = 460 + t$. Thus 100°F is 560°R.

Heat. Heat is a form of energy which is transferred from one body to another because of a temperature difference. The addition of heat to a substance will produce either a rise in temperature or a change of state, as, for example, the evaporation of water. Heat, as well as other forms of energy, can be measured in British thermal units (Btu). One Btu is the amount of heat required to raise the temperature of 1 lb of water at atmospheric pressure 1°F.

Specific Heat. The specific heat of a material is the amount of heat required to raise the temperature of 1 lb of the substance 1°F. Thus, from the above, the specific heat of water at normal temperatures is unity. However, specific heats vary with temperature and pressure.

Work. Work is done when a force is exerted on a body, and the body moves in the direction of the force. The units of work are foot-pounds (ft-lb). For example, if a weight of 10 lb is lifted 5 ft, 50 ft-lb of work is done. Work can be converted into heat, and 778 ft-lb equal 1 Btu so that work can be expressed in Btu by dividing the work in foot-pounds by 778.

Power. Power is the rate of doing work. The two common units of power are horsepower (hp) and kilowatt (kw). These are defined as

$$1 \text{ hp} = 33{,}000 \text{ ft-lb per min} = 2545 \text{ Btu/hr}$$
$$1 \text{ kw} = 44{,}240 \text{ ft-lb per min} = 3413 \text{ Btu/hr}$$

A hoist lifting a weight of 33,000 lb a distance of 1 ft in 1 min develops 1 hp. Another hoist which lifts the same weight in 6 sec does the same work but does it ten times as fast and hence develops 10 hp.

Enthalpy. Enthalpy (*h*) is the term used for the energy content of water and steam. In steam tables and charts, enthalpy is measured in Btu per pound.

Entropy. Entropy is an important but rather mysterious quantity. It will be sufficient here to define entropy as a measure of energy made unavailable or wasted. During the expansion of steam in an engine or turbine, if the entropy is not changed, no energy is wasted. If the entropy increases, however, some energy is lost and cannot be converted into useful work. Thus, the most efficient expansion is one which occurs at constant entropy and is called a "constant-entropy" process.

Power Cycle. A power cycle is a group of processes which form a closed circuit, the purpose of which is the conversion of heat energy into mechanical or electrical work. For example, the simple steam cycle consists of (1) pumping water into the boiler, (2) evaporating the water and superheating the resulting steam, (3) expanding the steam in a turbine or engine, and (4) condensing the exhaust steam. The condensate then goes to the feed pump, and the cycle is repeated.

Cycle Efficiency. Cycle efficiency is, like all efficiencies, a ratio and may be defined as the ratio between the work produced in the turbine or engine to the heat supplied to the steam in the boiler.

Steam Rate. The steam rate of a prime mover is defined as the number of pounds of steam required at the throttle per hour to develop either 1 hp or 1 kw. Since steam plants usually generate electrical power, the steam rate will hereafter be given as pounds per kilowatthour.

CHARACTERISTICS OF WATER AND STEAM

When water is heated under constant pressure, its temperature increases until a point is reached at which it begins to boil. During evaporation, the temperature remains constant. At each pressure there is a definite boiling temperature which is called the "saturation temperature" and corresponds to the pressure. Water at saturation temperature and pressure is said to be saturated. For example, the saturation temperature at 14.7 psia is 212°F. Water at 14.7 psia and 70°F is not saturated and must be heated to 212°F before it becomes saturated.

Steam free of water at saturation temperature is called "saturated steam." As long as water is present, the addition of heat will not raise the temperature but will merely evaporate more water. If saturated steam is removed from contact with water and heat is added, the temperature will increase, and the steam becomes "superheated." The condition of superheated steam may be specified by giving the temperature and pressure. Sometimes steam is referred to as having a certain superheat. This is the difference between its temperature and the saturation temperature corresponding to the pressure. However, if the steam is at saturation temperature, it may be dry (free of liquid water) or contain any amount of water. To specify the condition of such wet steam it is necessary to give the pressure (or temperature) and the quality, which is defined as the ratio of the weight of dry steam to the weight of the mixture of steam and water.

Water may exist at pressures higher than that corresponding to its temperature as shown by the steam tables. Water under such conditions is said to be "compressed." For example, water at 212°F under a pressure of 200 psia is compressed water. A characteristic of compressed water is that the addition of heat will not cause evaporation but will merely cause a rise in temperature until the boiling point or saturation point corresponding to the elevated pressure is reached.

Use of Steam Tables and Mollier Chart. Values of the various properties of water and steam have been determined on the basis of experimental data. There are several sets of tables, but the latest and most widely used is ' Thermodynamic Properties of Steam" by Keenan and Keyes, published by John Wiley & Sons, Inc. All thermodynamic data used here will be taken from these tables.

The tables are divided into four sections.

Table 8-1 is a tabulation of the properties of saturated water and steam based on temperature. If the temperature is known, then from the table pressure, enthalpy, and entropy may be found for saturated water and saturated steam. For saturated water enthalpy and entropy are represented by the symbols h_f and s_f and for dry saturated steam by h_g and s_g, respectively. The increase in enthalpy during evaporation, which is merely the difference between h_g and h_f, is given in the table with the symbol h_{fg}. Likewise, the increase in entropy during evaporation is designated by the symbol s_{fg}.

Table 8-2 is laid out in the same fashion except that values are given for a series of pressures instead of temperatures. The first table is used to find the properties of feed water and for cases where the temperature is known. The second table is used when pressure is known.

When the quality of wet steam is known, the enthalpy and entropy can also be computed from the steam tables. A pound of wet steam with a quality x consists of x lb of saturated steam and $(1 - x)$ lb of saturated water. If the enthalpy of the water h_f and steam h_g are found from the tables, the enthalpy of the mixture can be found as

$$\begin{aligned} h &= xh_g + (1 - x)h_f \\ &= xh_g + h_f - xh_f \\ &= h_f + x(h_g - h_f) \\ &= h_f + xh_{fg} \qquad (1) \end{aligned}$$

where h_{fg} is $h_g - h_f$, or the difference in enthalpy between saturated steam and water at the same temperature. Entropy of wet steam can be calculated in the same way.

Example 3: Find the enthalpy of steam at 100 psia and 95 per cent quality.

Solution:

$$h = 298.4 + 0.95 \times 888.8 = 1142.8 \text{ Btu/lb}$$

Table 8-3 gives the properties of superheated steam. Since the condition of superheated steam cannot be specified without knowing both temperature and pressure, this table is set up on that basis. If pressure and temperature are known, enthalpy and entropy can be read from the table.

Table 8-4 gives enthalpy and entropy values for compressed water at various temperatures and pressures Note that the effect of pressure on these properties is much less pronounced than the effect of temperature. For example, the enthalpy of saturated water at 200°F (p = 11.5 psia), h_f = 167.99 Btu per lb. For compressed water at 200°F and 600 psia, h = 169.30 Btu per lb. The difference between the two values of enthalpy is only 1.31, while the difference in pressures is 588.5 psia. For most calculations, it is sufficiently accurate to take the value for saturated water at the same temperature as the compressed water.

Data on steam can also be presented in chart form. Several types of charts can be devised, but the most useful one is the enthalpy-entropy or Mollier chart. Figure 8-1 is a skeleton Mollier chart which is intended to illustrate the use of the large chart which is published as a part of all standard steam tables. The enthalpy and

* Computed from Keenan and Keyes, "Thermodynamic Properties of Steam," Table IV, p. 75, John Wiley & Sons, Inc., New York, 1936. Table reprinted from Lichty, "Thermodynamics," 2d ed., McGraw-Hill Book Company, Inc., 1948, as adapted from Keenan and Keyes.

entropy of saturated steam can be determined by finding the intersection of the saturated-steam line and the proper pressure line. The enthalpy and entropy of superheated steam are found by locating the intersection of the lines representing the pressure and temperature of the superheated steam. If the pressure and quality of wet steam are known, enthalpy and entropy can be found at the intersection of the quality and pressure lines.

FIG. 8-1. Mollier chart for steam.

FIRST LAW OF THERMODYNAMICS

The first law of thermodynamics states that energy can neither be created nor destroyed but only altered in form. When applied to a boiler, turbine, or similar device operating under steady conditions, the first law says that the energy flowing in is equal to the energy flowing out. This energy may be carried by steam or water; it may be heat or mechanical work. This is expressed in equation form for 1 lb of fluid as

$$Q + h_1 = W + h_2 \qquad (2)$$

where Q = heat *in* per pound of fluid
W = work *out* per pound of fluid
h_1 = enthalpy of entering fluid
h_2 = enthalpy of leaving fluid

All quantities are expressed in Btu. If heat flows out or work in, the fact is expressed by a minus sign. The use of this equation will be illustrated by several examples.

Heat-transfer Devices and the First Law of Thermodynamics.

Example 4: A *boiler* receives water at 200°F and delivers steam at 400 psia and 600°F. Compute the heat added per pound of steam.

Solution: Water flowing into the boiler is evaporated into steam and superheated. Heat flows through the walls of the boiler and superheater tubes, but no mechanical work is done in the boiler. Therefore, the equation becomes

$$Q = h_2 - h_1 \tag{3}$$

where Q = heat added per pound of steam
h_1 = enthalpy of feed water
h_2 = enthalpy of superheated steam

The values for h are found from the tables and substituted in Eq. (3). Then,

$$Q = 1307 - 168 = 1139 \text{ Btu/lb}$$

Example 5: A *boiler* receives water at 200°F and delivers steam at 100 psia with 97 per cent quality. Compute the heat added per pound of steam.

Solution: Here the enthalpy of the steam is given by Eq. (1) as

$$h = 298 + 0.97 \times 889 = 1{,}160$$

and $$Q = 1160 - 168 = 992 \text{ Btu/lb}$$

Example 6: A *process cooker* receives steam at 20 psia with a quality of 95 per cent and discharges saturated water through a trap. Compute the number of pounds of steam required per hour to supply 100,000 Btu per hr to process.

Solution: A steam-heated cooker is like a boiler working in reverse. Steam enters and condenses, giving up heat. It is specified in the statement of the problem that the condensate is removed as saturated water, *i.e.*, water at the saturation temperature corresponding to the pressure. Equation (3) applies with

$$h_2 = 196.2 \text{ (at 20 psia)}$$
$$h_1 = 196.2 + 0.95 \times 960.1 = 1{,}108.3$$

and $$Q = 196.2 - 1108.3 = -912.1 \text{ Btu/lb}$$

The minus sign indicates that heat is flowing out of the steam. The weight of steam required per hour is

$$100{,}000/912.1 = 110 \text{ lb/hr}$$

In many cases involving the condensation of steam, the condensate may be "subcooled" or discharged at a temperature below the saturation temperature corresponding to the steam pressure. For most engineering computations, the enthalpy of the subcooled condensate may be considered as being equal to the enthalpy of saturated water at the actual temperature of the condensate.

Example 7: A *surface condenser* operating with a 28-in. vacuum receives 50,000 lb per hr of steam at a quality of 88 per cent. The atmospheric pressure is 30 in. Hg. Condensate is discharged to a hot well at 90°F. If cooling water enters at 75°F and leaves at 85°F, compute the gallons of water per minute required.

Solution: The steam side of the condenser is similar to the cooker of Example 6. The heat removed per pound of steam is

$$Q = h_2 - h_1$$

For wet steam at 2 in. Hg absolute (30 in. − 28 in.)

$$h_1 = 69 + 0.88 \times 1037 = 982 \text{ Btu lb}$$

The condensate is subcooled water because its temperature of 90°F is lower than the saturation temperature at 2 in. Hg (101°F), but its enthalpy can be found with sufficient accuracy by assuming it saturated at 90°F, so h_2 = 58 Btu per lb.

$$Q = 58 - 982 = -924 \text{ Btu/lb}$$

This is the heat removed from each pound of steam. The amount removed per minute is

$$-924 \times 50{,}000/60 = -770{,}000 \text{ Btu/min}$$

This heat must be carried away by the cooling water. The heat picked up by each pound of water may be calculated in two ways. The first method consists in finding the change in enthalpy of each pound of cooling water. The water enters at 75°F with an enthalpy of 43 Btu per lb and leaves at 85°F with an enthalpy of 53 Btu per lb. Therefore, each pound of water picks up

$$Q = 53 - 43 = 10 \text{ Btu/lb}$$

The second method consists in using the specific heat (amount of heat required to raise the temperature of 1 lb 1°F) which for water is unity. Therefore, each pound picks up

$$Q = 1 \times (85 - 75) = 10 \text{ Btu/lb}$$

The number of pounds of cooling water required is

$$770{,}000/10 = 77{,}000 \text{ lb/min}$$

and since 1 gal of water weighs 8.34 lb, the condenser requires

$$77{,}000/8.34 = 9{,}230 \text{ gal/min}$$

Example 8: An *open* (*direct-contact*) *feed-water heater* heats 50,000 lb per hr of water from 90 to 212°F with steam at atmospheric pressure. If the steam is saturated, compute the number of pounds per hour required.

Solution: The heat required per pound of water heated is

$$Q = 180 - 58 = 122 \text{ Btu}$$

and the total heat is 122 × 50,000 = 6,100,000 Btu per hr. Each pound of steam enters with an enthalpy of 1,150 Btu This steam is condensed in the heater to saturated water at 212°F with an enthalpy of 180. Hence,

$$Q = 180 - 1{,}150 = -970 \text{ Btu/lb of steam}$$

The number of pounds of steam required is

$$6{,}100{,}000/970 = 6{,}300 \text{ lb/hr}$$

The total flow of hot water from the heater is then

$$50{,}000 + 6{,}300 = 56{,}300 \text{ lb/hr}$$

Example 9. One hundred pounds per minute of *oil* is cooled in a *heat exchanger* from 200 to 100°F by water entering at 75°F and leaving at 90°F. If the specific heat of the oil is 0.45 Btu per lb per deg F, how many gallons of cooling water per minute are required?

Solution: The heat given up by the oil is

$$Q = 100 \times 0.45 \times (200 - 100) = 4500 \text{ Btu/min}$$

Each pound of water picks up

$$Q = 1 \times (90 - 75) = 15 \text{ Btu/lb}$$

The amount of water required is

$$4{,}500/15 = 300 \text{ lb/min}$$

or

$$300/8.34 = 36 \text{ gal/min}$$

Expansion of Steam in Turbines and Engines and the First Law of Thermodynamics. The behavior of steam in passing through an engine or turbine can be illustrated by a Mollier chart (Fig. 8-2). Steam at condition a is admitted to a turbine. If the steam is superheated, point a can be located on the Mollier chart at the intersection of the lines representing its temperature and pressure. If it is wet, the point is at the intersection of lines representing its pressure and quality. In Fig. 8-2, steam at point a is superheated, but the discussion to follow is also true for wet steam.

Since the purpose of the turbine is to convert as much of the heat energy of the steam as possible into work, it is desirable that the enthalpy of the exhaust steam be as small as possible. When steam is expanded to a definite pressure, the final point on the chart will be somewhere on the line representing that pressure. If the expansion is at constant entropy, the point will be directly below point a (point b). If friction is present, the entropy will increase, and the final point is at c, for example.

The ideal expansion takes place at constant entropy and may be represented on the Mollier chart as a vertical straight line.

The heat flow through the cylinder of a turbine or engine is quite small and may be neglected except in very small machines. For this condition, Eq. (2), which expresses the first law of thermodynamics, may be written as follows:

$$W = h_1 - h_2 \tag{4}$$

The application of this equation to the isentropic or ideal expansion of steam through a turbine is illustrated by Example 10.

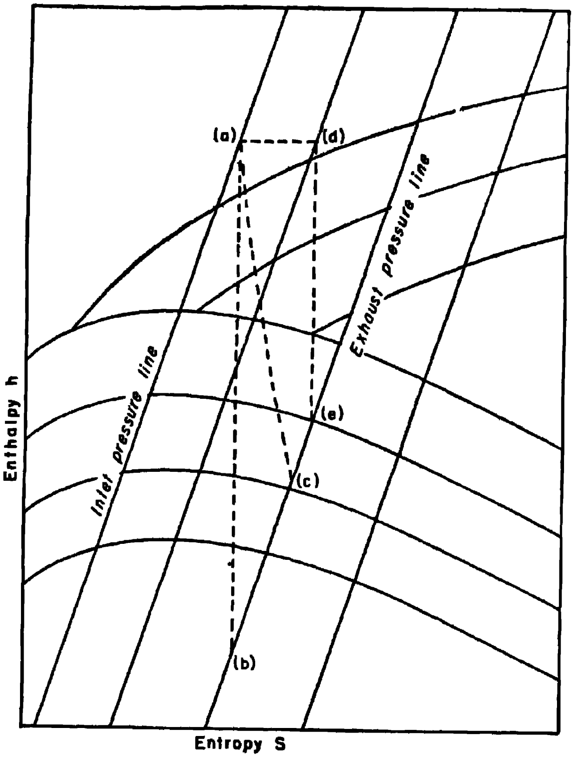

FIG. 8-2. Mollier chart showing turbine expansion lines.

EXAMPLE 10: A turbine receives steam at 1,400 psia and 840°F and expands to a pressure of 2 in. Hg abs. What is the steam rate in pounds per kilowatthour if the turbine expands isentropically?

SOLUTION: From the Mollier chart, h_1 is 1396 Btu per lb. The enthalpy of the exhaust steam h_2 can be found by going straight down the chart (constant entropy) until the 2-in. pressure line is reached and is 859 Btu per lb. By Eq. (4)

$$W = 1{,}396 - 859 = 537$$

Therefore each pound of steam develops 537 Btu of work. One kilowatt requires 3,413 Btu per hr, so the steam rate is

$$3{,}413/537 = 6.35 \text{ lb/kwhr}$$

The steam rate as determined from an isentropic expansion is called the "ideal" or theoretical steam rate and is the minimum steam flow required to develop 1 kw under ideal conditions. In the actual machine friction increases the entropy during expansion, and less work is done per pound of steam because the enthalpy of the exhaust steam is greater.

Throttling Processes and the First Law of Thermodynamics. A third general type of process involves the throttling or reduction of pressure by an orifice or throttle valve. Usually the heat losses are very small and can be neglected, and there is no external work done. The energy equation then becomes

$$h_1 = h_2 \tag{5}$$

i.e., the energy content of the throttled steam is unchanged.

This fact is the basis of the throttling calorimeter. If wet steam at moderate pressures is throttled to about atmospheric pressure, it will become superheated if not originally too wet. This can be seen on the Mollier chart by drawing a horizontal line (constant enthalpy) from the point representing the initial condition of the steam to the exhaust pressure line. The enthalpy of the superheated steam can be found from the tables or chart, and this is also the enthalpy of the steam at the higher pressure. The quality of that steam can be read from the chart or computed. This is illustrated by Example 11.

EXAMPLE 11: Steam is throttled from 100 psia to 20 psia and 250°F. Compute the initial quality.

SOLUTION: In this case, h_2 = 1,167.3 from the superheated steam tables or the Mollier chart (Fig. 8-2). At 100 psia, h_f = 298.4, and h_{fg} = 888.8

$$h_1 = h_f + xh_{fg}$$

but h_1 is known to equal h_2, so

$$1{,}167.3 = 298.4 + (888.8)x$$
$$x = (1{,}167.3 - 298.4)/888.8 = 0.976$$

Hence the quality of the steam at 100 psia is 97.6 per cent.

When steam flows through a throttling governor on a turbine or engine, there is no enthalpy change through the valve. However, there is a decrease in the available energy of the steam, or, in other words, a decrease in the amount of work which can be developed. The effect of the throttling governor on available energy can be shown on a Mollier chart (Fig. 8-2). Steam at point *a* could be expanded isentropically to point *b* or throttled to point *d* and then expanded isentropically to point *e*. It can be seen from Fig. 8-2 that less work is done by the steam that has been throttled. The available energy is less because the entropy has increased.

SECOND LAW OF THERMODYNAMICS

The second law of thermodynamics deals with one of the fundamental principles of science, the concept that energy is being converted in all natural processes into forms in which less of the energy can be converted into work. This principle is met in so many fields of science that the many statements of the second law which appear in books on thermodynamics, physics, and chemistry often seem to be unrelated to one other. This discussion will be confined to that phase of the second law which is concerned with the efficiency of conversion of heat into work.

Let it be assumed that a source of heat exists at a constant high temperature T_1, that the heat which cannot be converted into work may be rejected to a reservoir such as the atmosphere or a large body of water at a constant temperature T_2, and that a suitable working medium such as steam or air is contained in a cylinder behind a gastight piston. This piston slides without friction in a cylinder so arranged that heat may be transferred to the working medium from the high-temperature source and rejected from the medium to a low-temperature sink or receiver. In 1824, Sadi Carnot demonstrated that the maximum amount of work could be obtained from a given quantity of heat if the following conditions exist: (1) The heat transferred from the source to the working fluid is transferred at the maximum possible temperature which is the temperature of the source T_1; (2) the heat that cannot be converted to work is rejected at the lowest possible temperature which is the temperature of the sink T_2; and (3) expansion of the working medium from T_1 to T_2 and compression from T_2 to T_1 must take place without friction or heat transfer. Under these ideal conditions, the theoretical or maximum efficiency of conversion of heat into work is independent of the working medium used and is given by

$$e = (T_1 - T_2)/T_1 = 1 - T_2/T_1 \tag{6}$$

Equation (6) is often used as a statement of the second law of thermodynamics.

Equation (6) shows that the theoretical efficiency can be increased by increasing the initial temperature T_1 or reducing the exhaust temperature T_2. Suppose cooling water is available at 70°F, or 70 + 460 = 530°R, and a source of heat exists at 700°F, or 700 + 460 = 1,160°R. Then the maximum possible efficiency under those conditions is

$$e = 1 - 530/1,160 = 0.543$$

Heat energy is low-grade energy which can be transformed into work only with difficulty in complicated apparatus and at relatively low efficiency. In all natural processes that involve heat transfer and fluid friction, the temperature level of the energy tends to decrease, and less of it may be converted into work.

RANKINE CYCLE

The ideal or theoretical cycle of the simple power plant is the Rankine cycle which is illustrated in Fig. 8-3. This cycle is performed in four pieces of equipment which are connected by suitable piping. They are (1) the boiler and superheater in which steam is generated by heat released by burning fuel, (2) the engine or turbine in which work is done by the expansion of the steam, (3) the condenser which converts the exhaust steam into water and rejects the waste heat to cooling water, and (4) a boiler-feed pump which returns the condensate to the boiler.

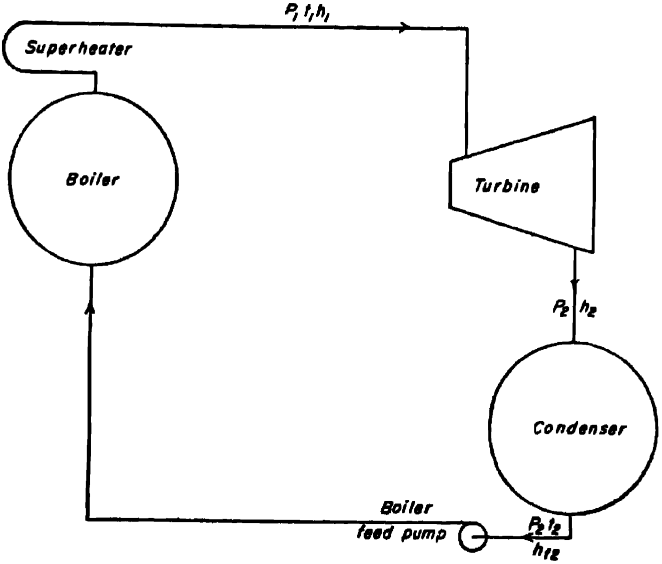

FIG. 8-3. Rankine cycle flow diagram.

The efficiency of this type of plant will be worked out under the following conditions: no pressure drop or heat transfer in the piping system, isentropic expansion in the turbine, saturated water in the condenser, and no work in the boiler-feed

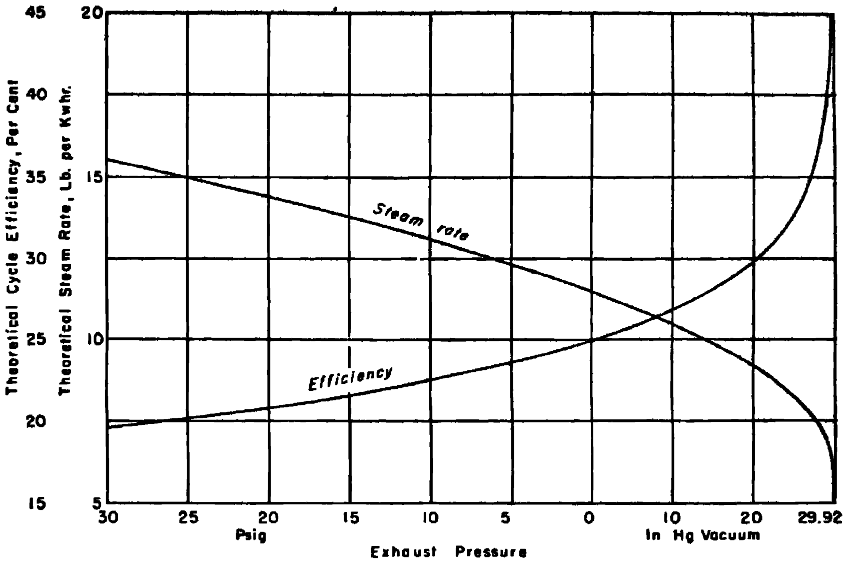

FIG. 8-4. Effect of exhaust pressure on steam rate and cycle efficiency.

pump (the amount of work required by the pump is very small for moderate boiler pressures and can be neglected for ordinary calculations). Then, from Eq. (1) for the first law, using the symbols from Fig. 8-3.

In the boiler and superheater

$$Q_{in} = h_1 - h_{f2}$$

In the turbine

$$W = h_1 - h_2$$

In the condenser

$$Q_{out} = h_2 - h_{f2}$$

$$\begin{aligned} \text{Efficiency} &= (\text{work output})/(\text{heat input}) \\ &= (h_1 - h_2)/(h_1 - h_{f2}) \end{aligned} \qquad (7)$$

where h_1 = enthalpy of steam leaving the superheater and entering the turbine, pressure p_1

h_2 = enthalpy of exhaust steam after isentropic expansion to the back pressure p_2

h_{f2} = enthalpy of saturated water at pressure p_2

The calculation of the efficiency of the Rankine cycle may be illustrated by Example 12.

EXAMPLE 12: Compute the efficiency of the Rankine cycle if steam is supplied at 400 psig and 720°F with exhaust at atmospheric pressure 14.7 psia.

SOLUTION: From the Mollier diagram (Fig. 8-2) or superheated-steam table at 414.7 psia and 720°F, h_1 = 1373 Btu per lb. After isentropic expansion to 14.7 psia, h_2 is found from the Mollier chart to be 1075 Btu per lb. At 14.7 psia h_{f2} is given as 180 Btu per lb in steam table 8-2. Then

Heat supplied in boiler and superheater = 1373 − 180 = 1193 Btu/lb
Heat converted into work in turbine = 1373 − 1075 = 298 Btu/lb
Heat rejected to cooling water = 1075 − 180 = 895 Btu/lb

Efficiency = 298/1193 = 25 per cent

The theoretical steam rate = 3,413/(298) = 11.45 lb per kwhr

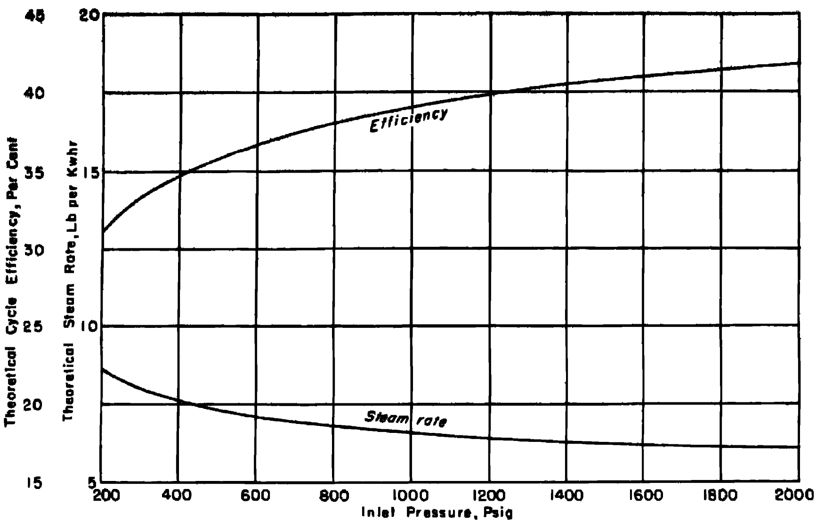

FIG. 8-5. Effect of inlet pressure on steam rate and cycle efficiency.

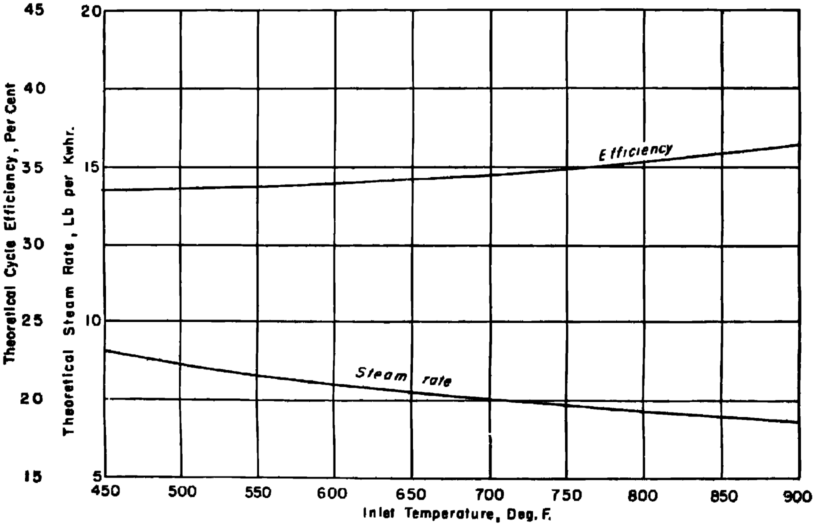

FIG. 8-6. Effect of steam temperature on steam rate and cycle efficiency.

The effect on the efficiency of the Rankine cycle of changing the back pressure from 14.7 psia to 2 in. Hg abs may be illustrated by Example 13.

EXAMPLE 13: Compute the efficiency of the Rankine cycle for the same data as in Example 12, except that the back pressure is 2-in. Hg abs.

SOLUTION: Upon isentropic expansion from 414.7 psia and 720°F. to 2 in. Hg, h_2 is found from the Mollier chart (Fig. 8-2) to be 918 Btu per lb. Also, at 2 in. Hg, h_{f2} is 69 Btu per lb. Then

Heat supplied = 1373 − 69 = 1304 Btu/lb
Work done = 1373 − 918 = 455 Btu/lb

Heat rejected in condenser = 918 − 69 = 849 Btu/lb
Efficiency = 455/1,304 = 34.9 per cent
Theoretical steam rate = (3,413)/(455) = 7.5 lb/kwhr

A comparison of the results of Examples 12 and 13 shows the improvement in efficiency and reduced steam rate which results from a reduction in the exhaust pressure. Figures 8-4, 8-5, and 8-6 illustrate the effect on steam rate and efficiency of changing the exhaust pressure, the initial pressure, and the initial temperature of the Rankine cycle from the conditions specified in Example 13.

INDUSTRIAL-POWER-PLANT CYCLES

Where electric power is the only output of the industrial plant, it is generally more economical to purchase power than to generate it unless low-cost or by-product fuel is available or the plant is large enough to justify the refinements of design found in central-station plants. Most industrial plants not only generate power but also furnish steam for space heating and process loads. Most of the energy in h-p steam cannot be converted into work in even the most modern power plants as indicated by the second law of thermodynamics However, by proper arrangement of the cycle, most of the energy in the exhaust steam may be used for heating or process purposes in industrial plants having a good balance between power and heating requirements. Under such conditions, much of the fuel cost as well as other boiler-plant costs are not chargeable to power, and the cost of such "by-product" power is quite low.

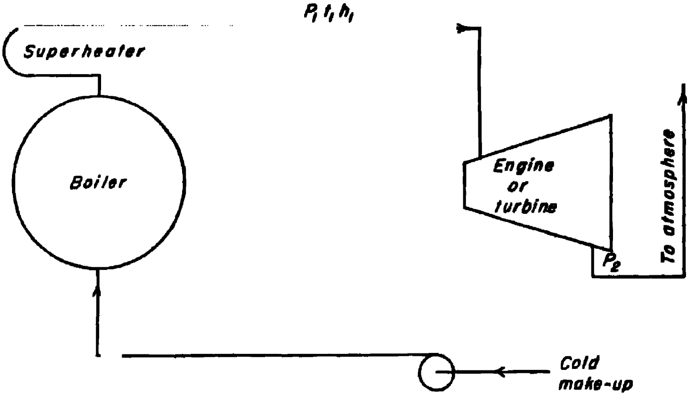

FIG. 8-7. Simple open cycle with exhaust to atmosphere.

The simplest power-plant cycle is shown in Fig. 8-7. Power is the only output, and most of the energy supplied in the steam-generating unit is wasted to the atmosphere. This cycle is used in portable plants and those burning waste fuel.

In Fig. 8-8, a direct-contact feed-water heater has been added to this cycle, and part of the energy in the exhaust steam is recovered in the heater, thus reducing the loss to the atmosphere. In Fig. 8-9, a heating or process load is added to the cycle of Fig. 8-8. If this load is too low to absorb all the exhaust steam, energy is wasted to the atmosphere. If the process load requires more steam than is needed by the turbine to generate the electrical load, a pressure-reducing valve is provided to by-pass steam around the turbine.

Figure 8-10 shows a cycle with an automatic-extraction turbine which exhausts to a condenser at low pressure and to a process load at an intermediate pressure. This cycle is used where the steam required for power is in excess of the steam required for process during a large portion of the total time of operation. Instead of wasting the energy in the surplus exhaust steam to the air, as in the cycle of Fig. 8-9, the sur-

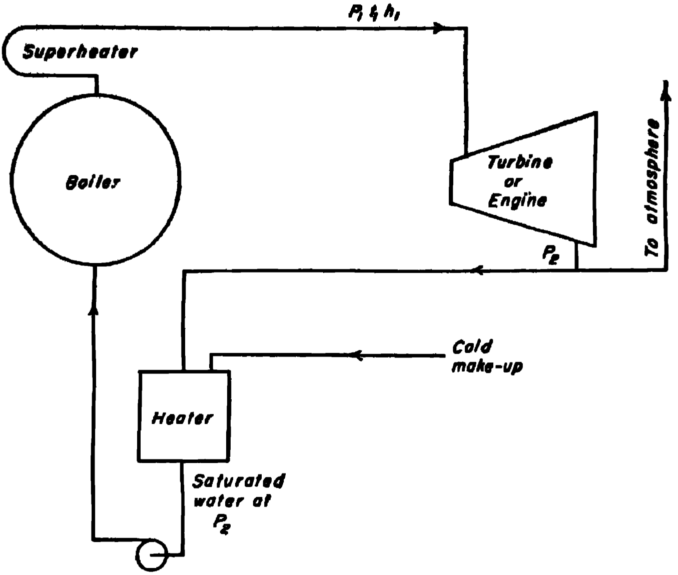

FIG. 8-8. Open cycle with direct-contact feed-water heater.

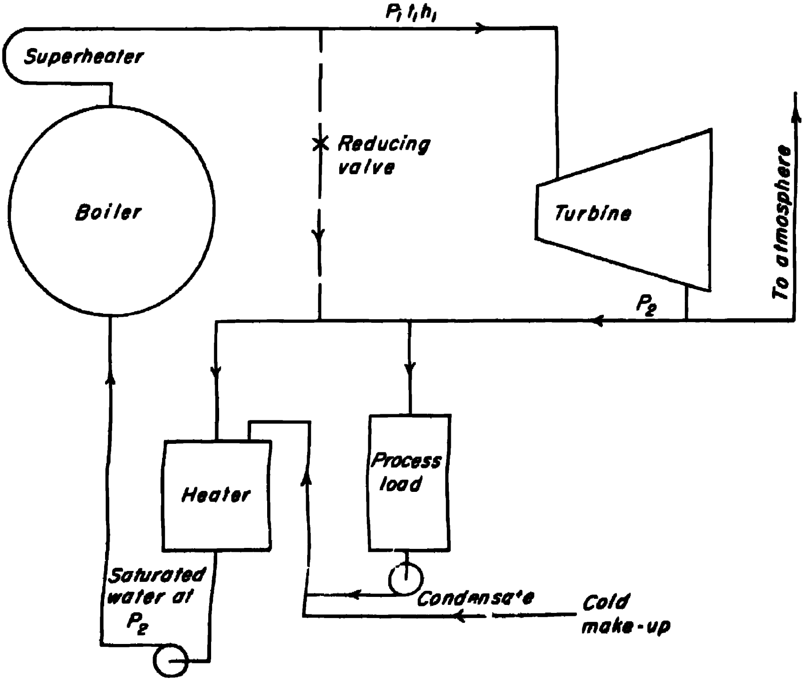

FIG. 8-9. Noncondensing cycle with process steam load.

plus steam is expanded to the condenser pressure, thereby doing more work. The loss of low-temperature energy is reduced.

The comparative performance of the various cycles illustrated in Figs. 8-3 and 8-7 to 8-10 is shown in Table 8-5 for constant initial steam conditions and a uniform power load of 1,000 kw. The amount of heat rejected to the atmosphere or to condenser cooling water should be compared. Also, in the cycles of Figs. 8-9 and 8-10, the process load could be so heavy that insufficient steam is available from the turbine, and h-p steam must be throttled to the process load. Then the energy rejected to

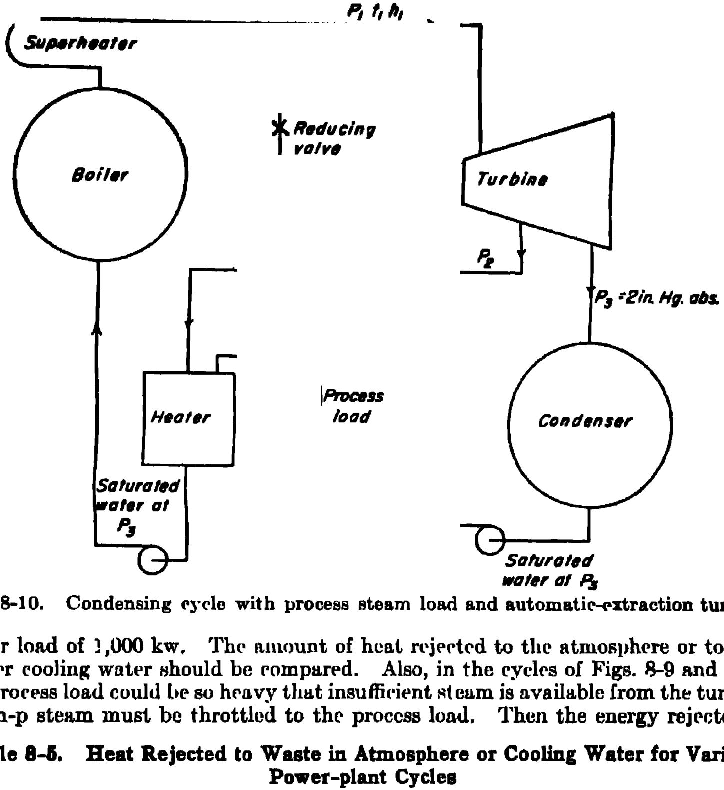

Fig. 8-10. Condensing cycle with process steam load and automatic-extraction turbine.

Table 8-5. Heat Rejected to Waste in Atmosphere or Cooling Water for Various Power-plant Cycles

Conditions: p_1 = 400 psig; t_1 = 720°F; isentropic expansion in turbine; power output of turbo unit = 1,000 kw; saturated water from condenser and direct-contact heater; 25°F subcooling of condensate from process loads; 60°F make-up.

the atmosphere or condenser is zero. (Actually, a small amount of steam must flow through the l-p section of the extraction turbine to keep it from overheating.)

Some industrial-power-plant cycles become very complex. Steam may be bled from an automatic extraction turbine at two different pressures instead of one. In some plants, a variable amount of steam at an intermediate pressure may be available as exhaust steam from steam hammers or steam engines and a mixed-pressure turbine may be used. This turbine operates like an automatic-extraction turbine except that steam at intermediate pressure, instead of being extracted, is supplied to the turbine and expanded to condenser pressure. Steam-engine-driven auxiliaries may operate on h-p steam and exhaust to a feed-water heater or a process load. In all cases, the ideal condition is one in which the heating and process load is supplied by steam which has generated power and in which the loss of low-temperature energy to condenser cooling water or atmosphere is reduced to a minimum.

FUELS*

BY GERALD B. GOULD, DOUGLAS HENDERSON, AND HENRY L. BRUNJES

Fuel and Power Consultants, Fuel Engineering Company of New York

The energy demands of the United States for industrial and utility steam-power purposes are met by the use of solid, liquid, and gaseous fuels—chiefly by bituminous coal. The approximate percentages contributed by each type of fuel to satisfy these requirements are bituminous coal, 70 per cent; anthracite coal, 2 per cent; fuel oil, 13 per cent; and natural gas, 15 per cent.

TOTAL MARKETED PRODUCTION

Bituminous Coal. In recent years, the production of bituminous coal has varied from a low of approximately 300 million tons in 1932 to over 600 million tons in 1944.

Table 8-6. Production of Bituminous Coal

	Per cent
West Virginia	27
Pennsylvania	24
Illinois	13
Kentucky	12
Ohio	5
Virginia	3
Alabama	3
Indiana	2
All others	11
	100

Table 8-7. Petroleum Refining Areas

	Per cent
California	29.5
Gulf Coast (Texas and Louisiana)	24.8
East Coast	17.3
Indiana, Illinois, and Kentucky	12.3
Texas, Arkansas, Louisiana inland	6.5
Oklahoma, Kansas, and Missouri	5.2
Rocky Mountain	2.4
Appalachian	2.0
	100.0

While practically half the 48 states produce bituminous coal, 89 per cent of the total is from eight states—all located east of the Mississippi River. The production is shown in Table 8-6.

Anthracite Coal. The production of anthracite is approximately 10 per cent that of bituminous, and of this about 85 per cent is used in domestic and commercial heating equipment. Practically all of it originates in Pennsylvania. In 1944, the total was 61 million tons.

Residual Fuel Oil. Production of residual fuel oil in 1944 amounted to 461.4 million barrels and was distributed among the several petroleum refining areas, in order of magnitude, as shown in Table 8-7.

Table 8-8. Production of Natural Gas

	Per cent
Texas, Louisiana, and Oklahoma	63.8
California	13.5
West Virginia, Kentucky, Pennsylvania, Ohio, New York	11.4
All others	11.3
	100.0

Natural Gas. The total marketed production of natural gas for domestic, commercial, and industrial fuel in 1944 was 2,486 billion cu ft. The total production was distributed as shown in Table 8-8.

DISTRIBUTION OF FUELS

The characteristics of the fuels economically available are limited in the first place by the location of the consuming plant. Because of the relatively high cost of overland transportation per unit of energy, nearly all coal is consumed within 300 miles of its place of production or at more distant points to which a substantial part of the transportation is by water. For the same reason coal from one producing district is unable to compete successfully with coal produced nearer to a given point of consumption, unless favored by distinctly lower production costs or by chemical and physical properties of the coal which make it better adapted to specific uses. This has resulted in a well-defined pattern of distribution which is described in detail below.

---

* Superior numbers refer to specific references listed at the end of this subsection.

The cost of transportation of fuel oil by pipe line or tanker and of natural gas by pipe line is considerably lower than for coal per mile per unit of energy. Thus both these fuels have been able to move from three to five times as far as coal to reach consuming areas to which suitable transportation facilities are available. The availability of both oil and gas at a given point of consumption, however, is determined by the cost of secondary distribution to the consumer. Gas, of course, can be delivered only to a service-connected consumer who is located either near a trunk pipe line or within the limits of a city gas-distribution system.

Crude oil or the lighter fuel oils can be transported by pipe line or by barge or tanker, but the heavy fuel oil commonly used by industry for steam generation cannot be transported by pipe line because of its high viscosity. Hence, heavy fuel oil is ordinarily marketed only within a short radius of refineries or waterside terminals from which it can move overland only by truck or railroad tank car. Generally such overland movement in the industrial area east of the Mississippi River is in the direction of some producing coal field, so that the further the oil moves, the greater is its cost to the consumer, while the cost of coal becomes less. The light oils can be transported overland by pipe line to secondary centers of distribution and consequently are economically available over a wider area, especially since these grades of oil are usually in competition only with the more costly domestic sizes of coal for residential heating or for use in diesel engines.

The result is that a large part of the total fuel-oil consumption is concentrated along the North Atlantic seaboard to which oil can be transported cheaply by tanker and which is most distant from the coal-producing fields of all the territory in the northern states east of the Mississippi.

A comparatively small part of the total fuel oil used in stationary plants or for residential heating is consumed near the oil fields because natural gas is usually produced in or near the same areas and costs much less per unit of energy at the point of production.

In summary, in 1941, 85 per cent of all the coal consumed in the United States for all purposes, except railroad fuel, was used in the northern industrial states east of the Mississippi River. In the same area in that year 70 per cent of all the fuel oil was used, and three-quarters of this was in the New England and Middle Atlantic states. On the other hand, 70 per cent of the natural gas used for fuel was consumed in the territory to the south and west of the preponderantly coal-burning area, and 83 per cent of this was used west of the Mississippi River.

Natural gas and the several grades of fuel oil all have substantially the same physical and chemical properties everywhere. On the other hand, the characteristics of the coal economically available at different locations relatively near each other in the Northeast (where most of the coal is consumed) vary in many important respects depending upon the location of the mines. Therefore, the pattern of fuel distribution in this area is of primary importance. This distribution pattern is described and the typical range of the chemical and physical properties of the coal available in each subdivision of the northeastern part of the country is given in the following material.

The industrial Northeast can be divided into six market areas, within any one of which the coals economically available for industrial use originate in only a few producing districts and have a distinctive range in their more important physical and chemical properties. These six divisions are shown on the accompanying map, Fig. 8-11. It should be noted, however, that the boundaries of these consuming areas have been determined primarily by the relative delivered cost of coal from the different producing districts and the quality of coal from competing producing districts. Neither is unchangeable, so that, with the passage of time and changing conditions, they will vary somewhat. Also these boundaries are not impassable, so that within a short distance of a boundary, coals available in the adjoining consuming area should be considered. For special purposes requiring a quality of coal not ordinarily economical for steam generation at a given location, a source of supply at some distance may have to be chosen.

Consuming Area I. Consuming area I embraces that part of eastern and southern New England adjacent to the seacoast and most distant by direct rail haul from any coal-producing field. The coal for industrial use comes almost entirely from the low- and medium-volatile fields of southern West Virginia by rail to tidewater at Hampton Roads and then to New England ports by collier. The typical quality characteristics of these coals are moisture, 2.5 per cent; volatile, 16 to 23 per cent; ash, 6.5 per cent; Btu, 14,300. The softening temperature of ash for coals from these fields varies widely but is usually found between 2400 and 2800°F. The grindability-index values are generally in the higher ranges, 80 to 95 on the ball-mill scale or 100 to 115 Hardgrove equivalent.

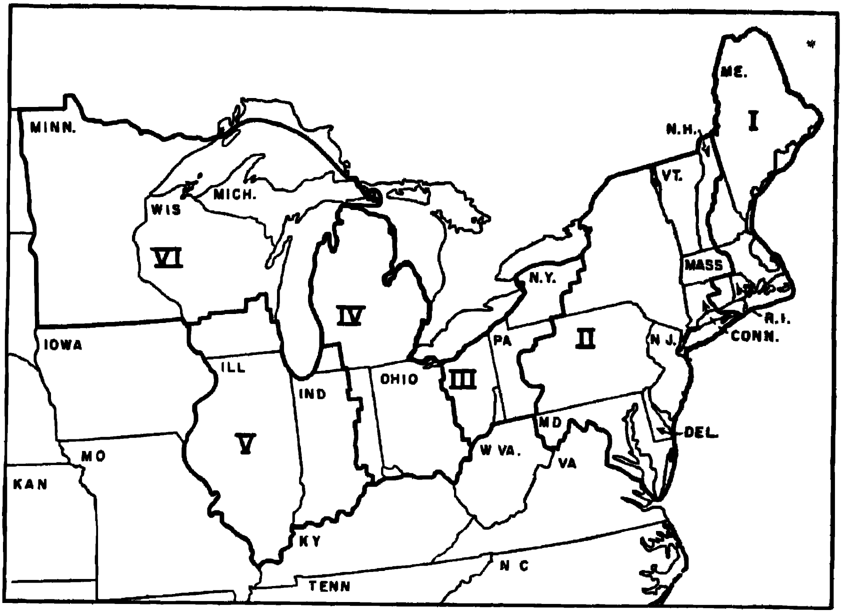

FIG. 8-11. Northeastern coal-consuming areas.

NOTE: These coal-quality figures and those in similar tables which follow represent a quality for industrial-steam sizes of coal that corresponds to the major part of production in each district. The quality of coal shipped by individual mines will vary considerably above and below these figures, in some cases by a substantial amount.

Consuming Area II. Consuming area II includes the western portion of New England, the eastern sections of New York and Pennsylvania, and all New Jersey, Delaware, and Maryland. Within this area lie the anthracite fields of Pennsylvania, and the low-, medium-, and high-volatile bituminous fields of central Pennsylvania and Maryland. Almost the entire output of these producing fields is consumed within this area. Immediately adjacent are the high-volatile bituminous fields of northern West Virginia, and a substantial part of its output is also shipped to this consuming area.

Industrial consumers in this area (except at points close to the mines) have an exceptionally wide range in the properties of coal available, from the small sizes of anthracite through the whole range of volatile content, softening temperature of ash, friability, grindability, and sulfur found in bituminous coal produced in the whole Appalachian region. Along the coast, heavy fuel oil is also available. Fuel selection and the design of steam-generating equipment in this area require careful study, depending upon the exact location of the plant.

The typical quality and character of the coals available are shown in Table 8-9.

Table 8-9

	Moisture, per cent	Volatile, per cent	Ash, per cent	Btu
Central Pennsylvania	2.5	18–23	8.0	14,000
Central Pennsylvania	2.5	30	8.0	13,800
Northern West Virginia (high volatile)	3.0	35	9.0	13,300

In the central Pennsylvania fields, the ash-softening temperature of the various classes of coal will vary from 2200 to 2900°F. The lower volatile coals are usually found easy to pulverize, having indexes of from 85 to 95 on the ball-mill scale, 105 to 115 on the Hardgrove. The higher volatile coals are somewhat harder, with indexes of from 60 to 75 ball-mill scale, 80 to 95 Hardgrove.

The northern West Virginia high-volatile coals have ash-softening temperatures of 2000 to 2300°F. Their grindability indexes range from 45 to 55 ball-mill scale, 60 to 75 Hardgrove.

Consuming Area III. Almost all points within consuming area III, which includes the western parts of New York State and Pennsylvania and the eastern part of Ohio, lie within a relatively short distance of mines which are themselves within the area. The industrial coal consumed in the area originates chiefly in western Pennsylvania and eastern Ohio. To a lesser extent it originates in the high-volatile fields of northern West Virginia adjoining it on the south.

The typical quality of these coals is shown in Table 8-10.

Table 8-10

	Moisture, per cent	Volatile, per cent	Ash, per cent	Btu
Western Pennsylvania	3.0	32.0	9.0	13,400
Western Pennsylvania	4.0	37.0	9.0	13,050
Eastern Ohio	5.0	37.0	10.0	12,600

The softening temperature of the ash in these coals is usually in the low or medium range, 2000 to 2500°F. Grindability values are from 40 to 50 ball-mill scale, 55 to 70 Hardgrove.

Consuming Area IV. Consuming area IV, which includes the western part of Ohio, the eastern part of Indiana, and the southern peninsula of Michigan, draws its supply of industrial coal delivered by all-rail haul almost entirely from the southern West Virginia and eastern Kentucky producing fields (chiefly the high-volatile mines), except in northwestern Ohio where Ohio coal is also economically available. At Michigan Great Lakes ports, these coals are available, as well as coals from Ohio and western Pennsylvania, and the high-volatile coals from northern West Virginia shipped by water from Lake Erie loading piers.

The typical quality of the coal available in this area (except for those already described as being available in other consuming areas) is moisture, 3.0 per cent; volatile, 34 to 37 per cent; ash, 6.5 per cent; Btu, 13,800.

The softening temperatures of ash in these coals vary over a wide range but are usually found in the medium or high range of 2400 to 2900°F. Their grindability indexes are from 35 to 50 ball-mill scale, 50 to 70 Hardgrove.

Consuming Area V. In consuming area V, which includes western Indiana, all of Illinois, and the southern part of Wisconsin, about two-thirds of the coal used by industry originates in the Indiana and Illinois mines. Nearly all the remainder comes from the high-volatile fields of southern West Virginia and eastern Kentucky. Some western Kentucky coal is also shipped into this area.

The typical quality of these coals, in addition to those already described, is shown in Table 8-11.

Table 8-11

	Moisture, per cent	Volatile, per cent	Ash, per cent	Btu
Illinois and Indiana	9.0	34.0	9.0	11,800
Illinois and Indiana	13.0	34.0	10.0	10,900
Western Kentucky	7.0	37.0	10.0	12,000

The ash-softening temperatures for these coals fall in the low and medium range, 2000 to 2400°F. The grindability-index range is 35 to 50 ball-mill scale, 50 to 70 Hardgrove.

Consuming Area VI. In consuming area VI, which includes the upper peninsula of Michigan, most of Wisconsin (from Milwaukee north), and all of Minnesota, the variety of coal available for industrial use is similar in its wide range to that encountered in consuming area 2, because a large part of the coal is transported via the Great Lakes from Lake Erie ports through which coal can be economically shipped from central and western Pennsylvania, both northern and southern West Virginia, and eastern Kentucky and Ohio. Illinois coal is also shipped into this area by rail and river. Fuel selection in this area must be made with particular reference to the fuels available at the exact location where they are to be used. The quality of coal shipped from all the producing fields that supply this area has been described above under the headings of the consuming areas which are principally dependent upon them.

Southeastern Consuming Area. In the territory to the south of that shown on Fig. 8-11, coal plays a minor part, except in Virginia, North and South Carolina, and Georgia, where bituminous coal is economically available from the southern West Virginia fields described under consuming areas I and IV and from the Alabama and Tennessee producing fields. Western Kentucky coal for industrial use is chiefly distributed in Kentucky and Tennessee. The typical quality of these coals is moisture, 3.0 per cent; volatile, 31 to 35 per cent, ash, 8.0 per cent, Btu, 13,500.

The softening temperature of ash for these coals is from 2100 to 2900°F. The grindability indexes are 35 to 55 ball-mill scale, 50 to 75 Hardgrove.

Western Consuming Area. West of the Mississippi, the coal-producing fields are relatively small and widely scattered. The coal is mainly distributed to market areas local to each producing field.

The rank of the coal from these fields shows a wide variation and covers groups from low-volatile bituminous to lignite. The various ranks of coal produced in 12 states are listed in Table 8-12 in the order of tonnage produced. The combined production of these states is approximately 10 per cent of the nation's tonnage. Reference should be made to Table 8-14 for typical analytical data pertaining to the rank.

Table 8-12

State	*Rank of bituminous produced*
Wyoming	High-volatile A, B, C, subbituminous A, B
Colorado	High-volatile A, B, C, subbituminous A
Utah	High-volatile A, B, C
Montana	High-volatile B, C, subbituminous A, B, C
Missouri	High-volatile B, C
Kansas	High-volatile A, B
Oklahoma	Low and medium volatile
North Dakota	Lignite
Iowa	High-volatile C, subbituminous C
Arkansas	Low-, medium-, and high-volatile A
New Mexico	High-volatile A, C
Washington	High-volatile A, B, C, subbituminous A, B

Table 8-13. Classification of Coals by Rank[*]

Legend: F.C. = fixed carbon; V.M. = volatile matter; Btu = British thermal units.

Class	Group	Limits of fixed carbon or Btu mineral-matter-free basis	Requisite physical properties
1. Anthracitic	1. Metaanthracite	Dry F.C., 98 per cent or more (dry V.M., 2 per cent or less)	
	2. Anthracite	Dry F.C., 92 per cent or more and less than 98 per cent (dry V.M., 8 per cent or less and more than 2 per cent)	
	3. Semianthracite	Dry F.C., 86 per cent or more and less than 92 per cent (dry V.M., 14 per cent or less and more than 8 per cent)	Nonagglomerating[†]
2. Bituminous[§]	1. Low-volatile bituminous coal	Dry F.C., 78 per cent or more and less than 86 per cent (dry V.M., 22 per cent or less and more than 14 per cent)	
	2. Medium-volatile bituminous coal	Dry F.C., 69 per cent or more and less than 78 per cent (dry V.M., 31 per cent or less and more than 22 per cent)	
	3. High-volatile A bituminous coal	Dry F.C., less than 69 per cent (dry V.M., more than 31 per cent); and moist[‡] Btu, 14,000[‖] or more	
	4. High-volatile B bituminous coal	Moist[‡] Btu, 13,000 or more and less than 14,000[‖]	
	5. High-volatile C bituminous coal	Moist Btu, 11,000 or more and less than 13,000[‖]	Either agglomerating or nonweathering[¶]
3. Subbituminous	1. Subbituminous A coal	Moist Btu, 11,000 or more and less than 13,000[‖]	Both weathering and nonagglomerating
	2. Subbituminous B coal	Moist Btu, 9500 or more and less than 11,000[‖]	
	3. Subbituminous C coal	Moist Btu, 8300 or more and less than 9500[‖]	
4. Lignitic	1. Lignite	Moist Btu, less than 8300	Consolidated
	2. Brown coal	Moist Btu, less than 8300	Unconsolidated

---

[*] This classification does not include a few coals which have unusual physical and chemical properties and which come within the limits of fixed carbon or Btu of the high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48 per cent dry mineral-matter-free fixed carbon or have more than 15,500 moist mineral-matter-free Btu.

[†] If agglomerating, classify in low-volatile group of the bituminous class.

[‡] Moist Btu refers to coal containing its natural bed moisture but not including visible water on the surface of the coal.

[§] It is recognized that there may be noncaking varieties in each group of the bituminous class.

[‖] Coals having 69 per cent or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of Btu.

[¶] There are three varieties of coal in the high-volatile C bituminous coal group, *viz.*, variety 1, agglomerating and nonweathering; variety 2, agglomerating and weathering; variety 3, nonagglomerating and nonweathering.

PROPERTIES OF FUELS

Coal. Coal is classified by rank, as shown in Table 8-13, as adopted by the ASTM under Standard Designation D-388-38. Within the limits for each group set by this scheme, there will be found in Table 8-14 representative proximate analyses typical of each one, using the normal seam-moisture content.

For industrial steam-generating purposes, the rank and grade of coal is customarily judged by the use of the proximate analysis, which includes moisture, volatile, ash, sulfur, and fixed carbon. Other physical properties that may affect the efficient recovery of the energy are commonly determined. These are calorific value, ash-softening temperature, grindability, and coking property. The facts disclosed by the proximate analysis and the effects of the various other properties both physical and chemical are briefly described.

Table 8-14. Proximate Analyses of Groups of Coal

Group or rank	Moisture	Volatile	Ash	Btu
Metaanthracite	2.0	2.0	20.0	10,925
Anthracite	4.0	3.5	10.0	12,775
Anthracite	4.0	6.0	10.0	12,900
Semianthracite	4.0	10.0	10.0	13,150
Low-volatile bituminous	2.0	16.0	7.0	14,325
Low-volatile bituminous	2.5	19.0	7.0	14,200
Medium-volatile bituminous	2.5	23.5	7.0	14,200
Medium-volatile bituminous	2.5	29.0	8.0	13,850
High-volatile bituminous A	3.0	33.0	9.0	13,400
High-volatile bituminous A	4.0	37.0	9.0	13,050
High-volatile bituminous B	6.0	37.0	9.0	12,500
High-volatile bituminous B	9.0	34.0	9.0	11,800
High-volatile bituminous C	12.0	34.0	10.0	11,050
High-volatile bituminous C	15.0	34.0	10.0	10,550
Subbituminous A	17.0	34.0	11.0	9,900
Subbituminous B	20.0	33.0	11.0	8,700
Subbituminous C	24.0	33.0	11.0	8,000
Lignite	37.0	26.0	7.0	6,800

Moisture. Moisture is present in coal in two forms, inherent and free (surface) water. The inherent or seam moisture is considered a natural part of the coal substance in its virgin state. Coal containing only this type of moisture does not have the appearance of wetness and may actually be dusty with relatively high percentages of water depending on the rank of the coal. The analyses given in Table 8-14 report this type of moisture.

After mining, the total moisture content may increase or decrease depending not only upon the wetting or drying due to climatic conditions during transportation and storage but also as a result of cleaning processes using water and the addition of water to minimize dust. This is the free water which is mechanically retained on the surface of the coal particles or between them and is visible or apparent to the touch.

The total moisture content of coal affects the efficiency of a steam-generating plant to only a slight extent. The loss is of the order of 0.1 per cent in efficiency for each 1.0 per cent of moisture. Excess surface moisture may have a very considerable adverse effect on pulverizer capacity, particularly when operating in a range close to the maximum. High surface moisture has a noticeable influence on the coking property of certain coals, particularly the high-rank, low-volatile coals with low inherent moisture. With certain types of stoking equipment, these coals often form a dense coke mat which can be definitely modified by the addition of water to the coal as fired.

Volatile and Fixed Carbon. The volatile content of coal, excluding moisture, is that part driven off by heating and is burned as a gas. The remaining combustible solid matter is the fixed carbon. Relatively small differences in the per cent of volatile or fixed carbon are usually of little practical significance to the steam-plant operator. There are, however, circumstances under which it is necessary or desirable to specify maximum or minimum permissible limits.

For hand- or stoker-fired plants with furnaces having inadequate space to mix the volatile matter with air for combustion, it is found important to specify an upper limit of volatile to minimize the loss of heating value or, of more likely importance, the emission of smoke. Under a given set of conditions, it is a reasonable presumption that the amount of smoke is proportional to the per cent of volatile, although it is often modified by the size consist of the coal and its coking property. Conversely, in pulverized-coal firing, it is often necessary to set a low limit in order to maintain flame propagation, particularly in completely water-cooled furnaces.

The varying composition of the volatile matter in coal is shown by data taken from tests made by the U.S. Bureau of Mines in determining the carbonizing and by-product properties of different types of coals. Table 8-15 gives the percentages of several of the volatile constituents in per cent of coal. The volatile matter of anthracite contains no tarry constituents, and the gas is approximately 85 per cent hydrogen.

Table 8-15. Volatile Constituents in Coal

Type of coal	Tar, per cent	Hydrocarbons in gas, per cent	Btu per cu ft of gas
Low-volatile bituminous	3.0	32	545
Medium-volatile bituminous	5.0	35	570
High-volatile bituminous A	6.5	37	605
High-volatile bituminous B	6.5	37	610
High-volatile bituminous C	6.0	32	555
Subbituminous B	3.0	22	450
Lignite	0.2	9	325

Ash. Ash, or the noncombustible mineral matter remaining after coal has been burned, is composed largely of compounds of silicon, aluminum, iron, calcium, magnesium, and the alkalies. Very small quantities of sulfates and phosphates are of common occurrence. While probably more than half the known chemical elements have been reported as occurring in coal, they have been too low in percentage to be of importance for recovery.[1] The typical limits of the common elements in coal ash are shown in Table 8-16.

Table 8-16

	Per cent
Silicon dioxide	40-60
Aluminum oxide	20-35
Ferric oxide	5-25
Calcium oxide	1-15
Magnesium oxide	½-4
Alkali oxides	1-4

The mineral matter associated with coal is from two sources, inherent and adventitious. Inherent mineral matter is usually small in amount in American coals, *i.e.*, less than 1 or 2 per cent and undetectable except as a residue of combustion. Its origin is the mineral matter of the living plant life that went to form the coal measure. The adventitious or extraneous ash is from clays, shales, pyrites, or other minerals occurring above, below, or as partings within the coal seam. These minerals may appear as isolated pieces of various sizes or as finely disseminated particles. Much of this extraneous ash can be and is removed by selective mining and various types of cleaning processes.

Apart from the economics of coal purchasing in which ash is bought and transported at the same rate as coal, the quantity present will have a significant effect on power-plant costs, refuse handling, and boiler and stoker upkeep. Increases in cost of ash handling and boiler and furnace upkeep will vary widely depending upon the individual plant and the amount of equipment installed for these purposes. An increase in ash content from 5 to 10 per cent requires the use of about 5 per cent more coal for a given amount of steam, while the quantity of refuse to be handled will be slightly more than doubled.

Sulfur. Sulfur is present in coal in three forms, an insignificant amount combined as sulfate, in an organic form combined with the coal substance, and as iron pyrites, the last assuming the greatest importance because of certain objectionable side effects introduced by the associated iron. Pyrites (or marcasite) is the disulfide of iron which in the combustion process can be broken down to ferric oxide and the oxides of sulfur or, under certain conditions, ferrous sulfide.

This compound easily fusible itself or in combination with other elements of the ash promotes the formation of clinkers or slags, and it is the likelihood of this occurring that creates in the mind of the user the thought that high sulfur content is responsible for the difficulty. The relationship between sulfur content and ash fusibility is very general as shown by a study of about 5,000 tests made on coals from the Appalachian region. These tests indicated that 70 per cent of the coals having 2 per cent or more of sulfur had ash fusing below 2500°F, while of those having 1½ per cent or less, 70 per cent fused over 2600°F. Coal from a particular mine, however, may be very low in sulfur content and still have a low softening temperature of ash.

Another difficulty relative to use of high-sulfur coal, aside from that of air pollution by the oxides of sulfur, is the corrosive nature of these products of combustion in the flue gases in the presence of water vapor. Relatively low temperature of the flue gases, *i.e.*, below 350°F, favors the formation of sulfuric acid, and as a consequence corrosion of the metal parts of economizers, air heaters, flues, etc., can be expected with correspondingly high maintenance costs.

Ash-softening Temperature. Coal ash, being a complex mixture of mineral compounds, does not have a definite melting point but a range or interval. One point in this interval, defined as the "softening temperature," has been used for many years as an indication of the tendency to form clinker and slag. The test procedure in use today is the result of the fundamental work of Fieldner, Hall, and Feild in 1918.[2] While other factors affect clinker formation, the softening temperature of ash as determined in the laboratory is a very useful figure in predicting the probable behavior of the ash residues from coal when burned either on grates or in pulverized form. There are other means of determining clinkering and slagging tendencies, but unfortunately most of them are either so expensive or laborious as to preclude their commercial use.

The present standard test is to pulverize the ash finely and mold it into a cone. This is mounted on a refractory base and subjected to a controlled rate of heating in an atmosphere conforming approximately to a composition of 60 per cent of oxidizing gases and 40 per cent of reducing. As the heating of the cone progresses, observations are made concerning three points of the melting interval. The first point is when there is a slight rounding of the sharp tip of the cone. This is noted as the temperature of initial deformation. The heating is continued, and when the cone deforms to spherical shape approximately one-half its original height, that point is noted as the softening temperature. The fluid temperature is the point at which the ash assumes such a high degree of fluidity that it flows over the refractory base. In many instances, all three of these points are important. The one most commonly used is the softening point (sometimes called "fusion temperature"), and it is understood to be the one used in analytical results in the absence of the other two.

One reason why the ash-softening temperature as determined in the laboratory does not always agree with the practical observation in the plant is the intimate mixing and pulverizing of the ash in the laboratory sample which does not occur in practice. The ash in coal may be either a very finely divided material in the coal substance or occur as sizable pieces of slate, shale, or pyritic matter which may or may not be evenly distributed throughout the coal mass. These different portions of the coal ash are likely to have different softening temperatures. There is always the possibility of certain isolated pieces fusing and forming the nucleus of a clinker or slag. The work done in connection with this problem by Gould and Brunjes in 1940[3] pointed out the importance of separating the material to determine the proportion of fusible and refractory material in both size and gravity fractions.

In this work, one instance was cited of a coal ash having a 2700°F softening temperature by standard test with about 73 per cent of ash fusing over 2600°F and 24 per cent fusing under 2200°F. If, in firing, the lower fusing material were concentrated in any portion, the expectancy would be for clinker trouble to occur; yet the standard test indicated refractory ash. This same coal burned in pulverized form, *i.e.*, ground to pass a 200-mesh sieve, had in physically separable portions of the coal about 15 per cent showing ash-fusion temperatures of less than 2300°F and 85 per cent fusing over 2700°F.

Grindability. The grindability index of coal is the measure of its resistance to pulverization. It is measured by two methods in common use—the ball-mill method proposed by Yancey, Furse, and Blackburn[4] and the Hardgrove-machine method proposed by Hardgrove.[5] In the ball-mill index 100 signifies the softest or most easily pulverized coal, while in the Hardgrove index it is a standard reference point in the scale. On the latter scale an index figure of 118 would be comparable to its 100 value in the ball-mill index. Both methods appear as tentative standards in the ASTM with a conversion table. A curve plotted from equivalent values is given in Fig. 8-12.

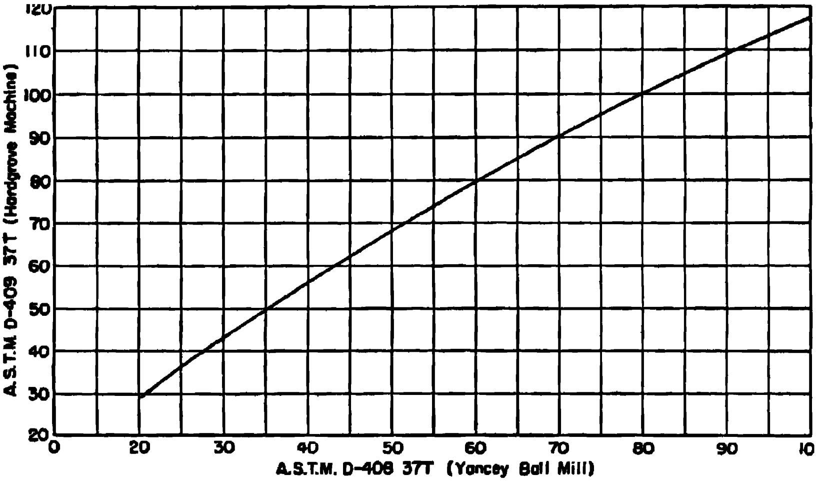

FIG. 8-12. Equivalent values of Hardgrove and ball-mill grindability indexes.

Coking Properties. The characteristic of coking has been and is still described by a number of terms, among them agglomerating, agglutinating, and swelling, all relating to the behavior of coal on heating. This property and its descriptive terminology are more important in the manufacture of coke than in burning coal for steam raising, but there are many instances when a convenient measure of the physical reaction of coal to heat in the furnace is desirable. In this connection, the visual observation of the coke mass after determining the volatile together with an estimation of its cohesiveness has been useful and is used as an indication of the rank of coals when fresh-mined samples are used. A grading proposed by Gilmore, Connell, and Nicolls[6] was based on this method and classified coals as noncoking, poor, fair, and good coking.

Within recent years, a comparatively simple means of determining the swelling power has been adopted as a tentative standard by the ASTM. This is designated as the free-swelling index. The test consists in rapid heating of the finely ground coal in a closed crucible after which the profile of the resulting coke button is matched against standard outlines. Seventeen profiles are given in the standard in half numbers from one to nine. Number one represents a nonswelling coal with a coherent button, while number nine is one swollen to the point of pressing against the crucible cover, a vertical expansion of approximately five times. Granular or noncoherent residues indicate a noncoking or nonagglomerating class of coal.

As a rule, all fresh-mined bituminous coal above high-volatile bituminous C in rank will coke and swell to some degree—the higher the rank, the greater the swelling power. Weathering or oxidation greatly affects the coking or swelling property and may destroy it entirely. The free-swelling index is often used as a means of detecting oxidized coal. When the normal swelling power of the particular coal is known and tests show profiles significantly below this value, it is safe to assume that weathering or oxidation has taken place.

Calorific Value. The calorific value as expressed in British thermal units (Btu) is the one definite measure of the energy in coal, all other items of the analysis representing those properties hindering or enhancing its efficient recovery. The Btu is defined as 1/180 the amount of heat required to raise 1 lb of water from 32 to 212°F.

It is most important to determine the Btu by means of the calorimeter since there is no reasonably accurate means of calculating this value from the other figures given in the proximate analysis.

Industrial Sizes of Anthracite. Compared with bituminous, the range in characteristics of anthracite is extremely narrow. The tonnage for industrial use is in the Nos. 3, 4, and 5 buckwheat sizes prepared through and over round-hole screens of openings as shown in Table 8-17.

Table 8-17. Screen Openings for Buckwheat Coal

Size	Through, in.	Over, in.
No. 3 buck	3/16	3/32
No. 4 buck	3/32	3/64
No. 5 buck	3/64	

Size and quality specifications are set by the Anthracite Committee of Pennsylvania and as of Sept. 1, 1947, are controlled by a state law fixing anthracite standards on sizes larger than No. 3 buck. The standard specifications for Nos. 3, 4, and 5 buckwheat are shown in Table 8-18.

The smaller sizes of anthracite are generally prepared, screened, and loaded with the aid of water. Consequently, the moisture content will run comparatively high, increasing with decreasing size consist. As shipped, the typical moisture limits of Nos. 3, 4, and 5 buckwheat are as shown in Table 8-19.

Table 8-18. Standard Specifications for Buckwheat Coal

	Oversize maximum, per cent	Undersize, per cent		Maximum ash, dry basis, per cent
		Maximum	Minimum	
No. 3 buck	10	20	10	15
No. 4 buck	20	30	10	15
No. 5 buck	30	No limit		16

Fuel Oil. The ASTM specifications classify fuel oil into five grades, Nos. 1, 2, 3, 5, and 6, and the detailed requirements for each are given in Table 8-20. Of these grades only No. 6, also termed bunker C or residual oil, is commonly used as an industrial fuel for steam purposes. Grades 1, 2, and 3 are the distillate oils which are marketed chiefly for residential domestic heating and certain specialty uses in industry. The distillate oils under a somewhat different grading also supply the diesel fuel market. Number 5 oil is usually a heavy product blended with distillate to lower the viscosity. Its market is a semi-industrial one and includes commercial heating plants and specialty uses.

Table 8-19. Moisture Limits of Buckwheat Coal

	Per cent
No. 3 buck	7–9
No. 4 buck	9–11
No. 5 buck	10–12

Number 6 or residual oil is generally tested for compliance with the standard specification and also for gravity and Btu content. The significance of these tests to the consumer will be given in a brief way. For a more detailed explanation reference should be made to the work of the committees on petroleum products of the ASTM.

Gravity. As oil is sold by volume and as its volume will vary according to the temperature, it is essential that a temperature reading be made in conjunction with

Table 8-20. Detailed Requirements for Fuel Oils[a]

Grade of fuel oil[b]	Flash point, deg F		Pour point, deg F	Water and sediment, per cent by volume	Carbon residue, per cent by weight	Ash per cent by weight	Distillation temperatures, deg F: 10 per cent point	90 per cent point		End point	Viscosity, sec: Saybolt universal (at 100°F)		Saybolt furol (at 122°F)	
	Min	Max	Max	Max	Max	Max	Max	Max	Min	Max	Max	Min	Max	Min
No. 1 (A distillate oil for use in burners requiring a volatile fuel)	100 or legal	165	0	Trace	0.05[d] on 10 per cent residuum		410			560[e]				
No. 2 (A distillate oil for use in burners requiring a moderately volatile fuel)	110 or legal	190	10[c]	0.05	0.25[f] on 10 per cent residuum		400	600						
No. 3 (A distillate oil for use in burners requiring a low-viscosity fuel)	110 or legal	230	20[c]	0.10	0.15			675	600[g]		45			
No. 5 (An oil for use in burners requiring a medium-viscosity fuel)	130 or legal			1.00		0.10						50	40	
No. 6 (An oil for use in burners equipped with preheaters permitting a high-viscosity fuel)	150			2.00[h]									300	45

[a] Recognizing the necessity for low-sulfur fuel oils used in connection with heat-treatment nonferrous metal glass and ceramic furnaces, and other special uses, a sulfur requirement may be specified in accordance with the following table

Grade of fuel oil	*Sulfur, max, per cent*
No. 1	0.5
No. 2	0.5
No. 3	0.75
No. 5	No limit
No. 6	No limit

Other sulfur limits may be specified only by mutual agreement between the purchaser and the seller.

[b] It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade.

[c] Lower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0°F under any conditions.

[d] The carbon residue on 10 per cent residuum may be increased to a maximum of 0.12 per cent when this oil is to be used in other than sleeve-type blue-flame burners. This limit may be specified by mutual agreement between the purchaser and the seller.

[e] The maximum end point may be increased to 590°F when this oil is to be used in other than sleeve-type blue-flame burners.

[f] To meet certain burner requirements, the carbon-residue limit on this oil may be reduced to 0.15 per cent on 10 per cent residuum.

[g] This requirement may be waived if the API gravity is 26 or lower.

[h] The amount of water by distillation plus the sediment by extraction shall not exceed 2.00 per cent. The amount of sediment by extraction shall not exceed 0.50 per cent. A deduction in quantity shall be made for all water and sediment in excess of 1.0 per cent.

the density determination so that delivery volumes can be calculated back to the standard basis of measurement which is the specific or API gravity at 60°F. For fuel oil, the API (American Petroleum Institute) gravity is customary. This scale is related to the specific gravity as follows:

$$\text{Degrees API} = \frac{141.5}{\text{sp gr } 60°\text{F}/60°\text{F}} - 131.5$$

Correction of the observed volume to the standard basis is made according to the National Standard Petroleum Oil Tables prepared by the U.S. Bureau of Standards. Lacking such tables, a convenient method sufficiently accurate for most purposes is offered by the use of a coefficient of expansion of 0.00035 per deg F at 60° for oils ranging up to 14.9 API gravity and covers No. 6 grade. For example, if the observed gallonage at 110°F is 10,000, the volume at 60°F would be

$$[1.0 - (50 \times .00035)] \times 10{,}000 = 9{,}825 \text{ gal}$$

Calorific Value. The Btu value which must be made by a calorimetric test is necessary for the determination of the efficiency of operation. It is related in a general way to the API gravity for grade 6 as indicated by the approximate heat content shown in Table 8-21.

Table 8-21

API at 60°F	Btu per lb	Btu per gal
8	18,100	152,910
10	18,300	152,400
12	18,400	151,100
14	18,500	149,830

Flash Point. The flash point is the temperature at which the oil gives off a vapor that is inflammable when mixed with air. It is an essential test, for it indicates what safety precautions are necessary in storing and handling oil.

Water and Sediment. Water and sediment are undesirable and should be kept at or below the minimum allowable in the standard specification. Water interferes with proper combustion and continuous flame propagation. Sediments plug strainers, valves, burners, etc., and may have an abrasive action.

Viscosity. Viscosity is a characteristic of oil which is the measure of its resistance to flow. It is determined by the efflux time of a given quantity through a specified orifice and is reported for grade 6 as seconds Saybolt Furol (SSF) at 122°F. It is one of the most important determinations because the viscosity indicates the degree of preheating necessary for complete atomization at the burner. This preheat temperature is generally accepted as being the point at which the oil has a viscosity of 150 seconds Saybolt Universal, or approximately SSF 15. As viscosity differs among oils and varies inversely with the temperature, which variation may be different between oils, it is necessary to determine the point of SSF 15 by means of a plot of two viscosity points on the ASTM Standard Viscosity-Temperature Charts for Liquid Petroleum Products. For many oils, the proper temperature for atomization in relation to viscosity SSF at 122°F is as shown in Table 8-22.

Table 8-22

SSF at 122°F	*Atomization temperature, deg F*
50	165
100	195
150	205
200	215
250	220
300	225

Natural Gas. Natural gas is generally quite pure and consists chiefly of methane, the per cent of which, while varying widely, is usually found to be between 75 and 99 per cent, the remainder being principally ethane with small quantities of nitrogen and carbon dioxide. The gross Btu value per cubic foot ranges from 900 to 1300. A typical analysis would be as shown in Table 8-23.

Table 8-23

Methane	91.0%
Ethane	3.0%
Carbon dioxide	0.5%
Nitrogen	5.5%
Btu	1025

Gas volumes when reported have usually been corrected to a standard temperature and pressure. On the English system that base is 60°F and 30 in. Hg. The normal atmospheric pressure at sea level is 29.92 in. Hg but for convenience this has been called in round figures 30 in. for all gas work.

Gas volumes vary in direct proportion to their absolute temperatures. The latter figure is obtained by adding 460 to the Fahrenheit temperature. Gas volumes are inversely proportional to the absolute pressure which is the pressure in inches of mercury column plus 30.

For any given set of conditions, the particular gas volume is corrected both for temperature and pressure as shown in the following example.

Example: Determine the volume at standard conditions (60°F and 30-in. Hg) of 1,500 cu ft of gas which was metered at 90°F and 3-in. Hg, the barometer standing at 28.56 in.

Solution: $1{,}500 \times \left(\frac{60 + 460}{90 + 460}\right) \frac{(28.56 + 3.0)}{30} \quad 1{,}491.2 \text{ cu ft}$

Sometimes the metering of gases takes place over water, some of which will evaporate and exert a partial pressure. This will have to be considered in correcting the gas volume to standard conditions.

Table 8-24. Aqueous-vapor Tension

Deg F	Vapor tension, in. Hg	Deg F	Vapor tension, in. Hg	Deg F	Vapor tension, in. Hg	Deg F	Vapor tension, in. Hg	Deg F	Vapor tension, in. Hg
32	0.1804	48	0.3363	64	0.601	80	1.029	96	1.706
33	0.1878	49	0.3492	65	0.622	81	1.003	97	1.759
34	0.1955	50	0.3625	66	0.644	82	1.098	98	1.813
35	0.2034	51	0.3762	67	0.667	83	1.134	99	1.869
36	0.2117	52	0.3903	68	0.690	84	1.171	100	1.926
37	0.2202	53	0.4049	69	0.714	85	1.209	101	1.985
38	0.2290	54	0.4201	70	0.739	86	1.248	102	2.045
39	0.2382	55	0.4357	71	0.764	87	1.280	103	2.107
40	0.2477	56	0.4518	72	0.790	88	1.331	104	2.171
41	0.2575	57	0.4684	73	0.817	89	1.373	105	2.236
42	0.2677	58	0.4856	74	0.845	90	1.417	106	2.303
43	0.2782	59	0.5034	75	0.873	91	1.462	107	2.372
44	0.2890	60	0.522	76	0.903	92	1.508	108	2.443
45	0.3002	61	0.541	77	0.933	93	1.556	109	2.515
46	0.3118	62	0.560	78	0.964	94	1.605	110	2.589
47	0.3238	63	0.580	79	0.996	95	1.655		

Using the above example, the temperature correction remains the same. For the pressure correction, 28.56 in. + 3.0 in., or 31.56 in., is the absolute pressure of the gas. From this must be deducted the aqueous-vapor tension read from Table 8-24 for 90°F. The actual gas pressure becomes 31.56 in. − 1.417, or 30.143 in. Thus, the volume of dry gas at 60° is

$$1{,}500 \times \left(\frac{60 + 460}{90 + 460}\right) \times \frac{30.143}{30} = 1{,}423.2 \text{ cu ft}$$

COAL SAMPLING*

It should be borne in mind that in sampling the purpose is to represent by a small quantity the whole pile, or car, or barge of coal, as the case may be. One scoopful taken at random or a single lump selected here and there will not be representative. In taking a sample, always use a scoop of proper capacity for the increment weight chosen. Never use the hands, for there will be an involuntary inclination to select pieces or sections of either particularly good or especially bad appearance. The best samples are obtained from coal in motion, *i.e.*, while it is being unloaded or conveyed from one place to another. Whether the coal is in motion or at rest, sample increments of uniform weight should be spaced as evenly as possible over the whole lot being sampled. If the coal is in a pile, or car, or barge, the increments should be taken from a number of locations at different levels to avoid the results of segregation. The term "increment" designates that quantity obtained by a single motion of the sampling scoop through a stream of coal or into a pile or top of car or barge.

Table 8-25

Top size, in.	Weight of increment, lb	Number of increments
4	10	20
2	6	20
1¼	4	20
⅝	2	20

Size of the Gross Sample. The size of the gross sample will vary according to the per cent of ash and size of coal. The size-weight table (Table 8-25) is suitable for bituminous coals having up to 10 per cent ash. If it is suspected that the ash percentage is above this, it is advisable to double the number of increments.

---

* For further development of this subject, see G. B. Gould.[7]

Reduction of the Gross Sample. Samples obtained by reduction of the gross sample should be crushed or ground by passing through a suitable mill. After grinding, the sample may be divided by a riffle sampler or equivalent to quantities shown in Table 8-26, depending on the size of the largest piece. If no means is available for mechanical crushing and division, the gross sample should be placed on a hard, clean surface and all lumps broken down to smaller than ⅛ in. by means of a tamper. It should be carefully mixed and shoveled into a conical pile, and the pile flattened out, and quartered by drawing lines at right angles through the center. Opposite quarters should be rejected and the remainder mixed. This crushing, mixing, and quartering should be continued in accordance with the above size-weight relationships. The operations involved in this procedure are illustrated in Fig. 8-13.

Table 8-26

Size of largest piece, in.	*Limit of sample reduction, lb*
⅜	30
¼	15
⅛	2

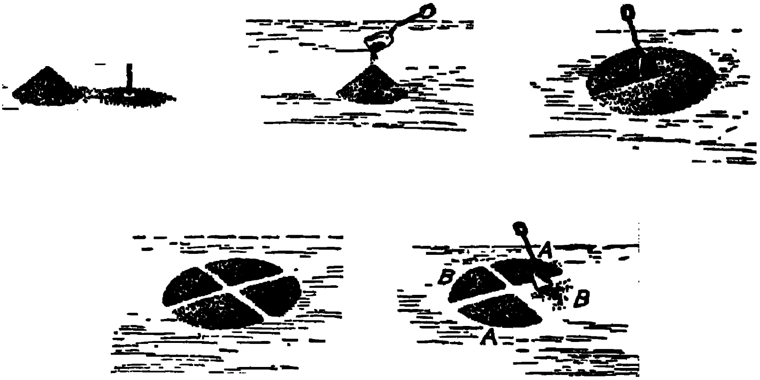

FIG. 8-13. Standard method of reducing gross coal sample by hand.

Sampling for Size Test of Anthracite. The gross sample should be systematically collected by suitable increments from various parts of the lot sampled. The increment weight for pea and No. 1 buck should be approximately 10 lb; for the smaller size, 5 lb. The gross sample weighing at least 100 lb should be mixed and reduced by quartering, without crushing, to the minimum amounts shown in Table 8-27.

Table 8-27

Size of coal	*Sample weight, lb*
Pea	50
No. 1 buckwheat	25
No. 2 buckwheat (rice)	10
No. 3 buckwheat (barley) . .	5

For ordinary operating requirements and when no dispute is involved, the foregoing simplified sampling procedure is sufficient. When greater accuracy is required reference should be made to the ASTM Standard D-492-46.

SAMPLING FUEL OIL

Methods for sampling fuel oil are given in detail by the ASTM in the Standard D-270-33. As conditions and facilities for taking samples are so variable, reference should be made to this whenever controversies are encountered or extreme accuracy is needed. The sampling of fuel oil in power plants is usually done by tapping the pipe line between pump and burner, although it is often necessary or required that samples be taken from cars, trucks, or tanks.

Sampling from a pipe line is accomplished by means of a fitting of three plug cocks constructed and placed to take a continuous sample from a cross section of the stream. The openings of these three cocks are set to obtain a steady stream at a rate to obtain 0.1 per cent of the lot as a sample but not to be less than 5 gal or more than 40 gal. The gross sample should be thoroughly mixed by a dasher stirrer or by rolling or shaking before the final 1-qt sample is withdrawn.

Cars, trucks, and tanks are sampled by means of a weighted beaker or bottle having an opening 1½ in. in diameter, the stopper of which can be withdrawn at the desired level. For full tanks of uniform cross section or diameter, one sample should be taken from the upper level at 10 per cent of the tank depth, three samples from the middle section, and one from the lower level 10 per cent of the tank diameter from the bottom. In horizontal cylindrical tanks, eight samples should be taken from the middle section. For partly filled tanks, reference should be made to the standard for the proper number of samples and levels. The composite sample should be at least 5 qt for vessels of uniform cross sections and 10 qt for horizontal cylindrical tanks.

For routine work, an all-levels sample from tanks is generally sufficient. This procedure consists in submerging a closed container to the draw-off level, then opening and raising it at such a rate that it will be nearly full when withdrawn. The gross sample of 5 to 10 qt should be mixed and 1 qt taken for the final portion.

FUEL PREPARATION AND BURNING EQUIPMENT*

BY OTTO DE LORENZI

Director of Education, Combustion Engineering—Superheater, Inc.

SOLID FUELS

The preparation of coal for steaming purposes consists in cleaning it by one of the several available dry or wet processes and sizing it so that it is suitable for the particular type of fuel-burning equipment on which it is to be used

Bituminous coal is usually sized at the tipple as it is loaded into cars for shipment. Sizing practice varies in the different coal fields Table 8-28 represents some of the commercially available sizes produced

Table 8-28. Sizes of Bituminous Coal

Name	Size characteristics	Use
Run of mine	Coal as it comes from the mine without screening	Steam raising purposes and locally for domestic heating
5 in lump	Will not pass through a 5 in round hole screen	Domestic heating and some industrial uses
5- × 2 in egg	Passes through a 5 in and retained on a 2-in round-hole screen	Domestic heating hand-firing, gas producers
2- × $1\frac{1}{4}$-in nut	Passes through a 2-in and retained on a $1\frac{1}{4}$ in round hole screen	Domestic heating hand firing, small industrial stokers gas producers
$1\frac{1}{4}$- × $\frac{3}{4}$ in stoker coal	Passes through a $1\frac{1}{4}$ in and retained on a $\frac{3}{4}$ in round hole screen	Domestic and small industrial stokers
$\frac{3}{4}$ × 0 in slack	Passes through a $\frac{3}{4}$ in round hole equivalent screen	Industrial stokers and pulverizers

The sizing of anthracite is well established, and all mines prepare sized coal Table 8-29 gives the trade names and standard sizing for anthracite

The characteristics of coal that govern the selection of fuel-burning equipment, more than any other, are the properties of *caking* and *free burning*

Table 8-29. Anthracite Sizing

Name	Size characteristic (round hole screen)	Use
Broken	Through $4\frac{3}{8}$ in screen and over $3\frac{1}{4}$ in screen	Domestic heating
Egg	Through $3\frac{1}{4}$ in screen and over $2\frac{7}{16}$-in screen	Domestic heating
Stove	Through $2\frac{7}{16}$ in screen and over $1\frac{5}{8}$-in screen	Domestic heating
Chestnut	Through $1\frac{5}{8}$ in screen and over $\frac{13}{16}$ in screen	Domestic heating
Pea	Through $\frac{13}{16}$ in screen and over $\frac{9}{16}$-in screen	Hand firing
No 1 buckwheat	Through $\frac{9}{16}$ in screen and over $\frac{5}{16}$-in screen	Domestic stokers
No 2 buckwheat (rice)	Through $\frac{5}{16}$ in screen and over $\frac{3}{16}$-in screen	Domestic stokers
No 3 buckwheat (barley)	Through $\frac{3}{16}$ in screen and over $\frac{3}{32}$-in screen	Traveling-grate stokers
No 4 buckwheat	Through $\frac{3}{32}$ in screen and over $\frac{3}{64}$-in screen	Traveling grate stokers and pulverizers

---

* Superior numbers refer to specific reference listed at the end of this subsection A portion of this material has been adapted by permission from *Combustion Engineering* published by Combustion Engineering-Superheater Inc

Caking coals, when heated in a furnace, pass through a plastic state during which the individual lumps fuse together into large masses of semicoke impervious to air flow. For this reason caking coals are burned in underfeed types of stokers as they have moving rams or other means for breaking up these masses of semicoke. Caking coals cannot be burned successfully on traveling- or chain-grate stokers because with these the fuel bed is undisturbed during its travel through the furnace. With spreader-stoker firing the caking is minimized owing to rapid oxidation during flight of the coal through the furnace atmosphere. This action results in a free-burning type of fuel bed.

In general, caking coals fall within the range of the high-volatile A, medium-volatile, and low-volatile bituminous coal groups (ASTM classification). Within these groups wide variation in behavior will be found.

Free-burning coals are ones in which the individual lumps do not fuse together but burn separately, or after fusion the masses break up quickly into fragments. Fuel beds of these coals need no agitation so that traveling- and chain-grate as well as spreader stokers are well adapted to them.

Anthracite, semianthracite, high-volatile bituminous C, subbituminous coal, and lignite fall into the free-burning ASTM classification.

The use of pulverized-fuel firing with any of the foregoing coals is governed by suitability for pulverizing and size of steam-generating unit with which it is to be used. Generally, anthracite and semianthracite are relatively difficult to pulverize and almost invariably call for stoker firing.

Coke breeze is another frequently available fuel for industrial steam making. It is a by-product in the manufacture of domestic and metallurgical coke. Usually all coke passing through a 3/4-in. round-hole screen is called "breeze." It is a low-volatile, free-burning, and extremely abrasive fuel which is burned almost exclusively on traveling-grate stokers.

There are many other solid fuels available for steam-making purposes, but most of them are limited in supply as they are by-products of some manufacturing process. Wet and dry wood, bark, spent-wood chips of various sorts, and bagasse all fall into this classification and are outside the scope of this section.

Equipment for Burning Solid Fuels

Stokers. Stokers available for feeding and burning various coals may be divided into four types:

1. Single-retort underfeed stokers
2. Multiple-retort underfeed stokers
3. Traveling- and chain-grate stokers
4. Spreader stokers

Single-retort Underfeed Stokers. The single-retort stoker, as illustrated in Fig. 8-14, is one that employs a stationary trough, or retort, open at the top and closed at the sides and at one end. The coal is fed into the trough through the open end by means of a reciprocating sliding bottom on which are mounted a feeder block at the hopper end and auxiliary pushers at intervals throughout its length. With each inward stroke the feeder block forces a quantity of coal into the retort.

Alternately moving and stationary grate bars extend laterally from each side of the retort to the dump grates located at the furnace side walls. The short lateral motion of the moving bars causes the coal to travel gradually toward the dump grates. The combined action of the feeder block, the auxiliary pushers, the sliding bottom, and the moving grate bars results in correct agitation, even distribution from front to rear, and a gradual feeding of the fuel toward the dump grates.

Air under pressure is supplied to the main wind box of the stoker directly below the retort. From here it enters the grate bars through openings in their underside at the retort ends. Some of the air flows through tuyère openings into the upper zone of the retort. The remainder is discharged from opening in the lower ends of the bars into the auxiliary wind box. It then passes up between the bars into the fuel bed. This design of air-distribution system provides a gradation in pressure so that, with decreasing fuel-bed thickness, there is a corresponding reduction in pressure.

The accumulated refuse on the dump grates is discharged periodically to the ash-pit as required.

Over-fire air ports are located in both the front and rear walls immediately above the retort. The over-fire air is used to complete the combustion of volatile matter rising from the distillation zone of the fuel bed.

Single-retort stokers for industrial application vary in size from approximately 3 ft 6 in. wide by 4 ft 0 in. long to a maximum of 12 ft 6 in. wide by 10 ft 0 in. long. Continuous coal-burning rates range from 250 to 5,400 lb per hr depending on the size and quality of the coal. Furnace heat-liberation rates for continuous operation should preferably be held to less than 40,000 Btu per cu ft per hr.

Multiple-retort Stokers. The multiple-retort stoker shown in Fig. 8-15 is one in which the underfeed section consists of a number of alternate, parallel, longitudinal strips comprising the retort and the tuyères. The retorts are open at both ends and the top but are closed on the sides. Tuyères form lateral extensions between adjacent retort sides. It is through these that air is supplied to this section of the stoker. No provision is made for air admission through the retorts. Thus, with this arrangement, approximately fifty per cent of the underfeed section is active grate area.

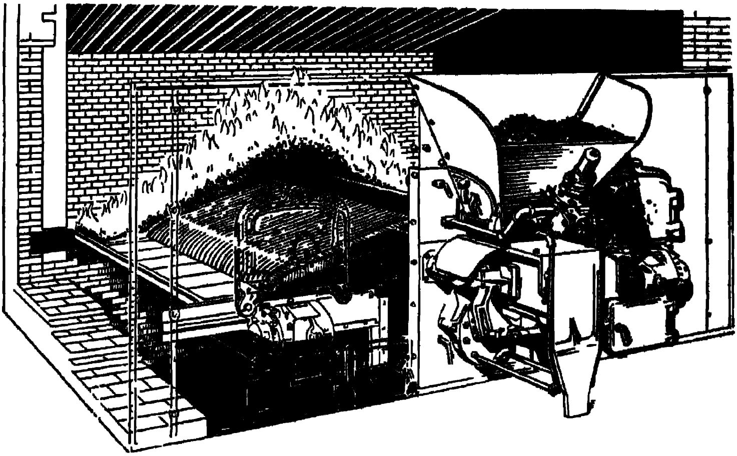

Fig. 8-14. View of a steam-driven Type E single-retort stoker with part of the front in phantom to show interior and fire on rear part of grate. (*Combustion Engineering—Superheater, Inc*)

At the lower end of the retort is an overfeed section comprising from 20 to 30 per cent of the total stoker area. It consists of deep, narrow bars with overlapping ribs grouped in movable carriers. A reciprocating motion is provided and arranged so that adjacent carriers have a slicing action for maximum agitation. The length of the stroke for alternate groups is adjustable from the stoker front. The entire overfeed zone is air-admitting and under damper control.

The ash-discharge section may be any one of three available types: dump grate, continuous ash discharge, and clinker grinder. When dump grates are used, the accumulated refuse is periodically discharged by lowering the dumps. With the continuous-discharge type the accumulated refuse is continuously moved through a gap between the bridge-wall overhang and the ash-discharge trays. This design is shown in Fig. 8-15. With the clinker grinder, a deep pit in which the grinder rolls are located is provided for ash accumulation. This refuse is then periodically discharged by operating the rolls.

In the operation of these stokers, coal is supplied to the retort by a reciprocating main ram. Secondary rams in the retort bottom and also the downward slope of the stoker cause the coal to travel progressively to the overfeed section. No lateral motion is provided to feed the fuel directly onto the tuyères. The shape of the throat through the front wall into the furnace for each retort allows the incoming coal to rise and form a relatively level bed. Ignition takes place at this point. The air supplied through the tuyères causes the coal resting on them to be consumed quickly. As a result a high ridge of smoldering caked coal remains over each retort. The feeding action of the rams advances the fuel, and some rolls on to the tuyères where it is burned at a high rate. Ignition penetration throughout the retort zone is relatively slow. To overcome this, the fuel-bed thickness is gradually decreased until the overfeed section is reached. In effect, the coal is lifted out of the retort because of its decreasing depth. This lifting action, aided by the shape of the auxiliary rams, maintains the supply of fuel to the tuyères. This side-feeding action is in step with the progressive lifting so that the fuel bed has a uniform height above and its top is parallel with the tuyère slope. A cross section of the fuel bed at the underfeed section will show a series of ridges over the retort and valleys over the tuyère.

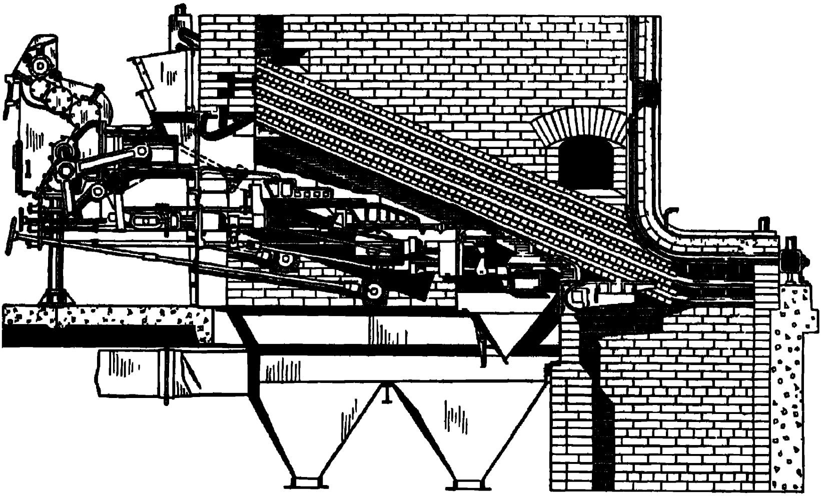

FIG. 8-15. Sectional side elevation showing details of the continuous-discharge type of multiple-retort stoker (*Combustion Engineering Superheater, Inc.*)

The height of the ridges and the depth of the valleys are governed by the caking characteristics of the coal.

Obviously it would be impossible to burn out uniformly a fuel bed that consists of alternately thick and thin ribbons of caked coal. Therefore, some means for leveling and compacting must be provided. It is for this purpose that a reciprocating overfeed section is used so as to shake down and level the fuel as it is discharged from the retorts. The slicing action between adjacent carriers serves effectively to break up large caked masses of coal and also minimize clinker formation. As a result the fuel bed in the overfeed zone is a level, intense coke fire requiring very little excess air to maintain low carbon loss in ashpit refuse.

Over-fire air ports are provided in the front wall above each retort to supply needed air for any unburned gas from the distillation zone.

The number of retorts for a satisfactory installation should never be less than four. The maximum number will depend on the furnace width available for installation. Stoker areas may vary from 70 to more than 500 sq ft. Continuous coal-burning rates will extend from 1,750 to 30,000 lb per hr depending on stoker size and coal quality. Furnace heat-liberation rates for continuous operation should preferably be held to less than 35,000 Btu per cu ft per hr.

Traveling- or Chain-grate Stokers. The traveling- or chain-grate stoker, shown in Fig. 8-16, provides a continuously moving, nonagitating type of grate surface. Coal is progressively supplied to the furnace in a level, uniformly thin bed, and the refuse is continually and automatically discharged to the ashpit. Prompt and rapid penetration of ignition is necessary for efficient operation. This is obtained by the use of suitably disposed arches which reflect heat onto the incoming green coal. The intensity of reflected heat will govern the speed with which it is possible to operate the stoker. It will also determine the rate at which ignition penetrates the fuel bed. The faster it is possible fully to ignite the coal, the higher the rate at which it can be burned.

The fuels customarily used on traveling- and chain-grate stokers are anthracite, coke breeze, lignite, and free-burning bituminous coal.

Anthracite and coke breeze have a low volatile-matter content and are relatively small in size with a very large percentage of "fines" or undersize. Unless provision is made to retain a maximum quantity of these "fines" in the furnace, excessive fly ash and high ashpit losses will result even though combustion rates are low. Arch design is an important factor. Furnaces in which the arch extends forward from the bridge wall to cover about 75 per cent of the stoker area make it possible to operate at relatively high combustion rates and excellent efficiencies. They ensure prompt and rapid penetration of ignition and minimize stratification by providing maximum turbulence in the furnace gas. Fly-ash carry-over is also reduced because much of it is redeposited on the fuel bed at the front of the furnace.

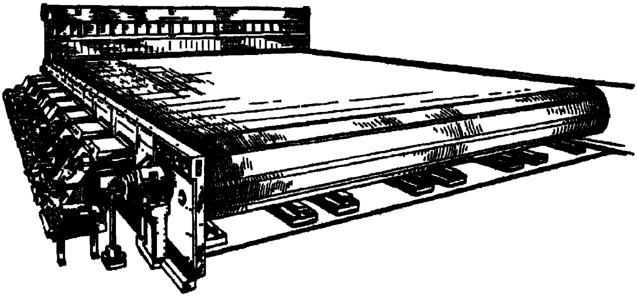

FIG. 8-16. View of a large traveling-grate stoker showing some details of construction. (*Combustion Engineering—Superheater, Inc.*)

Lignite, with its extremely high moisture content and tendency to "weather" when exposed to heat, is an ideal fuel for these stokers. Here again the use of rear-arch furnaces makes possible high combustion rates and excellent efficiency.

Free-burning bituminous coal is also suitable for chain-grate stokers. Because of the high volatile-matter content and more rapid penetration of ignition, somewhat shorter arches can be used.

The thin fuel beds on stokers of this type move relatively fast and are sensitive to air supply. Positive regulation is provided by a series of transverse zones, each under separate damper control.

Traveling- and chain-grate stokers for industrial purposes are built in sizes that range from 3 ft 0 in. wide by 9 ft 0 in. long to 24 ft 0 in. wide by 28 ft 0 in. long with corresponding areas of 27 to 672 sq ft. The allowable continuous-combustion rate for stokers of this type may range from 30 lb dry coal per square foot of grate per hour for anthracite to 50 lb dry coal per square foot per hour for lignite. Furnace heat-liberation rate should preferably be held below 55,000 Btu per cu ft per hr.

Spreader Stokers. The modern spreader stoker consists essentially of one or more units mounted on a cast-iron front, each comprising a coal hopper, a feeder which regulates the flow of coal in proportion to the load, and a distributor rotor which throws the coal into the furnace and distributes it to the grate. These stokers are available in two principal types: one for intermittent manual discharge of ash and the other for automatic continuous discharge of ash. The difference between these two designs lies in the grate construction. With the intermittent-ash-discharge type, either stationary or dumping grates are used. The plenum chamber below the grate for air distribution is sectionalized longitudinally into a number of compartments, one for each feeder unit. Dampers provide the regulation of air supply. The continuous-discharge design is provided with a traveling or chain grate. This grate is slowly and continuously moved forward to discharge the accumulated ash automatically. Transverse air compartments provide control of air distribution. In Fig. 8-17 some of the constructional details of a continuous-discharge spreader stoker are shown.

The spreader stoker uses the combined principles of suspension burning and the nonagitated type of fuel bed. Fresh coal is continually projected into the furnace above an already burning fuel bed. As a result the "fines" are quickly ignited and burned in suspension in the upper front furnace zone. The larger particles are exposed to the full effect of furnace temperature as they fall onto the fuel bed. The volatile matter is quickly driven off, and the tendency to coalesce is almost entirely destroyed. Thus the caking qualities have little or no effect. The active portion of the fuel bed is a thin layer of burning fuel on a thicker layer of accumulated ash Even distribution is required to maintain porosity for uniform air flow. Any localized thickening of the bed will set up high-resistance areas, and because of decrease of air flow through them, they are favorable to clinker formation. Ignition penetration is rapid and upward because fresh fuel is fed on top of an already burning bed.

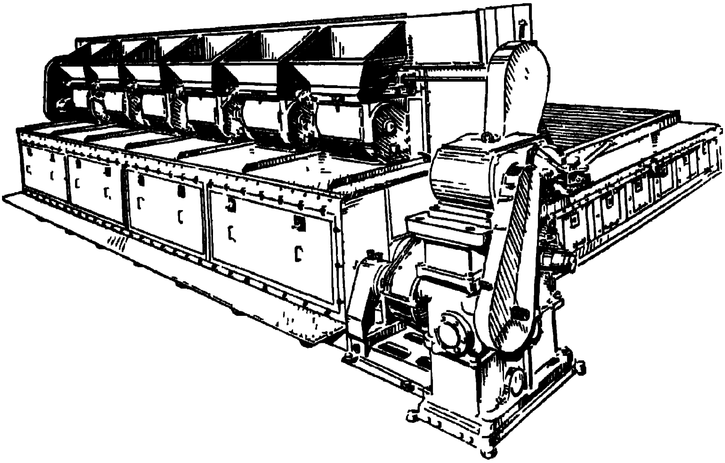

FIG. 8-17. A continuous-discharge-type spreader stoker. This stoker is 22 ft wide and 20 ft long. (*Combustion Engineering–Superheater, Inc*)

An outstanding characteristic of the spreader stoker is its ability to burn satisfactorily a wider range of fuels than stokers of any other type. Performance is best when fuel quality and sizing are good. This method of firing, however, was developed primarily to burn the lower grades of coal with high ash content and low ash-fusion temperature. Its operation with these fuels has been notably successful. It can handle with facility everything from semianthracite to lignite.

Since distribution to the grate is a most important factor, a satisfactory size consist of coal is necessary. A preferred specification is $\frac{3}{4}$ by 0 in. Under no condition should the top screen size exceed $1\frac{1}{4}$ in. "Bug dust" and similar size are also handled in a satisfactory manner.

Over-fire air or steam jets should always be provided to supply furnace turbulence which will break up any tendency toward gas stratification. Furnaces are of the "open type," devoid of any arches, with sufficient volume to keep the heat-liberation rate below 35,000 Btu per cu ft per hr at maximum continuous-operating rates where all refractory construction is used. For a suitably water-cooled furnace, this rate should not exceed 45,000 Btu per cu ft per hr.

Stoker areas may vary from 36 to 225 sq ft for the intermittent-ash-discharge type. For the continuous-discharge design these areas will range between 100 and 520 sq ft. Continuous-combustion rates should preferably be limited to less than 600,000 Btu per sq ft of grate per hour.

Pulverized Coal

Solid fuels, when burned in suspension, should contain an appreciable quantity of extremely fine dust so as to ensure prompt ignition. The amount of coarser material must be minimized if best combustion results are to be obtained.

The fineness to which coals should be pulverized will depend on many factors.

Caking coals, when exposed to furnace temperature, will swell and form lightweight, porous coke particles They may float out of the furnace before they are completely burned. As a result, carbon loss will be high unless pulverization is very fine. Free-burning coals, on the other hand, do not require the same degree of fineness because the swelling characteristic is absent.

High-volatile coals ignite more readily than those with a low volatile content. Therefore, they do not require the same degree of fine pulverization. With the exception of anthracite, however, the low-volatile coals are softer and may be said to have a higher grindability.

Some large furnaces may operate satisfactorily on high-volatile coal as coarse as 65 per cent minus 200 mesh. Small water-cooled furnaces, using low-volatile coal, may require a fineness of 85 per cent minimum through 200 mesh. Other influencing factors are burner and furnace design, disposition of furnace volume, length of flame travel, furnace temperature, and load characteristics. In general, however, small furnaces require finer pulverization than large ones.

The fineness of the product is usually expressed by the percentage of dust that will pass a sieve with specific size openings. For testing pulverized coal the most commonly used sieves are the 50-mesh sieve for determining the oversize and the 200-mesh sieve for determining the fine dust.

The mesh of a screen is designated by the number of openings per linear inch. Thus a 200-mesh screen has 200 openings to the inch, or 40,000 per sq in. The size of opening is governed by the diameter of wire used in making the screen. The U.S. Standard and W. S. Tyler are two commonly used screen sieves. The mesh and opening of these are shown in Table 8-30.

Table 8-30. Standard Screen Sizes

U. S. Standard			W. S. Tyler		
Mesh	In	Mm	Mesh	In.	Mm
20	0.033	0.84	20	0.033	0.83

Pulverizers. The three basic principles for grinding coal are impact, attrition, and crushing. The four commonly used pulverizer types are ball, impact, ring-roll, and ball-race. Some of these mills employ one grinding principle, while others may use a combination of two or even all three principles in their operation.

Ball Mill. A ball mill is essentially a horizontal rotating cylinder whose length is somewhat greater than its diameter. The interior is fitted with heavy cast liners and filled to slightly less than half with balls that vary from 1 to 2 in. in diameter. Pulverization is accomplished through continued cascading of the ball and coal mixture as the mill is rotated. It is due in part to impact of the falling balls, to attrition through their slipping over each other as well as over the liners, and to crushing as they roll over the liners and also over each other. The larger pieces of coal are broken principally by impact, and the fine grinding is done by the rolling and sliding action of the balls.

Impact Mills. Impact mills consist primarily of a series of swing hammers or lugs revolving in a closed chamber. Grinding is accomplished by a combination of impact on the larger particles and attrition on the smaller ones.

Ring-roll and Ball-race Mills. Ring-roll and ball-race mills include a large class in which the coal is pulverized between two surfaces, one rolling over the other. The rolling member may be either a roll or a ball. If balls are used as the grinding element, they are confined between two races, and pressure to crush the coal is obtained by forcing the races together with heavy springs. The balls may be driven by rotating either the upper or lower race. Some additional grinding pressure is obtained from the centrifugal force of the rotating balls. In ring-roll mills, either the rolls or the grinding ring is rotated. In the first case, pressure to crush is obtained from centrifugal force as the roll assembly swings pendulumlike against the grinding ring. In the second case, the roll assembly is stationary, and springs are used to provide crushing pressure on the coal layer between roll and rotating grinding ring.

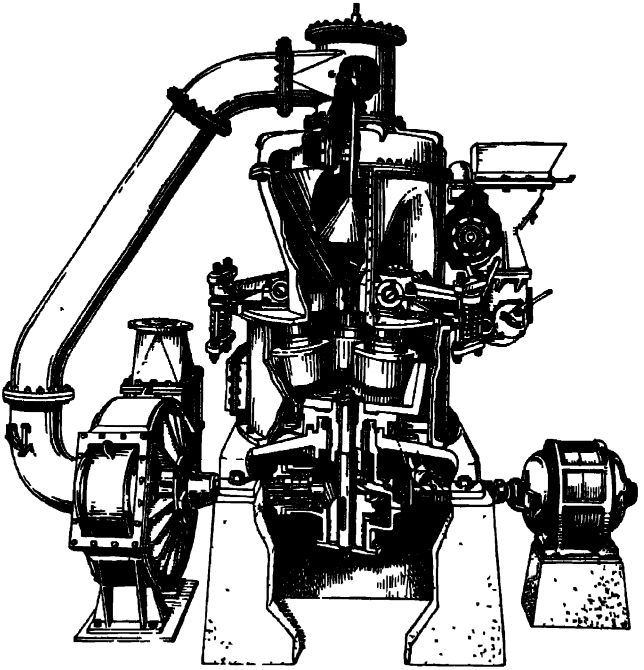

FIG. 8-18. A cut-away view showing interior details of the C-E Raymond bowl mill. (*Combustion Engineering—Superheater, Inc.*)

In all the mills just described an air system is provided to induce airflow for the purpose of removing the ground coal from them. In addition, some means of classification is used to maintain suitable size consist in the pulverized coal.

The C-E Raymond bowl mill, shown in Fig. 8-18, is of the ring-roll type. It consists essentially of a grinding ring carried by a revolving bowl. Stationary rolls, preloaded by adjustable spring pressure, are set so that they do not come in contact with the ring. A classifier, whose outlet is connected to the mill exhaust, is located above the grinding chamber. Fineness of coal at the classifier outlet is regulated to a large extent by position of adjustable vanes. A number of other influencing factors, however, will also have a bearing on vane setting.

Pulverizers will range in capacities from approximately 1,000 to 50,000 lb of coal per hour.

Some of the factors affecting mill capacity are grindability of coal, fineness required, moisture in coal, and air temperature available at pulverizer. Suitable correction for these must, therefore, be applied to obtain the true capacity of a given pulverizer.

Burners. The development of pulverized-coal firing for purposes of steam generation has been due, in large measure, to a better understanding of furnace design requirements. Uniform distribution of fuel and air to the furnace is also of prime importance. Turbulence provides the means for effective distribution and speed ignition of the incoming fuel and promotes rapid combustion by continually making available the free oxygen needed by the ignited combustible matter. These requirements are the governing factors in burner selection and application.

Methods used to fire pulverized coal are indicated by the manner in which fuel is injected into the furnace. These methods fall into three broad classifications, *viz.*, vertical firing, horizontal turbulent firing, and tangential firing. There are modifications, adaptations, and partial combinations of these three basic methods to make them suitable for variations in furnaces as well as in steam-generating-unit design.

Characteristics of the three basic firing methods differ widely, and each has its field of application. Thus the selection for any given installation is governed by a number of variables, of which the principal ones are size, shape, and volume of furnace available to develop the desired capacity. Furnace dimensions establish the maximum length of flame travel available The type of furnace-wall construction also influences selection, but rate of heat liberation may indicate a change in wall design. Quantity of coal to be burned, as well as its volatile matter and sulfur content, fusion temperature of ash, and fineness of pulverization will influence not only method of firing and type of wall construction to be used but also the method of ash disposal. Character of the load together with extent and duration of peaks and extremely low-load periods are also of great importance. In fact there are so many influencing variables that no hard and fast rules can be established. Much reliance must be placed on actual knowledge, supplemented by operating experience, which parallels the conditions surrounding the particular installation under consideration.

Each of the foregoing firing methods requires a different burner design because of variations in the manner in which air and coal are mixed to produce efficient and complete combustion. Fundamentally, however, all burner designs must be such that the air and coal are supplied to the furnace so as to provide stable and prompt ignition; positive adjustment and control of ignition point and flame shape, completeness of combustion; uniform distribution of excess air, temperature, and gas flow at furnace outlet; freedom from localized slag deposits; protection against overheating, internal fires, and excessive wear in the burner; and accessibility for adjustment and replacement of parts.

Vertical Firing. Details of a burner assembly for vertical firing are shown in Fig. 8-19. In this design the lower edge of the fuel nozzle is serrated to increase surface exposure of the issuing fuel stream to furnace radiation and thereby aid in speeding ignition. In addition, deflector plates, not shown in the illustration, are installed in the lower part of the burner housing. These deflectors cause the tertiary air to cut across individual fuel streams and thereby set up considerable turbulence which, in turn, promotes rapid penetration of ignition.

The air required for combustion is divided into three parts: primary air, secondary air, and tertiary air. The primary air, a relatively small percentage of the total supply, is used to transport the pulverized coal from the storage bin, or mill outlet, to the burner nozzle and then blow it into the furnace. The tertiary air, in approximately the same percentage as the primary air, is admitted under damper control through the burner housing around the fuel nozzles to the furnace. Secondary air, the major portion of total requirements, is admitted in a horizontal direction through a large number of small air ports which checkerboard the front wall of the furnace, and dampers are used to regulate quantity and distribution. This arrangement makes it possible to secure horizontal penetration between adjacent vertical fuel streams and thereby progressively supply the secondary air in a manner to ensure complete and uniform combustion.

Individual burners have capacities up to approximately 2,000 lb coal per hr. They are installed side by side on relatively close centers in an arch near the top of the furnace and project the coal vertically downward in a relatively thin flat stream. In this manner uniform distribution of fuel across the entire furnace width is obtained.

Horizontal Turbulent Firing. The development of direct-fired systems in which pulverized coal is transported directly from mill to burner, however, resulted in a demand for larger burners where individual capacity, in many cases, would be equal to that of the pulverizer. To meet these requirements it was necessary to provide a design in which the large concentrated fuel streams were quickly and uniformly spread out over a relatively wide area. In this manner high intensity of heat liberation in small sections of the furnace cavity is avoided, and there is instead an evenly distributed flow of heat through the furnace, although individual burner capacity may be as high as 150 million Btu per hr. These results are obtained through the use of designs similar to the one illustrated in Fig 8-20 in which a large central fuel nozzle is surrounded by a housing provided with adjustable vanes.

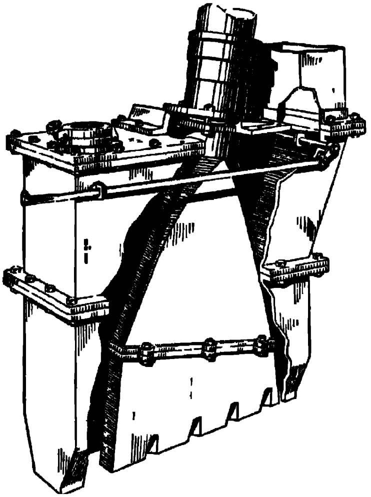

Fig 8-19 Details of a burner for vertical firing. (*Combustion Engineering—Superheater, Inc*)

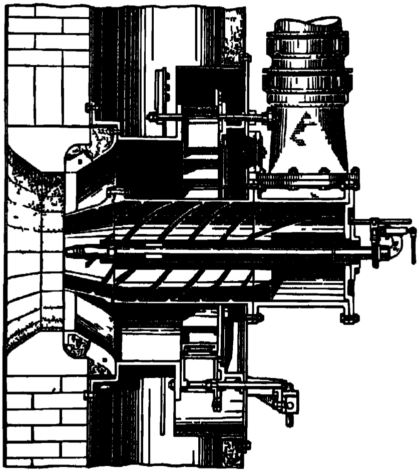

Fig. 8-20 A horizontal turbulent burner arranged for pulverized-coal and oil firing. (*Combustion Engineering—Superheater, Inc.*)

The central nozzle has a volute type of inlet so that rotation is imparted to the entering mixture of fuel and primary air. Vanes in the housing are used to control the degree of rotation imparted to the secondary air stream. As the streams from these two sections of the burner come together in the burner throat, their rotational motion establishes a high degree of turbulence and causes the mixture to spread quickly as it emerges into the furnace cavity. When looking directly at one of these burners in operation, the burning fuel and air mixture has the appearance of a large sunflower in which the flames seem to radiate, petallike, from the relatively dark center at the nozzle.

Tangential Firing. With tangential firing the burners are located in each of the four furnace corners close to the water screen, floor, or hopper bottom. Individual burner assemblies consist of two, three, or four fuel nozzles surrounded by secondary air-inlet boxes equipped with guide vanes and dampers. Many details of these burners are shown in Fig. 8-21.

In this method of firing, the fuel and air streams issuing from the four corners are directed along tangents to a small imaginary circle in the center of the furnace. No attempt is made to mix the secondary air and fuel at the burner, but sufficient primary air is used to ensure prompt ignition. Where these four streams meet, intense turbulence is set up, and a rotative motion is imparted to the burning mixture which spreads out and is uniformly distributed over the furnace cross section. The characteristic feature of uniformity of mixture in the furnace overcomes any effect such as results from unequal division of fuel or air with other methods of firing.

Furnace outlet temperature is a function of heat absorption by the waterwalls, as well as rate of heat liberation in the furnace cavity. Heat absorption by the walls varies with their cleanliness, as well as with the area subjected to direct radiation and convection transfer. Thus, to secure the required temperature of gas at the furnace outlet over a range in capacity, it is necessary to make a relative change in both furnace volume and area of heat-absorbing surface.

The foregoing requirements have led to the development of an adjustable tangential burner in which the fuel nozzles and air-directing vanes may be selectively tilted upward or downward by the operator through a range of 25 deg above or below horizontal. Thus, by directing the flames toward the upper zone of the furnace, the gas outlet temperature will be kept higher during the light load, or when walls are clean, than when the entire furnace is used. For heavy loads, or when walls are coated with dust, the entire furnace volume can be used by tilting the burners downward to maintain the outlet gas temperature below the point of slagging. At practically any given load point a change of approximately 200°F at furnace outlet or approximately 75°F in steam temperature, is available by operating the burner nozzles over the entire range of adjustment.

Ability to use the available furnace volume selectively, through positioning the zone of turbulent combustion and thereby varying effectiveness of furnace waterwall area, makes it possible to control furnace outlet temperature and thus regulate steam temperature over a wide range in capacity. A supplementary gas by-pass damper provides the means for final incremental steam-temperature adjustments.

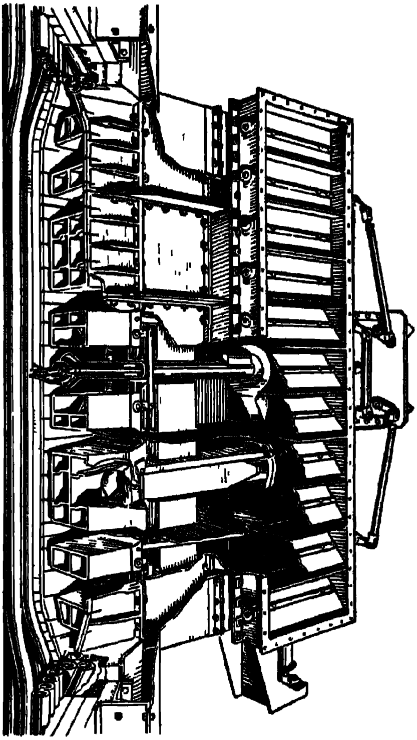

FIG. 8-21. Cut-away view showing details of tangential burner with adjustable coal nozzles. (*Combustion Engineering—Superheater, Inc.*)

LIQUID FUELS

Fuel oil may be defined as petroleum or any of its liquefiable residues remaining after the more volatile constituents have been removed.

Crude petroleum is sometimes burned in the state in which it is taken from the ground. In this condition, most of it will contain sufficient lighter gasoline fractions to lower the flash point and present a fire hazard. Through limited fractional distillation, or topping, the lighter gasoline can be removed, and a safe fuel oil can be produced. If the refining process is carried through extended fractional distillation

Table 8-31. National Bureau of Standards Detailed Requirements for Fuel Oils[a],*

* "Fuel Oil, Commercial Standards," National Bureau of Standards publication CS12-40.

[a] Recognizing the necessity for low-sulfur fuel oils used in connection with heat-treatment, nonferrous metal, glass and ceramic furnaces, and other special uses, a sulfur requirement may be specified in accordance with the following table:

Grade of fuel oil	*Sulfur (maximum) per cent*
1	0.5
2	0.5
3	0.75
5	No limit
6	No limit

Other sulfur limits may be specified only by mutual agreement between the buyer and seller.

[b] It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade.

[c] Lower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0°F under any conditions.

[d] For use in other than sleeve-type blue-flame burners, carbon residue on 10-per cent residuum may be increased to a maximum of 0.12 per cent. This limit may be specified by mutual agreement between the buyer and seller.

[e] The maximum end point may be increased to 590°F when used in burners other than sleeve-type blue-flame burners.

[f] To meet certain burner requirements, the carbon-residue limit may be reduced to 0.15 per cent on 10-per cent residuum.

[g] The minimum distillation temperature of 600°F for 90 per cent may be waived if API gravity is 26 or lower.

[h] Water by distillation, plus sediment by extraction. Sum, maximum 2.0 per cent. The maximum sediment by extraction shall not exceed 0.50 per cent. A deduction in quantity shall be made for all water and sediment in excess of 1.0 per cent.

and cracking, such fuels as gasoline, kerosene, gas oil, light fuel oil, lubricating oil, heavy fuel oil, residual tar, pitch, and petroleum coke are produced.

For industrial purposes heavy fuel oil, or bunker C oil, is the one used for steam making.

Properties of Fuel Oil

The important properties of fuel oil are specific gravity, heating value, viscosity, flash and fire point, sulfur content, ash content, and congealing point.

Density is one of the most important properties, since fuel oil is sold on a volumetric basis. Standard density is taken at 60°F and referred to water at 60°F. It is usually designated in degrees API, for which the American Petroleum Institute's standard formula is

$$\text{Degrees API} = \frac{141.5}{\text{specific gravity at } 60°\text{F}/60°\text{F}} - 131.5$$

Between specific gravity of all petroleum products and their higher heating value there is a relationship which has been expressed in a formula by the U.S. Bureau of Standards[1] as

$$\text{Heat of combustion at constant volume (Btu per lb)} = 22{,}320 - 3{,}780 \times \text{sp gr (at } 60°\text{F}/60°\text{F)}$$

To provide standardization for fuel oil the National Bureau of Standards has established specifications for five different grades. The details of these specifications are given in Table 8-31.

Oil Analysis

It will be noted that grade 6, which is sometimes designated as heavy industrial fuel oil or bunker C oil, is specified mainly by viscosity. An average analysis of grade 6 oil may be taken as carbon, 87.3 per cent; hydrogen, 10.8 per cent, sulfur, 1.2 per cent; nitrogen, 0.2 per cent; oxygen and indeterminates, 0.5 per cent; and higher heating value, 18,500 Btu per lb

For handling fuel oil from storage tanks to burner nozzles, there is usually installed a compact duplex interconnected assembly of strainers, oil heaters, pumps, and automatic regulators, together will all other auxiliary equipment and instruments that may be required.

Oil Temperature

When pumping oil to storage tanks, or from them to oil heaters, heating to a temperature of approximately 100°F is ordinarily required. For use with steam-atomizing burners, heating to approximately 185°F is desirable. For mechanical atomization, the oil requires still greater fluidity and must therefore be heated to approximately 220°F.

Oil Pressure

For steam-atomizing burners the oil pumping pressure may vary from about 2 psi at minimum capacity to 125 psi at maximum. This pressure range is based on a fuel piping system of adequate size for the capacity required because burner capacities are obtained through the use of steam for atomization.

With mechanical atomization, oil pressure is used to produce atomization. The pressure required, therefore, depends on the load, as well as the sprayer plate used, and will ordinarily vary from 50 to 250 psi.

Oil Burners

Oil burners are classified according to the method used for securing atomization as follows:

1. Air-atomizing burners
2. Steam-atomizing burners
3. Mechanical-atomizing burners

Air-atomizing Burners. Only a relatively few industrial installations have burners of the air-atomizing type, and, therefore, our discussion will be confined to steam- and mechanical-atomizing types.

Steam-atomizing Burners. Steam-atomizing burners may be subdivided into two general groups: the *outside mix* and the *inside mix* according as the oil and steam mix outside or inside the burner nozzle.

Outside-mix nozzles usually produce a flat flame and are used generally with the natural-draft types of burners. In these the air supply is controlled by varying furnace draft with intermediate regulation provided by front-wall dampers. Burners of this type are used for relatively small installations where only moderate capacities are required and relatively wide furnaces are available.

Inside-mix types of nozzles will give a flat or hollow conical flame, depending on the design of tip used.

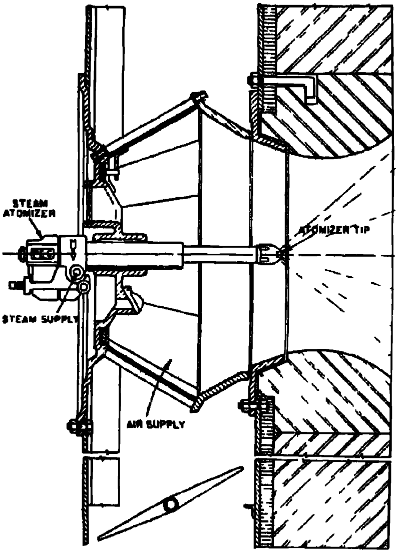

FIG. 8-22. Typical conical-flame, forced-draft, steam-atomizing burner. (*Peabody Engineering Corp.*)

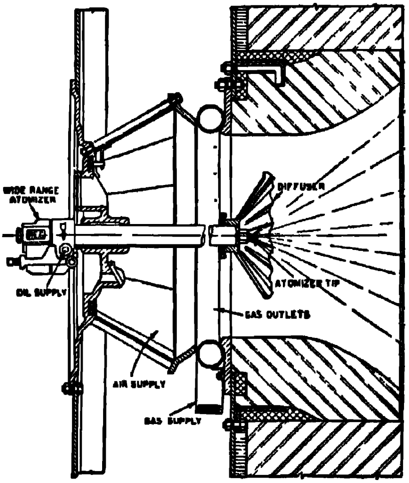

FIG. 8-23. Combination mechanical-atomizing and gas ring type of burner. (*Peabody Engineering Corp.*)

Nozzles that produce a conical flame are the ones which find greater acceptance for industrial steam making. With these is used a circular housing having some form of controllable register. For natural-draft installations, the air supply is provided by furnace suction, as well as by the aspirating effect of the steam as it issues from the burner nozzles. When large-capacity burners are required, the air is supplied to the burner register by a forced-draft fan. The pressure and volume of the air supply are governed by the fuel-injection capacity of the nozzles.

A forced-draft burner of the steam-atomizing type is shown in Fig 8-22. In the design illustrated a multiblade register is used to vary air flow and regulate its spin. An inside-mix steam atomizer provides a strong conical-shaped spray, and interchangeable tips are used to modify flame spread and oil capacity. Individual burners of this type may have capacities up to 120 million Btu per hr, and furnace liberation rates should preferably be held below 30,000 Btu per cu ft per hr at maximum continuous capacity.

Mechanical-atomizing Burners. Mechanical-atomizing burners consist of four principal elements: the atomizer, the diffuser, the air register, and the refractory burner-throat opening.

The *atomizer* is designed to break up the oil mechanically into a fine, mistlike, uniform spray which will burn with a minimum of excess air when projected into the furnace.

The *diffuser* is a shield, in the form of a perforated hollow metal cone, mounted near the furnace end of the mechanical-atomizer gun assembly. It protects the base of the spray from the high-velocity air and stabilizes the flame to prevent it from being blown away from the atomizer tip.

The *air register* is an integral part of the oil-burner assembly and usually consists of a series of overlapping vanes which deliver the air for combustion to the furnace throat with the correct degree of spin.

The *refractory burner-throat opening* has a carefully shaped contour designed to hold the air around the flame and simultaneously assist combustion by radiating heat to the burning fuel. A typical mechanical-atomizing-burner assembly is shown in Fig 8-23.

The capacity range for a given atomizer-tip orifice is limited to approximately 1½ or 2 to 1, with an oil-pressure change of as much as 200 psi. Thus, for satisfactory operation over reasonably wide load ranges, it is necessary to have a multiplicity of burners, as well as several sizes of atomizer assemblies for each burner.

Recently several systems have been developed for widening the operating range of mechanical atomizers to as much as 10 to 1 without the necessity of constantly changing sprayer plates and tip orifices Thus, with properly applied control it is possible to have satisfactory and close automatic regulation for fluctuating load conditions.

Individual burners of the mechanical-atomizing type may have capacities up to 100 million Btu per hr, and maximum continuous furnace-liberation rates should preferably not exceed 30,000 Btu per cu ft per hr.

GASEOUS FUELS

The principal gaseous fuels used for steam-generating purposes are, in the order of their importance, natural gas, blast-furnace gas, blended refinery gas, and coke-oven gas Performance characteristics of these gaseous fuels are governed by the characteristics and proportions of the various simple gases they contain Of greatest importance are ignition temperature, the speed at which various proportions of the gas and air will burn, flame temperature, and amount of heat radiated from the burning gas.

For industrial purposes, natural gas is the one that has widest application. Blast-furnace gas, blended refinery gas, and coke-oven gas are by-products of a manufacturing process and are usually not available except in the plant where produced. Consequently, our discussion will be confined to the use of natural gas.

Natural Gas

Natural gas is probably the closest approach to an ideal fuel because it can be burned with very low excess air and contains little or no solid residue. It consists

mainly of methane (CH_4) with smaller quantities of other hydrocarbons, principally ethane (C_2H_6), although carbon dioxide (CO_2) and nitrogen (N_2) are usually present in small amounts. Sometimes there are also appreciable amounts of hydrogen sulfide (H_2S). Oxygen (O_2) is present only when there has been an infiltration of atmospheric air. Helium, a rare inert gas, is contained in natural gas from some Texas fields. In Table 8-32 are shown typical analyses of natural gas.

Natural gas when found in areas containing oil deposits may be impregnated with heavy saturated hydrocarbons, which are liquid at ordinary pressure and temperature. This *wet* gas is then dried by stripping from it those liquids which constitute the so-called "casing-head gasoline." In view of the foregoing, it is well to remember that the terms "wet" and "dry," when associated with natural gas, refer to its gasoline content, not to its moisture content. For pipe-line transmission the gas is usually saturated with water vapor, by means of steam jets, to reduce gasket maintenance.

Natural-gas Burners. Burners for natural-gas firing are generally divided into l-p and h-p designs. This classification is derived from the gas pressure required to provide satisfactory operation.

Low-pressure Burners. Low-pressure burners are usually operated with gas pressures of from $\frac{1}{8}$ to 4 psi. A multijet construction delivers the gas in many small streams to discharge opening in the burner throat. Air for combustion, induced by furnace draft, flows around the jets and the gas-air mixture is then burned as it enters the furnace. Dampers are used to regulate air supply. Burners of this design are used where moderate capacities are desired for boilers having relatively wide furnaces.

High-pressure Burners. The use of high pressures for pipe-line transportation of gas over long distances is necessary to maintain low production costs. As a result the pressure in the gas main serving a plant may be 30 to 50 psi. Regulators are used to provide pressure step down to burner main and to maintain a constant pressure so that automatic regulators are effective in varying gas flow to meet fluctuations in steam demands. Where h-p gas is available, the burner operates on pressures from 2 to 25 psi.

High-pressure gas burners may be classified into four main types, each indicative of the manner in which gas is discharged into, and mixed with, the air for combustion.

The *gas-ring* type of burner is one in which a gas ring in the form of an annular manifold, located between air register and furnace wall, surrounds the burner opening. A series of orifices drilled around the inner surface of this ring spray gas angularly in the form of a screen across the air stream toward the center of the burner opening. Operation can be easily maintained with excess air as low as 7 per cent. Figure 8-23 shows a burner of this type, provided for alternate use of fuel oil.

The *center-diffusion-tube* type of burner is one in which the gas head with its orifices is located at the center of the burner. For combination firing, either a mechanical-atomizing or steam-atomizing oil-gun assembly is inserted through an inner sleeve in the gas tube. In this design, Fig. 8-24, the gas, as well as the oil, leaves the burner tip in the shape of a hollow cone and at a wide angle to the entering air. A diffuser plate, integral with the gas tip, assures steady and prompt ignition. Integral adjustable dampers are used to control air quantity and produce the desired spin necessary for good combustion.

The *turbine* type of gas burner is one using revolving instead of fixed orifices. These orifices distribute gas transversely to the air stream while rotating at high speed. With this design, the energy in the gas under pressure is utilized to perform the mechanical mixing and proportioning of the gas and air for combustion.

The *tangential* type is one in which banks of burner assemblies are located in the four corners of the furnace. Air and fuel-gas streams are directed along paths tangent to a small circle at the furnace center. This arrangement provides added turbulence and mixing and is well adapted to steam-generating units of large size.

Furnace Liberation. There are many natural gas-fired installations operating at high furnace heat-liberation rates. However, tests have demonstrated that there is a decided tendency for the burning mixture to short-circuit the available volume so that continuous or incomplete combustion may extend into the boiler and superheater zones of the unit. By providing generous furnace volume, based on a liberation rate which does not exceed 30,000 Btu per cu ft per hr at maximum continuous capacity, much operating difficulty can be avoided. The capacity of an individual burner is as high as 120 million Btu per hr.

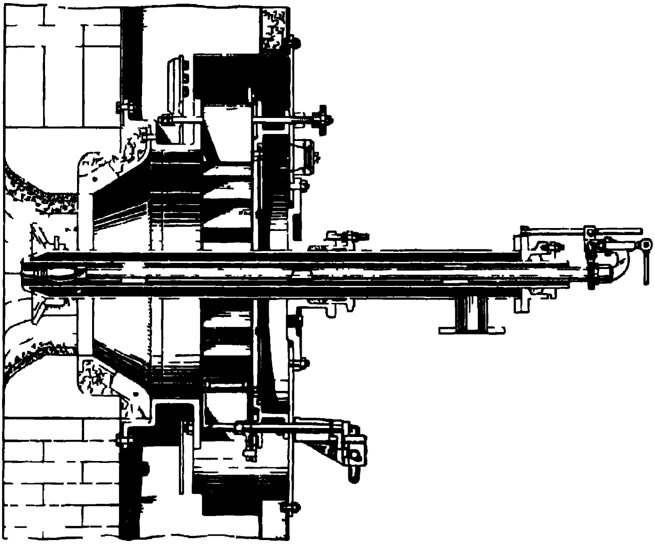

Fig. 8-24. Combination steam-atomizing oil and natural-gas burner of the center-diffusion tube type. (*Combustion Engineering-Superheater, Inc.*)

SUPPLEMENTARY FUELS

In the foregoing we have discussed burner designs which can alternately and without difficulty handle both liquid and gaseous fuels. Necessary provision can also be made for pulverized coal firing in the same burner casing by providing a suitable nozzle for the particular type of burner in use. Under these conditions the furnace design should be developed for the basic fuel or the one which will have the greatest influence from the standpoint of both economy and operation.

In some instances stokers may be used to burn the solid fuel. In these cases it is advisable to provide a separate burning zone for each fuel and the outlet of the two zones is then combined to provide a common inlet to the boiler section. This minimizes slag deposits on heat-absorbing surfaces because the products of combustion do not mix until the combustion process is completed.

BOILERS AND BOILER AUXILIARIES*

BY OTTO DE LORENZI

Director of Education, Combustion Engineering—Superheater, Inc.

The modern steam-generating unit, in its simplest form, consists of a grate, a furnace, and a boiler The larger and more comprehensive designs include mechanical fuel-burning equipment, water-cooled furnaces, superheaters, boiler surface, heat-recovery apparatus, and related auxiliaries. For maximum over-all reliability and operating economy, each component part must be correctly proportioned and properly related to the other elements of the unit so as to comprise a balanced design.

CAPACITY AND RATING

At present the means for expressing capacity and rating of modern steam-generating units is not clearly defined. These modern units usually consist of several different types of heat-absorbing equipment, and, therefore, combined performance cannot be expressed in either boiler horsepower or equivalent evaporation. This has led to the now generally accepted practice of stating capacity in actual pounds of steam generated per hour at a specific pressure and temperature and from feed water at a definite temperature. A more exact means for expressing capacity is in Btu per hour input to the steam, thereby accounting for variation in pressure, steam temperature, and feed-water temperature. This latter method has not yet been adopted by engineers for general use, but the transition which is now taking place will result in the development of more rational standards

TYPES OF BOILERS

A wide variety of boilers is now in general use for industrial and central-station steam plants. All boilers for these purposes fall into two general classifications: fire-tube boilers and water-tube boilers. Any discussion of these must, of necessity, be a general one. Description and illustration will include principal boiler types and some of their applications, together with range in size, capacity, pressure, and steam temperature.

Fire-tube Boilers. A fire-tube boiler is one in which tubes comprising the heat-absorbing surfaces are water-touched on the outside surfaces, while flue gas flows through them.

Fire-tube boilers are relatively inexpensive, but their overload capacity is limited, and exit gas temperature rises rapidly with increased output. The horizontal return-tubular boiler, commonly called the "HRT boiler," is the most widely used of this type.

An HRT boiler consists of a cylindrical shell into the ends of which heads are fitted. These heads are provided with suitable openings into which the tubes are expanded. Tube diameters may vary from 2 to 4 in. The present standard for shell construction is fusion welding so that there are no overlapping seams or butt-strapped joints. Shell sizes may vary from 54-in. diameter by 12-ft length to 108 in. diameter by 20-ft length.

Boilers of this type are principally used in small heating and industrial plants where the pressure and capacity requirements are relatively low and where only a limited amount of superheat is needed. The capacity usually falls in the range from 1,000 to 15,000 lb steam per hr with design pressure up to 250 psi and up to 150°F superheat. Rates of evaporation should not exceed 7 lb per sq ft per hr and preferably should be held at approximately five pound.

---

* A portion of this material has been adapted by permission from *Combustion Engineering*, published Combustion Engineering-Superheater, Inc.

For coal firing, the smaller boilers are usually equipped with hand-fired grates and the larger sizes with stokers. Oil, gas, and waste fuel are also frequently used. A typical stoker-fired installation in which an HRT boiler, equipped with a girth-type superheater, is used is shown in Fig. 8-25.

A modification of the standard HRT boiler, which is compact, semiportable, and requires a minimum of refractory setting, is the C-E Premier boiler shown in Fig. 8-26. It consists essentially of two shells of different diameters joined together end to end to form a single unit. The shell having the larger diameter is at the rear and has a series of short tubes in its lower section. These tubes form the flues between the furnace and the rear combustion chamber. In the upper portion of the larger diameter shell are long tubes which extend forward through the small shell and conduct the flue gas from the rear combustion chamber to the smoke box at the front. Design pressure is limited to approximately 150 psi, and the capacity range is from 1,000 to 12,000 lb of steam per hr.

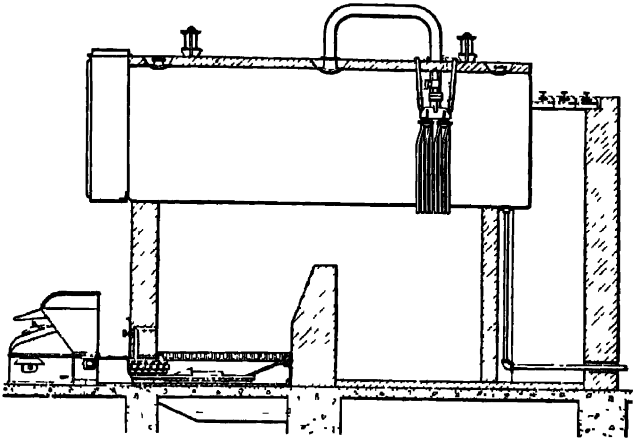

FIG. 8-25. A small modern unit comprising an HRT boiler equipped with girth-type superheater and fired by a single-retort stoker. (*Combustion Engineering Superheater, Inc.*)

These boilers are used primarily for small- and medium-sized industrial and heating plants. They are principally coal fired. Hand or stoker firing may be used. Oil, gas, and wood have also been used as fuel. In the case of wood, a Dutch-oven furnace is frequently installed.

Water-tube Boilers. A water-tube boiler is one in which the tubes comprising the heat-absorbing surfaces contain water, while the flue gas flows over their outside surfaces.

Water-tube boilers are broadly classified into the straight-tube and bent-tube types, each of which has a number of design variations. They are used almost exclusively for pressures above 150 psi and capacities over 15,000 lb steam per hr.

The horizontally inclined straight-tube boiler, in its best known forms—the sectional-header and box-header types—was at one time by far the most widely used. As pressures and capacities were gradually stepped up, however, their use declined because the required rate of steam output per foot of furnace width soon exceeded the circulation limit. As a result, the bent-tube boiler, because its greater design flexibility makes it possible to meet the demands of modern h-p and high-capacity installations, has now practically replaced the straight-tube type.

Straight-tube Boilers. The *box-header boiler* takes its name from the boxlike uptake and downtake headers which form the tube sheets and handhole sheet at each end of the main tube bank. Stay bolts are used to brace these box headers against internal pressure. The main tube bank is inclined at a slope of from 1 to 3 in 12 in., and may be arranged for either horizontal or vertical baffling as required. The boilers may be of the longitudinal or cross-drum type.

The *longitudinal drum* type of box-header boiler (see Fig. 8-27) consists of one, two, or three parallel drums to which the uptake and downtake headers are attached.

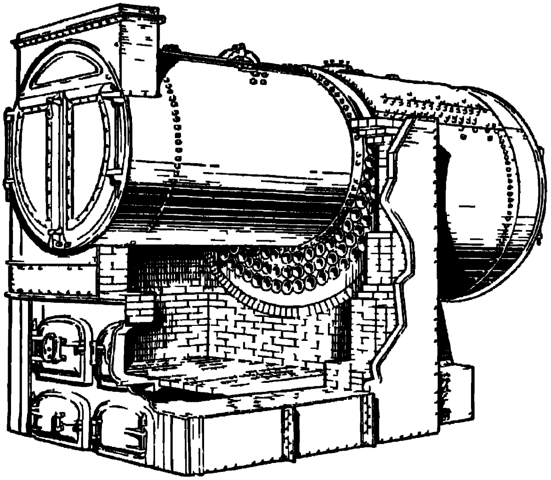

FIG. 8-26. A Premier boiler arranged for hand firing. (*Combustion Engineering–Superheater, Inc.*)

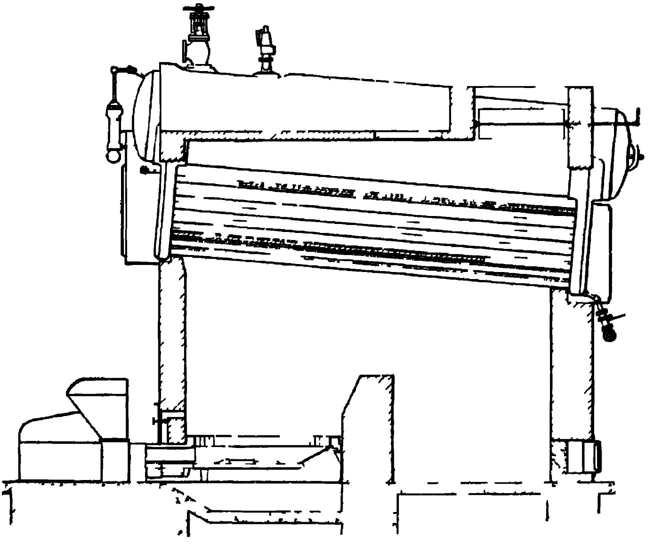

FIG. 8-27. A horizontally baffled inclined-tube box-header boiler equipped with single-retort stoker. (*Combustion Engineering–Superheater, Inc.*)

These drums may be either horizontal or parallel with the tube bank, and their number and diameter will depend on the capacity desired. Box-header boilers, because of the stayed and riveted construction, are limited to a maximum design pressure of 300 psi and the capacity ranges from 4,000 to 90,000 lb steam per hr.

The *cross drum* type of box-header boiler uses a single drum, arranged transversely to the tube bank and located above the downtake header. The front or uptake header is connected to the drum by horizontal circulating tubes, and connecting nipples complete the circuit between the downtake header and drum. Either longitudinal or cross baffling can be used. The cross-drum box-header boiler shown in Fig. 8-28 is provided with a combination of horizontal and cross baffling. The superheater is usually arranged above the tube bank, which limits superheat to approximately 200°F.

The *sectional-header boiler* is made up of a number of sinuous forged-steel headers into which the tubes are rolled. The tube bank carried between these headers contains the major portion of the heating surface and has a slope of 3 in 12 in Tube lengths are preferably 18 to 20 ft. The size of a boiler is varied by changing the heating surface in individual sections and by increasing or decreasing the number of sections. Two or three sections may be placed in series by using interconnecting nipples. This construction is used when an interdeck superheater is required or where an exceedingly high tube bank is necessary, as in the case of waste-heat or single-pass design. These boilers are generally of the cross-drum type using circulating and connecting nipples to complete the circuit with the tube bank. Steam drums vary in diameter from 42 to 72 in., depending on capacity and pressure. Design pressure varies from 160 to 2,000 psi, with capacity ranges between 1,000 and 525,000 lb steam per hr. Some features of this type of boiler are shown in Fig. 8-29.

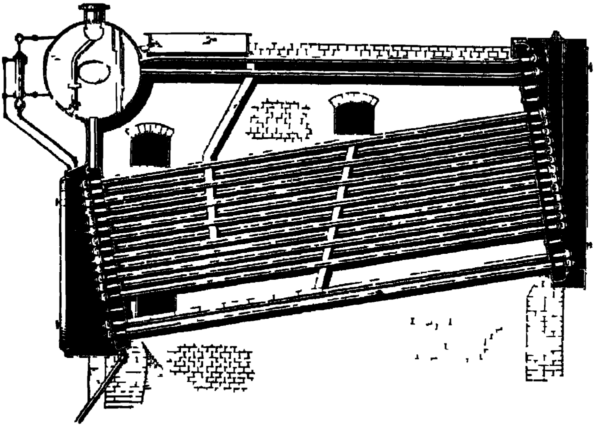

FIG 8-28. A cross-drum box-header boiler arranged with combination baffling (*Combustion Engineering--Superheater, Inc.*)

Bent-tube Boilers. Bent-tube boilers of conventional design usually have a lower, or mud drum, which is interconnected by means of bent tubes with one, two, or three upper steam-and-water drums. The heating surface, except in a few designs, is arranged in two or three banks, and vertical baffles or a combination of vertical and cross baffles are used. Superheaters may be located intertube in the first boiler bank or interbank between the first and second tube banks. Owing to flexibility in design these boilers may range in capacity from 6,000 to 1 million lb steam per hr with a design pressure range of from 160 to 1,800 psi with steam temperature 950°F. There are, of course, capacity pressure and steam-temperature limitations for each specific design. These will be covered in the discussion to follow.

The *four-drum* boiler was one of the first of bent-tube type to be extensively used. It consists of three upper steam-and-water drums and one lower water or mud drum. The tubes for interconnecting these drums are arranged in three banks with baffling to provide for three passes of the flue gas over this surface. The number of tubes in each row varies with the boiler size and diameter of lower drum. Capacity is usually the governing factor in determining boiler width and also influences vertical distance between lower and upper drums. There are several different ways in which tubes may be installed in the several boiler banks to provide rapid and positive circulation as well as adequate steam distribution to the various upper drums. The four-drum boiler shown in Fig. 8-30 is of a conventional type. The front and middle boiler banks are connected into both the front and middle upper drums to equalize discharge of the steam-and-water mixture and thereby improve circulation and reduce carry-over with the steam. Boilers of this general type are usually designed for pressure from 160 to 1,000 psi and a capacity range of from 7,500 to 350,000 lb steam per hr.

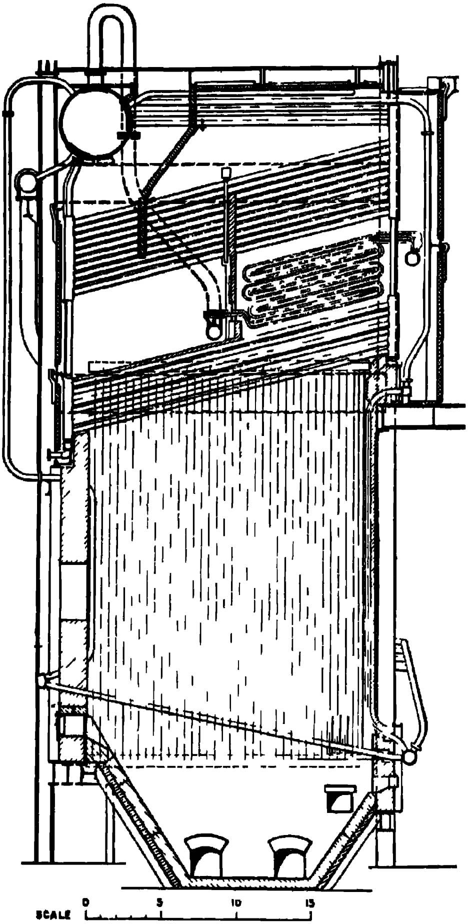

FIG. 8-29. A pulverized-fuel-fired sectional-header boiler of the cross-drum type equipped with an interdeck superheater. Furnace is fully water cooled by a bottom screen. Capacity 176,000 lb of steam per hr at 450 psi and 750°F. (*Combustion Engineering Superheater, Inc.*)

The *low-head* type of bent-tube boiler has been designed for limited space conditions so that it could compete with both the HRT and the cross-drum box-header

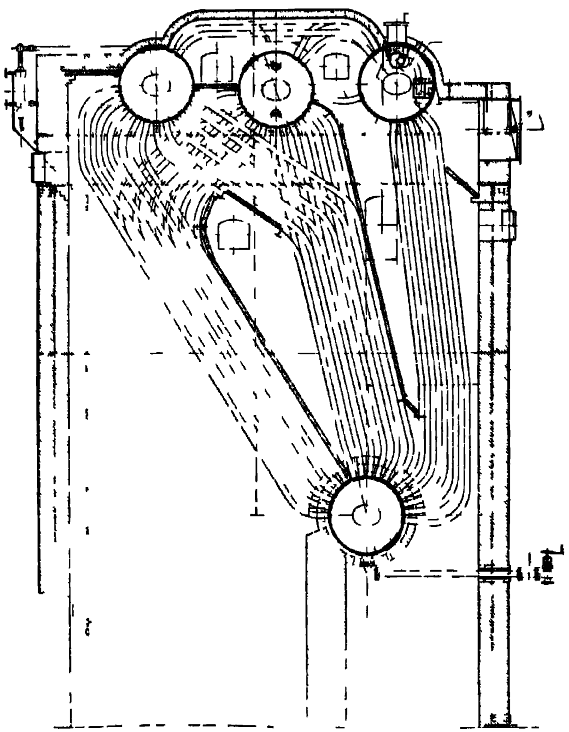

Fig. 8-30. A four-drum bent-tube boiler in which the first boiler bank is connected into both the first and middle upper drums. (*Combustion Engineering-Superheater Inc.*)

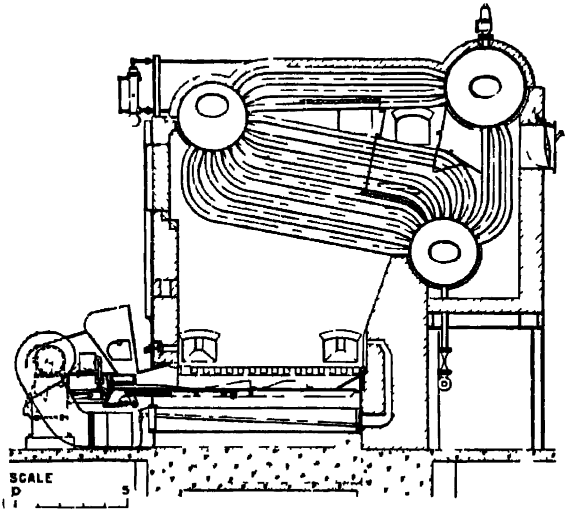

Fig. 8-31. Low-head bent-tube boiler fired by a single-retort stoker. (*Combustion Engineering-Superheater Inc.*)

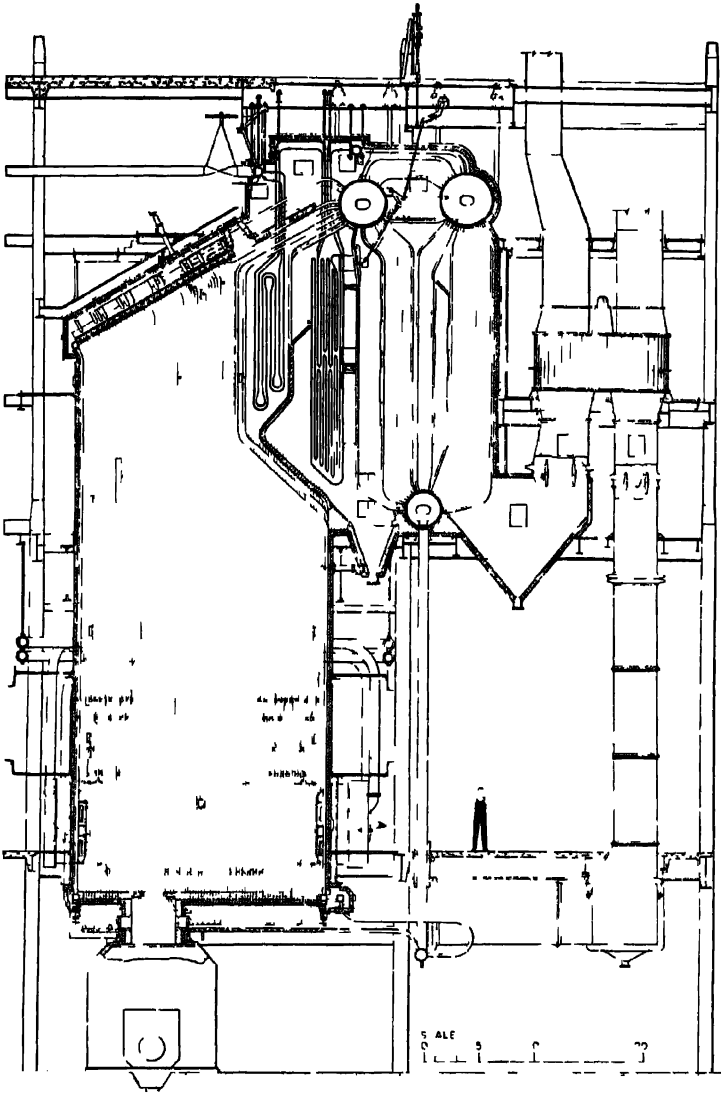

FIG 8-32 A pulverized-fuel-fired public-utility type steam-generating unit with tangential burners continuous slag-tap furnace three drum boiler and air heater Capacity, 400 000 lb of steam per hr at 875 psi and 900°F (*Combustion Engineering Superheater Inc*)

boilers Many of its characteristic features are shown in Fig 8 31 Its capacity range varies from 6,000 to 10 000 lb steam per hr with a design pressure range from 150 to 450 psi When operated at relatively high capacity the exit gas temperatures are higher than with straight-tube or other bent-tube design of similar size These boilers are well standardized as to construction and are available in a relatively wide range of sizes

The three-drum boiler, *high-head design*, is one that has never been standardized to the same extent as the four-drum types. Many have been installed in public-utility and large industrial plants. This boiler is provided with two upper steam-and-water drums and a lower mud drum. The tube banks are varied in design and arrangement for the specific condition under which this boiler is to be operated. This is perhaps best illustrated in Fig. 8-32 which shows one of several units installed for a large public-utility plant. The boilers have fully water-cooled furnaces arranged for pulverized-fuel firing. A large two-stage interbank superheater is used to provide a steam temperature of 900°F. Following the superheater is the convection surface arranged in two banks. Finally, external to the boiler is a large air heater. This unit has an over-all efficiency of 85 per cent at a capacity of 400,000 lb steam per hr at 875 psi and 900°F. It is of interest to know that the distribution of heat-absorbing surfaces, exclusive of air heater, is as follows: boiler, 47.4 per cent; furnace, 17.6 per cent, and superheater, 35 per cent.

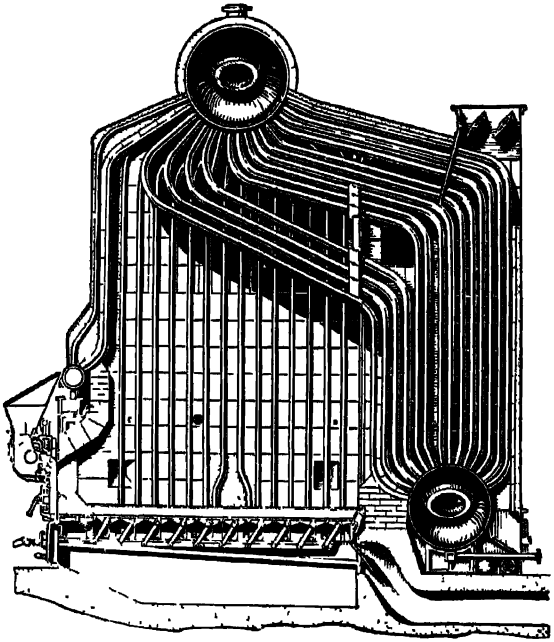

FIG. 8-33. A package-type boiler equipped with spreader stoker. (*Combustion Engineering Superheater, Inc.*)

Two-drum boilers are perhaps the simplest of the bent-tube types. Originally they were limited in application owing to low capacity and wet steam resulting from improper arrangement of tubes entering the upper steam-and-water drum and faulty drum internals which were ineffective in separating water from the steam. Modern redesign, however, has changed this so that boilers of this type are now available in well-standardized units for the capacity range from 15,000 to 300,000 lb steam per hr with design pressure from 160 to 1,000 psi and steam temperature up to 900°F. Typical of the small- and medium-sized industrial steam-generating units is the *package type* shown in Fig. 8-33. These may be fired by spreader stokers, single-retort underfeed stoker, oil, or gas. The capacity ranges from 18,000 to 45,000 lb steam per hr in a series of standard sizes. For larger capacities a steam-generating unit of the type shown in Fig. 8-34 is used. These are available in standardized sizes up to a capacity of 300,000 lb steam per hr with design pressure up to 1,000 psi and steam temperature up to 900°F Pulverized-fuel, oil, and gas firing are most frequently used, however, and with some furnace modifications stokers of any type may be readily applied. A particular feature in this design which contributes to uniformity of furnace condition, as well as to steam dryness and distribution, is the symmetrical arrangement of the unit in relation to the furnace center line. As a result of this, the gas enters the tube bank at low velocity at a practically constant temperature across the full width of the unit. There is no concentration of heat in any particular spot, and furnace conditions are uniformly constant The release of steam to the drum is uniform along its length, thereby eliminating surging water level and periodic carry-over of water slugs into the superheater.

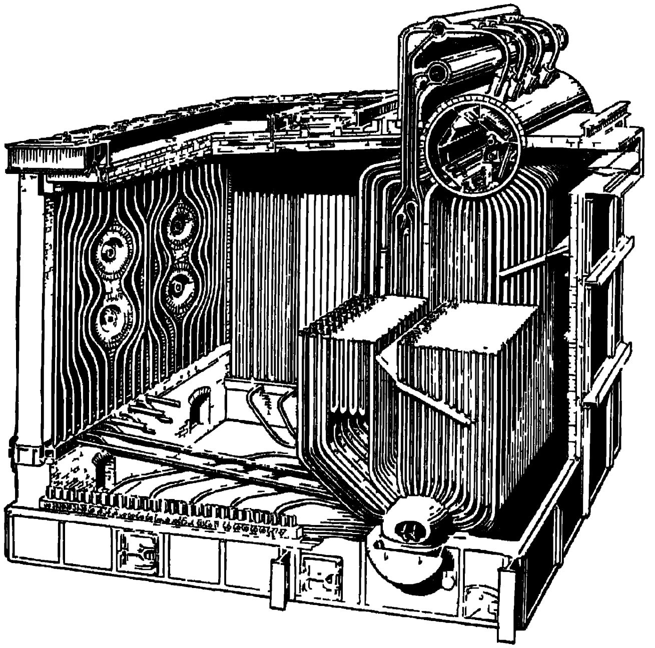

FIG. 8-34. Sectional view of a steam generator arranged for pulverized coal, oil, or gas firing. (*Combustion Engineering- Superheater, Inc*)

High-pressure steam generators are by far most widely used in the modern central stations of the public utilities. These units consist of completely water-cooled furnaces, large superheaters, and sometimes reheaters, boiler convection bank, economizers in some cases, and large air heaters. The amount of convection surface installed will frequently depend on whether or not an economizer is used. The unit designs are not entirely standardized because they are selected to meet exacting specifications which all too frequently vary from installation to installation. Generally there are two pressure classifications: 900 to 1,000 psi and 1,200 to 1,700 psi. Steam temperature ranges from 850 to 1050 F, and provisions are usually made for maintaining constant temperature from maximum load down to some predetermined partial load point. In addition to other operation requirements, furnace volume, together with disposition and extent of furnace heat absorbing surfaces, plays an important part in determining superheater location, arrangement, and size, as well as amount of boiler convection surface needed Thus for high pressure and high steam temperature, when complete furnace water cooling is used, most of the steam is generated in the furnace walls. As a result, only a small convection bank is required

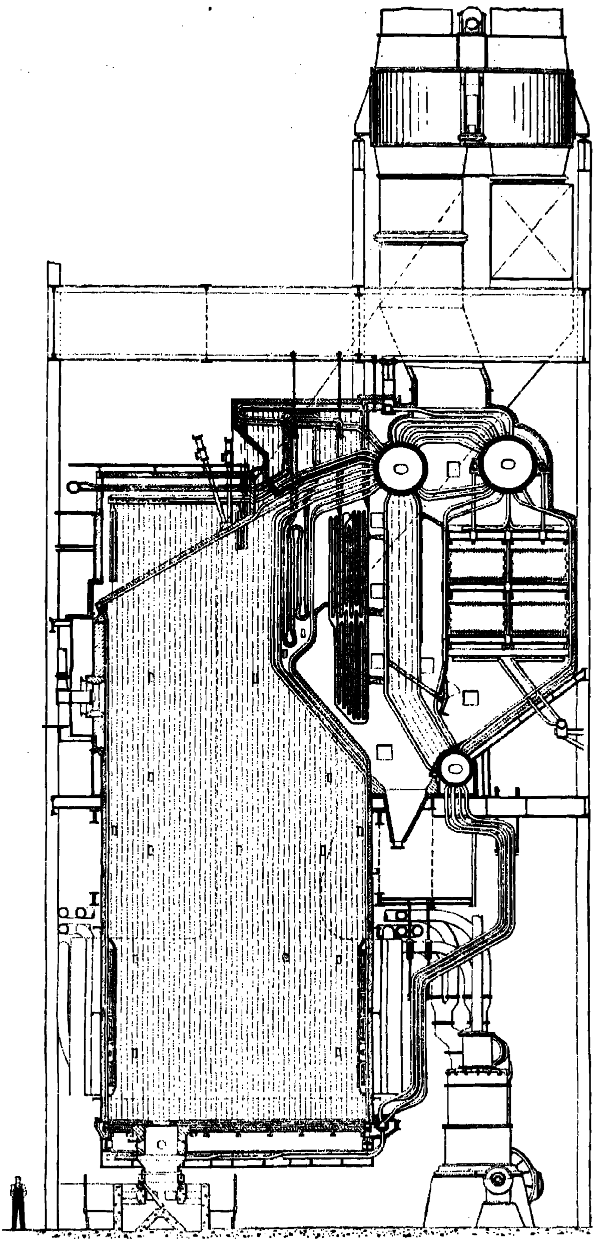

FIG. 8-35. A large steam-generating unit having a capacity of 1,000,000 lb of steam per hr at 1625 psi and 955°F. Continuous slag-tap furnace arranged for tangential firing, with vertically adjustable burners, is used. (*Combustion Engineering—Superheater, Inc.*)

between the superheater outlet and the economizer inlet. An arrangement of this general type is shown in Fig. 8-35 where the unit has a continuous capacity of 1 million lb steam per hr at 1,675 psi and 955°F at an over-all efficiency of 88.8 per cent. In this instance, the heat-absorbing surface, exclusive of the air heater, is disposed as follows: boiler, 14.6 per cent; furnace, 12.4 per cent; superheater, 34.7 per cent; and economizer, 38.3 per cent. There are a number of additional arrangements of high-capacity h-p units which will be used to illustrate other subject matter in this section.

SUPERHEATERS AND DESUPERHEATERS

The superheater is a device for imparting additional heat to saturated steam so that its temperature is raised and its volume increased. It consists of heat-absorbing

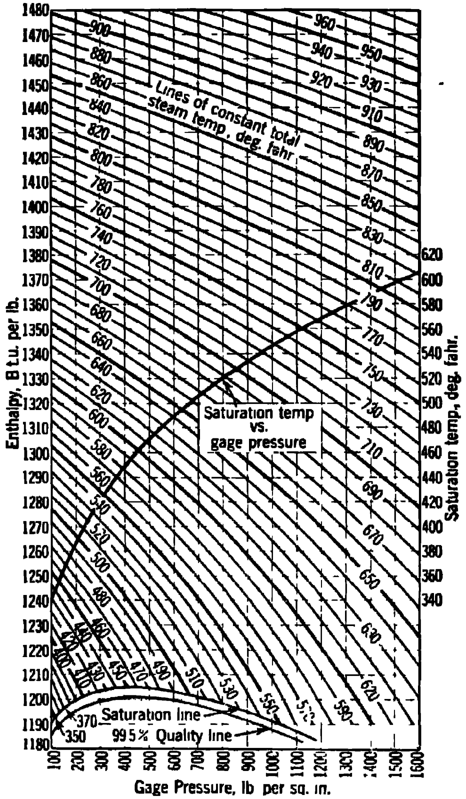

FIG. 8-36. Variation in heat content of steam at different pressures and temperatures. (*Combustion Engineering—Superheater, Inc.*)

surface, located in the path of the flue gas, which receives saturated steam after it has been removed from the generating portion of the boiler.

The properties of saturated steam approximate those of a perfect gas. It contains no moisture, and it cannot condense until it reaches saturated-steam temperature. With saturated steam, the heat available depends entirely on pressure, while with superheated steam there is additional heat proportionate to the degree of superheat. All these factors are illustrated by the series of curves in Fig. 8-36 which show variation in heat content of both saturated and superheated steam at different pressure and up to a temperature of 900°F. Also included is a curve of saturated-steam temperature for various pressures.

The characteristic of a convection-type superheater is rising steam temperature with capacity increase, while that of a radiant type is falling steam temperature. Practically all present-day superheaters are of the convection type in which heat is absorbed from the hot flue gas as it impinges and flows around the tubes. If the superheater is so located that it is not entirely shielded by boiler surface, it will also receive heat through radiation from the furnace. As a result steam-temperature variation over a range in capacity will be less marked than with a straight convection type. By referring to Figs. 8-32 and 8-35 it will be noted that the first bank in each of these superheaters is the combination convection and radiant type because it is located behind the equivalent of one row of boiler tubes. The second bank of these superheaters is of the straight convection type. The superheater shown in Fig. 8-34 is of the convection type as it is located behind a baffle which shields it from the radiant heat. The interdeck superheater shown in Fig. 8-29 is also of the straight convection type. The girth-type superheater shown in Fig. 8-25 employs both radiant and convection absorption and a measure of steam-temperature adjustment may be obtained by changing the clearance between the superheater elements and the boiler shell.

The performance of a superheater is closely related to operation of the turbine to which steam is supplied. Materials used in these prime movers are carefully chosen, and running clearances are limited so as to obtain satisfactory steam rates. Thus it becomes not only desirable but necessary to provide constant steam temperature over a wide range in load for modern h-p high-temperature installation.

By-pass Damper Control. One means available for providing constant steam temperatures from some predetermined partial load to full load is the by-pass damper. With this arrangement the quantity of hot gas passing over the superheater surface is varied to maintain the desired steam temperature. The superheater is designed to provide full steam temperature at the predetermined partial load point, usually not less than 75 per cent of full load, and therefore is oversize at the higher capacities. The steam temperature will rise unless some of the gas is by-passed to reduce effectiveness of the superheater. Automatic controls may be used to make necessary by-pass damper adjustments and thereby easily maintain temperature to within plus or minus 10°F.

Adjustable Burner Control. In the previous discussion we have indicated a number of variable factors which govern superheater performance. The amount of superheater surface and its location in a given steam generating unit are fixed by the steam temperature required at some specific capacity and by the fuel used. The performance of this superheater at capacity points other than that for which it is designed, will depend upon temperature and mass flow of the gas sweeping over its surface, temperature of the feed water, cleanliness of the furnace heat-absorbing surfaces, and output at which the unit is operated. The contour of the temperature-capacity curve is fixed, and it can be shifted bodily upward or downward only by changing either the amount of gas that flows over the superheater or the entering gas temperature. The change in gas flow may be secured by some form of by-pass damper arrangement, as previously discussed. The gas-temperature change can be accomplished by selectively using all or part of the provided furnace volume and area of heat-absorbing surfaces. By combining variable gas flow with variable furnace temperature, it is possible to secure control of steam temperature to within plus or minus 3°F over a wide range in capacity.

Control of furnace outlet temperature is possible with tangential firing. With this arrangement, fuel and air from burner assemblies located in each of the four corners are directed along tangents to a small circle lying at the furnace center. A high degree of radiation and convection transfer is secured through the sweeping action of the flame envelope over the wall surfaces. The regulation of furnace temperature is then secured, as graphically illustrated in Fig. 8-37, through changes in angularity of the burner nozzles. Thus, by directing the incandescent turbulent mass of burning fuel toward the upper zone of the furnace, the resulting outlet temperature will be made higher during light load, or when walls are clean than would be the case with fixed burners which constantly use the entire provided furnace volume. For heavy loads or when walls are coated with dust the entire furnace volume can be used to maintain the desired outlet temperature by tilting the burners downward. Now, by adjusting the burner nozzles to the proper angularity for any given and reasonably varying load condition a by-pass damper can be confined to its most effective operating range. Thus the combination of adjustable burner nozzles with a by-pass damper provides a more positive combination for maintaining steam temperature with less variation from normal, over a far wider operating range than when a by-pass damper and fixed burners are used.

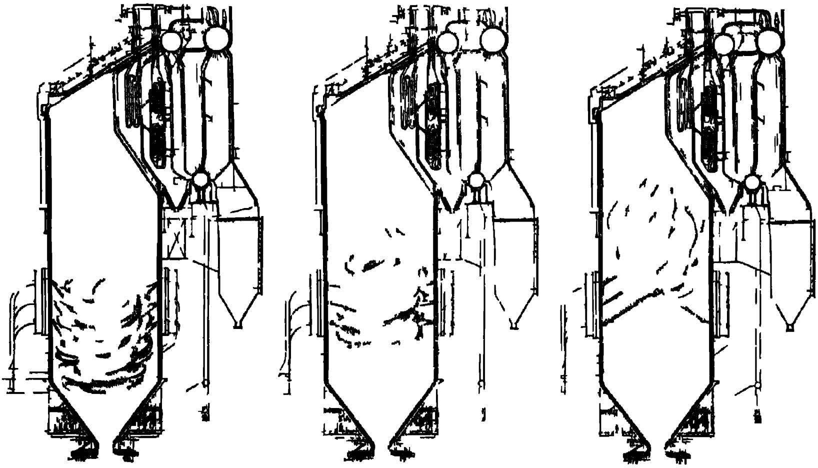

Fig. 8-37. Diagrammatic sketch showing how the zone of turbulent burning may be selectively positioned by adjustment of burner nozzles. (*Combustion Engineering-Superheater Inc.*)

Desuperheaters. An alternate or sometimes supplementary arrangement to the by-pass damper for steam temperature regulation is some form of desuperheater. Desuperheaters are used to effect a reduction in temperature of the superheated steam. They are preferably located between sections of the superheater, especially where the final steam temperature is above 850 F. In these interstage installations, the steam is first passed through a primary superheater where it is raised to some intermediate temperature which may be only slightly below that finally desired. It is next passed through the desuperheater in which its temperature reduction is controlled so that after continuing through the final stage of the superheater the required temperature is maintained at the outlet. Desuperheaters do not necessarily extend the range over which constant steam temperature is obtained except in those cases where the superheater is of considerably increased size.

Desuperheaters may be either of the direct contact or the noncontact type. The selection for any specific installation will be governed principally by the water available for use as the temperature regulating medium. This is not important with the noncontact type where a tubular heat exchanger is used since the steam to be desuperheated is separated from the cooling medium and the heat is transferred through the tubular wall. In some instances noncontact desuperheating coils may be installed in one of the boiler drums. The principal objection to this design is its relatively low capacity because parts must not occupy so much space in the drum that they cannot be assembled in place and must be small enough to handle conveniently through the boiler-drum manhole opening. In the direct-contact type, however, the cooling medium is injected into and mixed with the superheated steam to effect a reduction in temperature. The cooling medium is usually water, and it must therefore be comparatively free of solids. In most installations, condensate or feed water will be of sufficient purity to permit its use for this purpose.

A combination of adjustable burners, together with interstage desuperheating, is effective for maintaining constant steam temperature over a wide capacity range. With this arrangement, the response to changes in operating conditions is rapid, and deviation from present temperature can be held to less than plus or minus 5°F provided the load does not fall below superheater design point.

The use of desuperheaters has not been particularly popular with steam-plant operators even though several designs are available. Perhaps the reasons for this might be the following: With the direct-contact type where water is injected into the steam to effect temperature reduction, there is the ever-present possibility of moisture carry-over into the final superheating stage if the sprays are improperly adjusted or controlled. Also, the noncontact types are large heat-exchanger types of vessels suitable for h-p and high-temperature operation and are, therefore, bulky, heavy, costly, and subject to service interruptions common with equipment of this type

HEAT-RECOVERY EQUIPMENT

Heat-recovery equipment is apparatus forming part of a steam-generating unit but which is not part of the steam-generating or superheating sections. Feed-water-heating and air-heating apparatus, arranged to recover heat from flue gas leaving the steam-generating section of a unit, are known as "economizers" and "air heaters," respectively

Economizers. The most suitable material for h-p economizers, except as regards corrosion, is steel tubing because of the following advantages: thinner tube walls, smaller diameter, closer spacing, more compact arrangement of heating surface, better heat transmission for a given weight of surface, and lower cost.

The temperature of feed water entering any type of economizer should never be less than 125 F if sweating and resulting external corrosion are to be avoided

Internal corrosion in steel economizers is most frequently due to dissolved oxygen in the feed water which must, therefore, be properly conditioned to overcome this difficulty The method employed for this conditioning should be based on recommendations of those who are well qualified to advise on feed-water treatment Some form of deaerating heater may reduce the oxygen content to the required minimum for the specific operating conditions. In some instances supplementary chemical treatment may also be indicated

Steel-tube economizers are arranged in vertical or horizontal banks of tubes The vertical types are known as "integral economizers" and the horizontal types as "separate economizers."

Integral Economizers Integral economizers are used only in conjunction with bent-tube boilers They are arranged like an additional bank of boiler tubes and are located within the boiler setting Either the one- or two-drum type may be used. The one-drum type employs a lower drum from which the economizer tube bank extends upward to terminate in the rear steam-and-water drum of the boiler section In this design the feed water is introduced into the lower drum, makes one pass through the tube bank, and is then discharged directly from these tubes into the boiler drum. The flue gas is directed over the economizer tubes by properly located baffles. The upper drum of a two-drum integral economizer is divided into two compartments by a partition plate which likewise divides the tube bank into two sections. The feed water is introduced on one side of the partition and discharged from the other side through connecting tubes into the upper steam-and-water drum of the boiler. The water therefore makes two passes through the economizer in flowing from one compartment through part of the tube bank to the lower drum and then back through the remainder of the tube bank to the other compartment of the rear drum. An economizer arrangement of this type is shown in Fig 8-38.

Integral economizers have a low water velocity owing to multiplicity of parallel circuits and therefore also have a low waterside pressure drop. This characteristic is not conducive to good distribution or positive circulation but is favorable to internal oxygen corrosion unless suitable water conditions are continuously and carefully maintained.

Separate Economizers. Separate economizers are the most widely used type. They employ horizontal steel tubes arranged in staggered closely spaced rows, with the gas flowing transversely to the axis of the tubes. The water flows progressively through the tubes, upward or downward from row to row, and usually in counterflow relation to the gas. Upward flow of water is preferred by some engineers, particularly if there is any possibility of steam being generated in the economizer. Many downflow applications, however, are in successful use. These economizers are available in either the accessible type or the continuous-tube type which has no provision for access to the interior of the tubes.

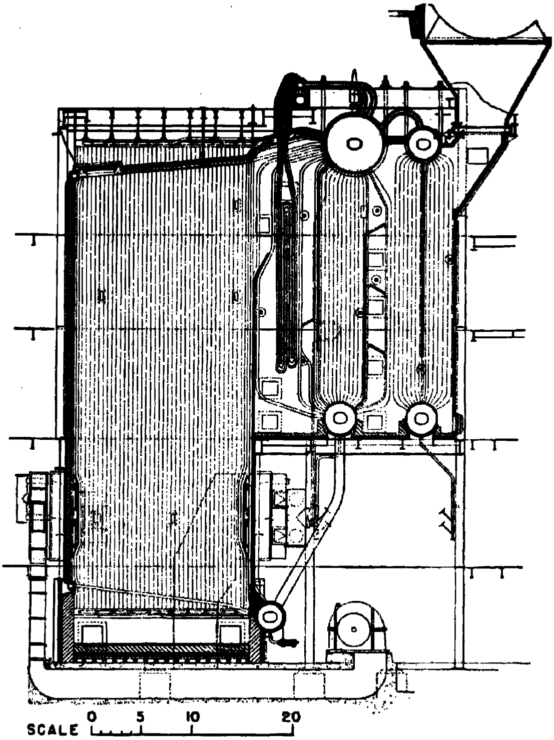

FIG. 8-38. One of several large steam-generating units equipped with two-drum integral economizer and arranged for tangential firing of blast-furnace and coke-oven gas. Capacity 200,000 lb of steam per hr at 325 psi and 700°F. (*Combustion Engineering—Superheater, Inc.*)

The *accessible type* is provided with flanged return bends or other means for ready access to the interior. It is used where feed water is poor, and the economizers, therefore, require periodic inspection and cleaning.

The *continuous-tube type* affords no access to the tube interiors and is used where good feed water makes internal cleaning unnecessary. The recent advent of inhibited hydrochloric acid cleaning for internal tube surfaces may lead to the adoption of this design for many installations where provision for mechanical tube cleaning would otherwise be very necessary.

An economizer is frequently located outside the boiler setting as a separately supported and encased unit. The stoker-fired steam-generating unit shown in Fig.

into which the heating surface of the regenerative mass is fitted. This surface is made up of thin metal sheets which are notched and undulated so that when compactly assembled space remains through which the air or gas can flow. The heating surface may also be arranged in two layers, as shown in Fig. 8-44, to minimize any replacement of the cold end which may become necessary owing to corrosion. Sheets in these two layers may be of different materials, each of which is best suited to the conditions which exist in its particular zone of application. Suitable seals are used to minimize leakage through the heater and thus maintain its performance.

Heaters of this type may be of either the vertical- or horizontal-flow design as best suits the particular application. They are compact since 1 in. in height of the particular heating surface used will recover approximately as much heat as a 1-ft length in a standard plate-type heater or 2 ft in a tubular-type heater with equivalent resistance to flow of gas and air. For the installation shown in Fig. 8-35, two vertical-flow heaters are used for each steam-generating unit, and they are located side by side above the boiler as shown. For the installation shown in Fig. 8-32, two vertical-flow heaters for unit are located in the rear of the boiler as shown.

FURNACES FOR STEAM-GENERATING UNITS

To design furnaces for steam-generating units properly requires detailed knowledge of many influencing factors which vary from installation to installation. For this reason it is difficult to establish a complete set of standards which can be applied to cover any and all conditions. In material entitled "Fuel Preparation and Burning Equipment" the preferred limits of fuel-burning and heat-liberation rates for the various type, of equipment available were indicated. There was, however, no discussion as to some of the basic furnace design principles which govern in various types of installations. An abbreviated discussion of these will follow in order to provide a background which should be of some assistance when making comparisons or evaluations.

Single-retort Stokers. Furnaces for most single-retort stokers are of the simplest form because they are devoid of arches and consist essentially of four refractory walls (see Figs. 8-25 and 8-27). If the heat-liberation rate is limited to not more than 45,000 Btu per cu ft per hr, they will have reasonably low maintenance and very infrequent outages due to refractory failure. In some cases water-cooled side-wall clinker chills at the dump-grate line will minimize clinker adhesion. With some of the newer steam-generating units, water-cooled furnaces are a part of the standardized design. In practically all those now available, ample furnace volume is provided so that at full capacity heat liberation is well below that allowed for less favorable construction. The single-retort stoker can be substituted for the spreader type shown with the package-type unit of Fig. 8-33. In all cases the heat-liberation rate should be based on effective primary-furnace volume and not include parts of boiler passes or other similar ineffective zones.

Multiple-retort Stokers. Multiple-retort stoker furnaces, except for size, were originally quite similar in design to those used with the single-retort type. Application and use of water-cooled surface, however, enabled the combustion engineer to develop the full fuel-burning capacity of these machines in removing the restrictions imposed by all refractory-furnace construction. More recent design modifications, made possible through further extended use of water-cooled surface, have improved operation still more by providing added turbulence to the furnace gas to overcome stratification which existed because of slow rate of flow. Regardless of furnace design, the maximum continuous heat-liberation rate should preferably be kept below 35,000 Btu per cu ft per hr even though water cooling is used. The reason for this is that furnaces for stokers of this type are quite large, and, therefore, the ratio of wall area to volume is relatively low which, in turn, means somewhat higher furnace temperatures.

Furnace turbulence to break up gas stratification may be produced in a number of ways. Over-fire air and steam jets are effective, particularly when located in the bridge wall and directed forward to blow above and parallel to the fuel bed. They may be easily and inexpensively applied to existing installations. Their use, however, requires power to drive the over-fire-air fan or exhaust not less than 1 per cent of the steam generated up the stack. For new installations it is possible to build in furnace turbulence so that it may be continually produced without an expenditure of power or steam. The means available for this purpose is the rear-arch type of construction, well illustrated in Fig. 8-45. With this design, an arch is located parallel with and in close proximity to the fuel bed and extends forward from the rear wall to cover approximately fifty per cent of the stoker length. Its action is to produce turbulence and mixing by directing the products of combustion, rising from the rear portion of the fuel bed, forward at relatively high velocity and causing them to intermingle with those rising from the forward part of the fuel bed. This results in elimination of all stratification and provides uniformity of gas composition and temperature at entrance to heat-absorbing surfaces of the boiler because combustion is completed in the lower furnace zone.

Spreader Stokers. Spreader stokers are usually installed in the conventional open-type furnaces where heat-liberation rates, at continuous capacity, should preferably be held below 35,000 Btu per cu ft per hr. The operation of these stokers is sensitive to the amount of water-cooled surface which may be installed. Usually bare tubes on relatively wide centers are used to avoid the tendency toward smoke which is frequently present when too much cooling effect is used. Owing to the open type of furnace, as well as fuel-bed characteristics and fuel sizing, there is always considerable stratification of the furnace gas. This may be effectively broken up through the use of steam jets or high-velocity over-fire-air jets.

Spreader-stoker fuel beds are characteristically sensitive to air flow. They operate best when approximately 90 per cent or more of the air required for combustion is flowing through them. Because of this the amount of over-fire air that can be used for cinder-return systems and turbulence-producing jets is definitely limited in volume and must therefore be supplied at relatively high pressure to be effective. When steam jets are used they should be of the non-air-aspirating turbulence-producing type so that air supply is under control, with the maximum possible amount passing through the fuel bed.

The steam-generating unit shown in Fig. 8-36 is representative of the dumping type spreader-stoker application for the small industrial plant. For larger capacity, the continuous-discharge design as shown in Fig. 8-46 finds increasingly frequent applications, particularly where low-quality fuels are available.

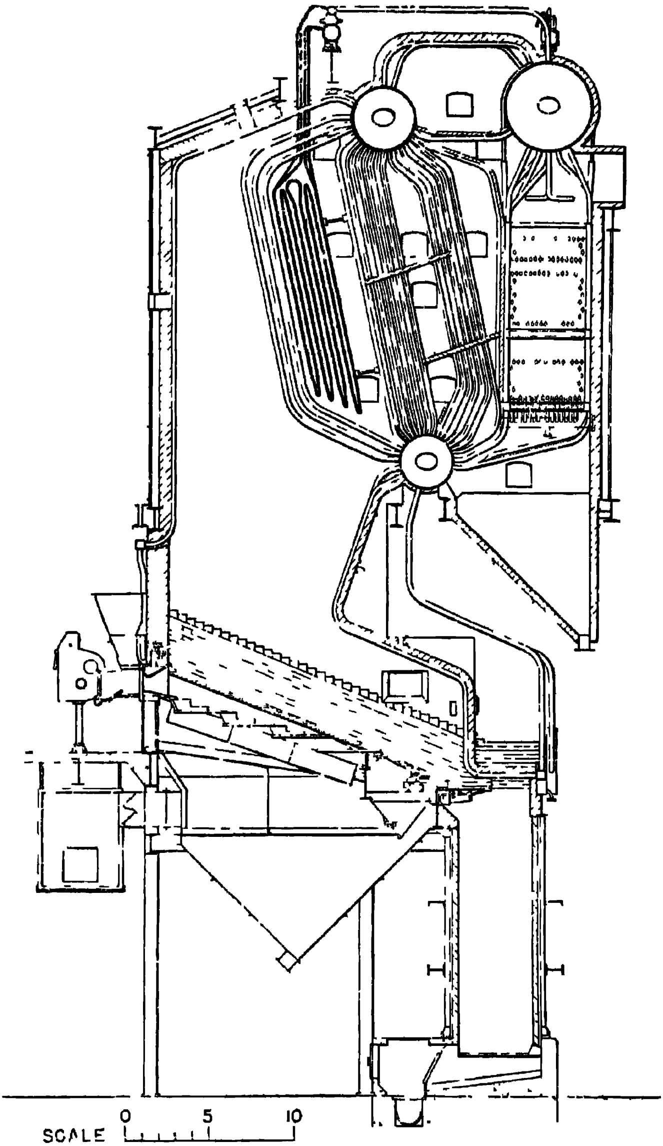

Fig. 8-45. One of several steam-generating units each with a capacity of 150,000 lb of steam per hr at 405 psi and 725°F. A continuous-discharge multiple-retort stoker with rear-arch furnace is used. Water walls are applied to the furnace walls at the sides, rear, and front. (*Combustion Engineering—Superheater, Inc.*)

Traveling- and Chain-grate Stokers. The basic furnace contour for traveling- and chain-grate stokers is practically the same, regardless of fuel burned Modifications in height and length of arches are, of course, necessary when the fuels have such widely varying characteristics as those between anthracite and free-burning bituminous coal or coke breeze and lignite No attempt will be made to fix definite standards for dimensions Several typical furnace arrangements will be shown, and furnace-heat-liberation-rate limits will be presented merely as a guide to what constitutes a good furnace

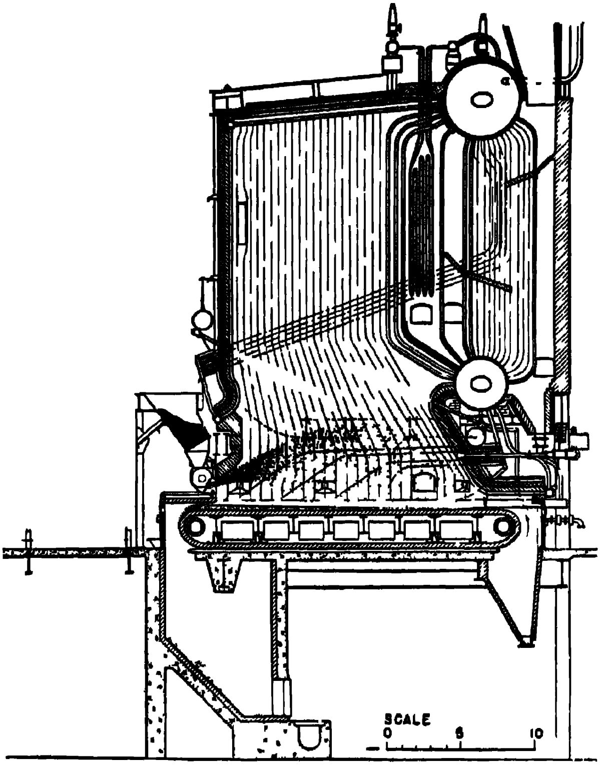

Fig 8-46 A two drum steam-generating unit equipped with continuous-discharge-type spreader stoker Capacity 150 000 lb of steam per hr at 450 psi and 750°F (*Combustion Engineering—Superheater Inc*)

Many of the earlier installations were of the *front arch* type in which the arch extended rearward from the front wall to cover from 30 to 40 per cent of the stoker length The primary purpose was to assure prompt and rapid penetration of ignition by reflecting heat onto the incoming green fuel bed The height of the arch above the fuel bed together with its length were a function of volatile content in the fuel and the maximum rate at which it was burned Front-arch furnaces almost invariably require over-fire air jets to break up gas stratification which results from low rates of flow A front-arch furnace designed for free burning bituminous coal is shown in Fig 8-47 With this installation a side-wall clinker chill and an overhanging water back are used to minimize refractory maintenance Over-fire air jets are directed angularly downward toward the rear of the furnace from a point just above the nose of the arch

At present a number of installations operating with Middle Western bituminous coal have furnaces in which arches cover a portion of both the front and the rear of the stoker This *combination-arch* arrangement did much to further stabilized ignition and improve combustion not only with these Middle Western fuels but also with anthracite, coke breeze, and lignite

Originally, when burning such undersize fuels as anthracite No. 4 buckwheat and river coal in front-arch furnaces, there was considerable carbon loss in fly ash and ashpit, even at low combustion rates The combination-arch furnace provided only a partial remedy Additional experimenting however, finally resulted in development of the *rear-arch* furnace With this design, well illustrated in Fig 8-39, stability of ignition is assured by utilizing the principle of raining particles of incandescent fine coal onto the incoming fuel This is accomplished through a modification in air distribution, coupled with the use of a long, low arch over the rear of the stoker

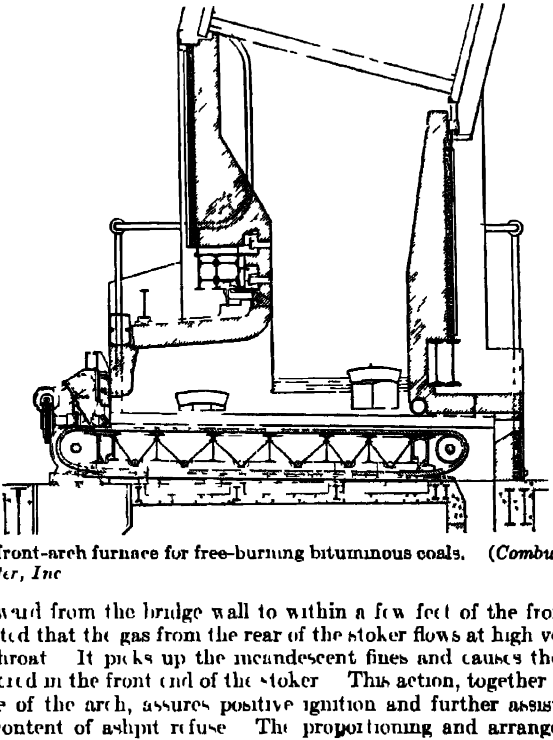

Fig. 8-47 A front-arch furnace for free-burning bituminous coals. (*Combustion Engineering Superheater, Inc*

extending forward from the bridge wall to within a few feet of the front wall The arch is so located that the gas from the rear of the stoker flows at high velocity toward the furnace throat It picks up the incandescent fines and causes them to be continually showered in the front end of the stoker This action, together with radiation from the nose of the arch, assures positive ignition and further assists in reducing combustible content of ashpit refuse The proportioning and arrangement of arch surface are governed by the fuel to be burned, capacity developed, and stoker proportions The length will vary from 60 to 75 per cent of stoker length, the height above the grate from 2 to 4 ft, and the throat opening from 3 to 7 ft Arches of this type lend themselves to the maximum of water cooling, and the amount of surface applied will be governed largely by the operating conditions

Over-fire air may be used to advantage even with rear-arch designs and their built-in furnace turbulence The operation of these jets maintains a high rate of turbulent mixing during low-load operation, when gas volume and velocity fall below their effective values

For the furnace design described the maximum continuous furnace-liberation rates should preferably be held to between 40,000 and 55,000 Btu per cu ft per hr. Combustion rates per pound of dry coal per square foot of grate per hour will vary from 30 for anthracite and coke breeze to 50 for subbituminous coal and lignite.

Pulverized Coal. The present-day pulverized-coal-fired furnace, regardless of firing method employed, is of water-cooled construction. Size of unit together with its pressure and temperature, space available, fuel characteristics, ash-fusion temperature, type of burner, and method of ash removal are all contributing factors. They not only determine furnace volume and extent of water cooling employed but also ultimate design of the steam-generating unit as a whole. The maximum continuous rate of heat liberation should preferably be held to between 15,000 and 22,000 Btu per cu ft per hr.

The type and number of burners used, as well as their arrangement, will determine furnace dimensions. Minimum front-to-rear depth is governed by the distance between burners and front row of tubes in boiler bank, which is required to assure completion of the combustion process. Width is governed by the horizontal spacing plus the distance that must be provided between the burner and furnace side walls to minimize the effect of any flame impingement. The height is selected so that the indicated furnace volume is obtained, but in no case may it be less than the minimum allowable distance between the bottom burner row above the furnace water screen, water-cooled hopper bottom, or slag hearth, plus the vertical spacing of burner rows, plus minimum allowable distance between top burner row and roof.

Furnace volume is usually determined by using the allowable heat-liberation rate for ash-fusion temperature and quality of the coal to be employed. Wherever possible, there should be provided a combination of volume and water-wall cooling that will result in a furnace outlet temperature which is below ash-fusion temperature of the lowest quality fuel it may be necessary to use. With coals having a high percentage of low-fusion ash, it is necessary to use greater furnace volume so as to increase the amount of water-wall surface that can be installed and thereby secure comparatively low gas temperature at the entrance to the boiler bank. With high steam temperature, the requirements of the superheater may govern furnace outlet temperature.

After required volume and minimum dimensions have been determined, the furnace is proportioned so that length, height, and width finally chosen will provide the most suitable design for available space conditions.

Finally to complete the furnace it is necessary to select the type of furnace-bottom construction that will be best suited to the installation

If the ash is to be collected and removed in a dry state, either the bottom water-screen or the hopper-bottom furnace construction should be used With the *water-screen* type of installation a series of tubes, tied into the circulation system of the water walls and boiler, is located above the furnace floor to provide a shielded and cooled zone in which the collected ash is maintained at a temperature below its fusion point. This construction is used for the units shown in Figs. 8-29, 8-31, and 8-42. In the *hopper-bottom* design the front- and rear-wall tubes are bent at their lower end to provide a floor slope greater than the angle of repose for ash. A self-cleaning water-cooled floor is thus formed. A transverse gap is provided in the hopper valley through which the ash is discharged to an enclosed pit This type of construction is particularly well adapted for the application of vertically adjustable burners as shown in Fig 8-37.

When the ash is to be collected and drained from the furnace in molten form, the *continuous-slag-tap* construction is used. With this design a water-cooled floor, covered with a layer of special refractory, forms the hearth on which the molten slag is collected. A slag-drip opening is located in the bottom near the center of the hearth. Around this opening a water-cooled ring is used to form a slag dam and drip ledge so that a relatively constant thickness of slag is maintained over the hearth. Any excess slag accumulation continually drips through this opening and is quickly quenched and shattered into granular form by dropping into a suitably enclosed water-filled chamber. This construction is illustrated in Figs. 8-32 and 8-35.

Liquid and Gaseous Fuels. When consideration is being given to the installation of oil- or gas-burning equipment, it is well to remember that results obtainable depend more on furnace design than on the burner. For best results, however, the two should be properly coordinated. Practically all units for either of these fuels are arranged for the alternate use of the other. While their appearance may therefore be the same, there is a marked difference in heat absorption throughout. With oil firing there is considerable radiant heat transfer to the furnace cooling surfaces owing to flame luminosity. With natural gas the flame is nonluminous, and therefore there is more convection heat transfer in the boiler section. This is particularly significant in superheater design, and if uniform performance is required of either fuel some means must be provided for by-passing a portion of the products of combustion around the superheater.

Furnace designs frequently follow accepted pulverized-fuel practice. The extent of water cooling is governed by temperature requirements at the superheater inlet, and furnace heat-liberation rates are preferably held to between 20,000 to 30,000 Btu per cu ft per hr at maximum continuous load point.

Types of Wall-cooling Surfaces. The most effective types of furnace wall-cooling constructions are ones which employ bare tubes, arranged to satisfy the requirements established by the several variables on which design is to be based.

The *bare-tube type* of construction may be defined as one in which the wall-cooling surface is composed of plain bare tubes or bare tubes having extended metallic surfaces welded to them. The cooling surface is directly exposed to furnace temperature and capable of absorbing heat at an extremely high rate. When plain tubes are used, they may be spaced on uniformly close or wide centers to cover the furnace wall areas that require protection. In the bare-tube types, with welded metallic extended surfaces or fins, there is unit metal construction without heat gaps capable of the same high rate of heat absorption as the plain tube. The two fins, each 1 in. wide, are located on diametrically opposite sides of the tube. The tubes are then spaced so that the gap between adjacent fins is $\frac{1}{8}$ in. Thus there is a continuous metallic surface forming the interior lining of the furnace.

With any type of water-cooled construction, downcomer tubes must be provided to supply the water-wall headers. Riser tubes must also be provided to complete the circuit and return the steam generated in the walls to the boiler. The flow areas of these downcomers and risers depend on the amount of wall exposed, the effective head of water on the wall, and the amount of heat absorbed. Illustrations of the several large steam generating units clearly show the extent of water cooling used as

Table 8-33

1. Fuel characteristics	Types of fuel available to plant: Ash content Ash-fusion temperature Comparative fuel prices Comparative operating efficiency Lower grade secondary fuel which it may be necessary to use if primary fuel source "dries up" Comparative operating costs with the available fuels: For handling fuel For handling refuse For repairs and maintenance For auxiliary power
2. Capacity and steam conditions	Maximum continuous capacity Extent, duration, and frequency of peak loads Design or operating pressure Steam temperature if superheat is required Feed-water temperature
3. Space conditions	Cubical contents of space available or required Shape of space
4. Cost..	Comparative cost of designs considered High- or low load-factor plant Value of reliability and flexibility Value of incremental increase or decrease in efficiency Operating costs for use in economic evaluations
5. Individual preference	Experience or familiarity: In a particular plant or industry With a certain type of fuel or equipment Uniformity with old equipment already installed should not jeopardize value of plant extension or betterment

well as the arrangement of downcomer and riser systems which tie the wall surface into the boiler circuit

EQUIPMENT SELECTION

The ability properly to select and coordinate equipment so as to produce a well-designed steam-generating unit requires not only a broad background of experience which covers each separate element and its relation to the others but also a wide variety of available designs in order that the particular needs of a given project may be satisfied No attempt will be made to discuss the many details that enter into equipment selection The principal factors, however, which exert most influence, together with some of the secondary ones, are outlined in Table 8-33

Table 8-33*a*. Fuel-burning and Steam-generating Equipment Combinations

Boiler types	Continuous capacity ranges Pounds of steam per hour				Design pressure range	Steam temperature range
	1,000 to 15,000	15,000 to 35,000	35,000 to 200,000	150 000 to 1 000 000		
Firetube	Hand fired Single retort Multiple-retort Spreader stoker Traveling-grate Oil Gas	▨	▨	▨	Up to 250 psi	Up to 150 deg F superheat
3 Drum low-head		Single-retort Multiple-retort Spreader stoker Traveling grate Oil Gas	▨	▨	Up to 400 psi	Up to 150 deg F superheat
2-Drum * vertical			Multiple-retort Spreader stoker Traveling grate Pulverized coal Oil Gas	Traveling grate ** Multiple retort ** Continuous ash discharge spreader ** Pulverized coal Oil Gas	Up to 1000 psi	900 F
3 or 4 Drum vertical	▨				Up to 1500 psi	925 F
Sectional header	▨			▨	Up to 2000 psi	900 F
Special utility type	▨	▨	▨	Pulverized coal Oil Gas	Up to 2500 psi	1050 F ***

* Up to 225,000 lb per hr on Coal and 300 000 lb per hr on Oil and Gas
** Occasionally for capacities exceeding 200 000 lb per hr
*** Present maximum used Design and materials available for higher temperature

The most frequently encountered combinations of fuel-burning and steam-generating equipment, together with capacity, pressure, and steam-temperature ranges, are shown in Table 8-33*a* This table is intended to serve no purpose beyond providing a convenient comparison of the various equipment combinations used for the several operating conditions There is no satisfactory short cut to equipment selection, and final decision should, therefore, always reflect the seasoned judgment of engineers who have specialized in steam-plant engineering

LOCAL AND REMOTE GRAPHIC POWER MEASUREMENTS AND TOTALIZING*

BY W. E. PHILLIPS

Section Head, Engineering Dept., Leeds and Northrup Company

Graphic instruments, which make a graph of an electrical quantity as a function of time, have become increasingly important in the study, operation, and control of electrical power systems and also to consumers of electrical power. The development of new principles, the demand for increased speeds of response, and the adaptation of established principles to new designs have resulted in a wide diversity of instruments. It is the purpose of this subsection to describe well-established principles and designs used in the graphic metering of electric power and related quantities and the telemetering of these measurements.

Graphic meters are commonly referred to as "recording instruments" or by the simpler term "recorders."

Telemetering of electric power and related quantities will also be described. The American Institute of Electrical Engineers defines telemetering as the indicating, recording, or integrating of a quantity at a distance by electrical translating means. It is possible to extend current and potential transformer secondary or similar leads so that a reading may be obtained at a considerable distance, but the extension of leads in this manner will not be considered telemetering. Totalizing of electric-power measurements will be defined for purposes of this text as the recording of the algebraic sum of several individual measurements. In general, individual and totalizing recorders will be at the same location.

UTILIZATION OF GRAPHIC POWER MEASUREMENT

Graphic power measurements are found to be *necessary* to the operation of electrical power systems and industrial plants under normal as well as abnormal conditions. Their use can be broadly classified under the headings of electrical generating stations, electrical power systems, and industrial-plant operation.

NOTE: For purposes of this discussion, the term "electrical power system" is defined as a multiplicity of electrical generating stations operated as an integrated system under the supervision of a central-system operator.

Operation of Electrical Generating Station. The utilization of graphic power measurements in individual electrical power plants is widespread, and the following applications are typical:

1. The graphic recorder is used by the operator to ensure that the station is delivering its assigned schedule of electrical load.
2. The graphic recorder is an excellent medium for operating a remote indicating system of which the Selsyn system is typical. A system of this type provides a visual indication for the turbine and boiler rooms of the station load by means of large-dial indicators.
3. Automatic control of unit and station load has become increasingly important, and devices have been added to the graphic instruments to provide the necessary intelligence and limiting features for the automatic control.
4. Graphic power records are helpful in the economic studies of unit and station efficiencies since the graphic record of power output can be compared with the charts of steam flow, temperature, pressure, etc.

---

* Superior numbers refer to specific references listed at the end of this subsection.

System Operation. The practice of telemetering electrical power and allied quantities to a central point, usually the system operator's office, is now considered to be necessary for the intelligent and efficient operation of power systems. Telemetering has been termed the "eyes" of the system operator since it enables him at a glance to determine that the electrical power system is functioning as desired.

Some of the advantages of having station generation and major tie-line loads telemetered to the system operator's office and the totalizing of these loads to obtain total system generation,[*] total interchange,[†] system "net" load,[‡] etc., are as follows:

1. With the enormous growth of power systems, both as to the number and the capacity of the generating stations, most of the system operator's time would be consumed in obtaining telephoned data if telemetering were not provided. Telemetering reduces verbal communications by at least 50 per cent, thus relieving both system and station operators for other duties without constant interruption Under extreme conditions, when verbal communication between the station and system operator has been interrupted, it has been possible to operate for more than a day with telemetering as the only link

2. Telemetering provides a means of loading a system on a prearranged basis Such a loading means might conceivably consist of telemetering to each generating station the total system load and assigning to each station a scheduled output for each system load. Thus each station operator can determine immediately that his station load is correct.

3. Telemetering is used to give the system operator a continuous record of the individual tie lines to adjacent systems, and by totalizing the algebraic sum of these tie lines a reading of net interchange is obtained. Thus the system operator is informed at all times as to the interchange loadings

4. The value of telemetering at times of system trouble or under abnormal conditions is not subject to any strict evaluation. It has been found in some cases that major interruptions and trouble have been prevented because the system operator has had prompt and complete information regarding the loads on different parts of the system. With this information it has been possible intelligently to isolate parts of the electrical system and continue operation without serious outages

5 The records of the graphic instruments are found to be of value when economic and load-growth studies are being made of a power system.

6. The trend in automatic load-frequency control at the present time is to locate the master control elements at the system operator's office. Thus telemetering and totalizing perform many functions in connection with the automatic load frequency control.

Industrial-plant Operation. The utilization of graphic meters for measuring electrical power and related quantities in industrial plants is legion, and their use is an absolute necessity if optimum economic and efficient results are to be approached with respect to the cost of electrical power

In general, most electrical rates consist of an "energy" and a "demand" charge In addition, the rate schedule may include other charges based on power factor, fuel costs, etc.

The energy charge is based on kilowatthours consumed during the month, and usually the cost per kilowatthour decreases with increased consumption

The demand charge is usually based on the maximum rate at which kilowatthours are used over a specified period, usually 15 min for industrial loads. This charge is intended to cover the fixed costs of the equipment which the utility company must provide to supply this maximum demand A high maximum demand is often the result of a few peaks caused by abnormal and perhaps avoidable conditions In some cases the monthly demand charge for an entire year may be based on the maximum demand which was registered during a single abnormal period Thus the cost of a single peak may be enormous.

Graphic power and power-factor recorders can be used to study and also provide a continuous record of the plant load and power factor. In many instances a new peak demand may be avoided by disconnecting a portion of the electrical load for only a few minutes. In other cases possibly a rescheduling of work to prevent coincident peaks in different departments may produce the desired result.

---

[*] Total system generation is the sum of the loads on all generators on the system

[†] Total interchange is the algebraic sum of power interchange with adjoining power systems

[‡] System net load is the total system generation plus the power being fed into the system minus the power being fed out of the system over its interconnecting tie lines with adjacent systems

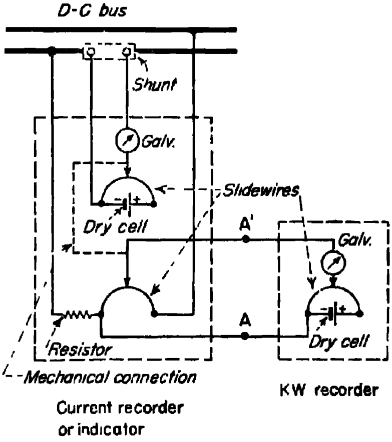
Power factor may be improved by ensuring that motors are not oversized, by installing overexcited synchronous motors, or by installing capacitor banks.

The graphic power meter is also useful in many processes. A typical example is one which occurs in the chemical industry in connection with stirring. As the chemicals are stirred they go through a critical point where the viscosity changes rapidly. A record of the power input to the motor driving the stirring mechanism provides an excellent indication of when this critical point is reached.

PRIMARY ELEMENTS USED FOR GRAPHIC MEASUREMENTS

Direct Current and Voltage. The d'Arsonval (moving coil, permanent-magnet field) measuring element is used almost exclusively for the graphic metering of direct current and voltage. This type of primary element has been described widely in existing literature, and it is not felt to be necessary to describe it in this text.

Direct-current Watts. Two methods are commonly used for the graphic measurement of d-c watts. The first method employs an electrodynamometer as the measuring element. The current coil is connected to the output of a shunt which is in series with the load being measured. The potential coil is connected in the conventional manner. Since current is drawn over the leads from the shunt, it is necessary that the meter calibration take into account the resistance of these leads. Any change in the shunt-lead resistance will introduce an error in the reading. Errors are also introduced because of residuals and stray field effects so that the order of accuracy is lower than when an electrodynamometer is used for a-c measurements.



8-48. Measurement of d-c watts

A second method of measuring d-c watts, which overcomes the objections of having to take into account shunt-lead resistance and results in accuracies of high order, consists of two recorders connected as shown in Fig. 8-48. The instrument that measures current may be an automatically balanced indicator rather than a recorder.

The current recorder or indicator operates on the potentiometer principle from the millivolt drop of the current shunt. Since it is a conventional potentiometric measurement, the accuracy is independent of the lead resistance between the shunt and the recorder or indicator. A retransmitting slide-wire is mounted on the current recorder or indicator and moves with and assumes the same position as the recorder or indicator measuring slide-wire. A potential proportional to the d-c bus voltage is applied to this retransmitting slide-wire.

The output potential from this slide-wire, *i.e.*, the potential between *A-A'* (Fig. 8-48), is proportional to the current recorder or indicator position and the d-c bus voltage. More exactly, it is proportional to the product of the current and voltage which is watts. It should be noted that the voltage across the retransmitting slide-wire is independent for all practical purposes of the resistance of the leads connecting the slide-wire to the bus potential since the slide-wire and its series coil, which are made of extremely low-resistance temperature-coefficient material, have a total resistance of approximately 60,000 ohms.

The output of this retransmitting slide-wire is recorded potentiometrically by the kilowatt recorder (Fig. 8-48).

The measurement of kilowatts is based entirely on the potentiometric principle, except for the supplying of the bus potential to the retransmitting slide-wire, and consequently the accuracy is inherently of high order. As was pointed out previously, the method of supplying the potential to the slide-wire introduces no practical error.

Alternating Current. The primary elements used in connection with graphic measurements of a-c power and related quantities are the thermal wattmeter, the electrodynamometer, the induction-disk watt-hour meter, and the Kelvin balance. The principles and theory of the latter three have been thoroughly explained in previous literature, and it is not necessary that they be repeated.

The thermal wattmeter, which is the newest of the primary elements adapted to graphic metering, produces a d-c millivoltage proportional to input watts. It is in all respects a true wattmeter—the polarity of its output reverses with reversal of watts; it measures the product of voltage, current, and the cosine of the angle between them; it is independent of wave shape to a high degree because of the fact that its output depends on heating (root-mean-square) values.

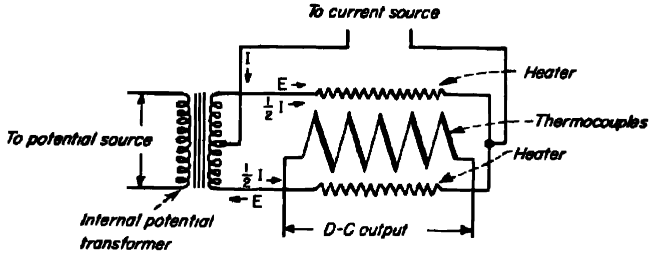


FIG. 8-48a. Thermal wattmeter.

The theory of one type of thermal wattmeter, commonly referred to as a "thermal converter"—which is typical of all—will be readily understood from the following explanation.

A single-element thermal converter, complete with its internal potential transformer, is shown in Fig. 8-48a. Two such elements are used for conventional three-phase, three-wire metering.

The current and potential circuits are connected to the thermal converter as indicated in Fig. 8-48a. The current I divides as shown so that one-half flows through each heater. The potential causes a current designated as E to flow through both heaters in series. It should be noted that these two currents are in the same direction in the top heater and in opposite directions in the lower heater. It will be clear by inspection that the vector sum of the currents in the upper heater will be greater than that in the lower heater when the phase angle between the two currents I and E is less than 90 deg. Thus more heat will be produced in the upper heater than in the lower heater since the heaters have equal and constant resistances. Small thermocouples are located adjacent to the heaters, and the thermocouple junction at the upper heater is raised to a higher temperature than that located at the lower heater. The output emf of the thermocouples is proportional to this difference in heating which in turn is proportional to watts input to the thermal converter. This is demonstrated mathematically as follows:

Using E as a reference vector, $\dot E$ and I may be expressed as follows when the current is leading the voltage by θ°.

$$\text{Vectorial } E = \dot E = E + j0$$
$$\text{Vectorial } I = \dot I = I\cos\theta + jI\sin\theta$$

The current in upper element is

$$\dot E + \tfrac{1}{2}\dot I = \sqrt{(E + \tfrac{1}{2}I\cos\theta)^2 + (j\tfrac{1}{2}I\sin\theta)^2}$$

The heating in the upper element is proportional to the current squared. Thus

$$\text{Heating in upper element} = (E + \tfrac{1}{2}I\cos\theta)^2 + (j\tfrac{1}{2}I\sin\theta)^2 \qquad (1)$$

The current in the lower element is

$$\dot{E} - \tfrac{1}{2}\dot{I} = \sqrt{(E - \tfrac{1}{2}I\cos\theta)^2 + (-j\tfrac{1}{2}I\sin\theta)^2}$$

The heating in the lower element is proportional to the current squared

$$\text{Heating in lower element} = (E - \tfrac{1}{2}I\cos\theta)^2 + (-j\tfrac{1}{2}I\sin\theta)^2 \qquad (2)$$

The difference in heating is proportional to Eq. (1) − Eq. (2) =

$$(E^2 + EI\cos\theta + \tfrac{1}{4}I^2\cos^2\theta - \tfrac{1}{4}I^2\sin^2\theta) - (E^2 - EI\cos\theta + \tfrac{1}{4}I^2\cos^2\theta - \tfrac{1}{4}I^2\sin^2\theta) = 2EI\cos\theta \qquad (3)$$

Since 2 is a constant of calibration, the difference in heating is proportional to the product of E, I, and the cosine of the angle between them, which is power.

CONNECTION OF PRIMARY ELEMENTS

Alternating-current Watts. The connection of the primary elements for measuring polyphase a-c power is subject to considerable latitude on the part of the engineer. In general, the problem resolves itself into the equating of cost against required accuracy, keeping in mind the degree of unbalance between phases which may be experienced.

Totalizing current transformers are sometimes used so that the currents of several circuits may be totalized. This permits the use of only one primary measuring element for the measurement of several circuits. The use of totalizing transformers introduces certain hazards in that several current-transformer secondary circuits are brought into a common piece of equipment, *viz.*, the totalizing transformer. The possibility of trouble spreading from one secondary circuit to another is thus increased. Also the use of totalizing transformers is limited owing to the fact that all circuits must be in parallel, *i.e.*, supplied from a common bus.

Many different and special connections have been used for measuring a-c power. However, the connections employed in most cases are those described in the following paragraphs. Only three-phase metering will be considered since practically all graphic metering is confined to three-phase systems.

The fundamental principle upon which polyphase-power measurement is based is that enunciated by Blondel. This theorem states that for a system of N conductors the total power can be measured by means of $N - 1$ wattmeter elements.

As an illustration of this principle, if a three-phase system having a grounded neutral return is examined, it will be seen that it is in reality a four-wire system, and consequently three elements are required for correctly measuring the power under any condition of load unbalance. If we consider the above system further and state as a premise that no current flows through the ground-return circuit, it can be considered to be a three-wire system, and the power can be measured correctly by two wattmeter elements. As a further step in considering such a system, if we state that the load on all three phases is identical, *i.e.*, balanced voltages and currents and the same value of power factor, one element measuring the power in one phase only has a constant relation to the total three-phase power and can be used as measure of total three-phase power.

The connections and vector diagrams for these types of metering are shown by Figs. 8-49*a*, 8-49*b*, and 8-49*c*.

A modification of a two-element meter is quite often employed when measuring the power in a three-phase circuit with a grounded neutral. This is commonly referred to as $2\tfrac{1}{2}$-element metering and has the advantage that it measures the three-phase power correctly for unbalanced currents.

The connections and vector diagram for this type of metering are shown by Fig. 8-50. The vector diagram shows balanced voltages. The currents are unequal in magnitude and displaced by different phase angles with their respective voltages.

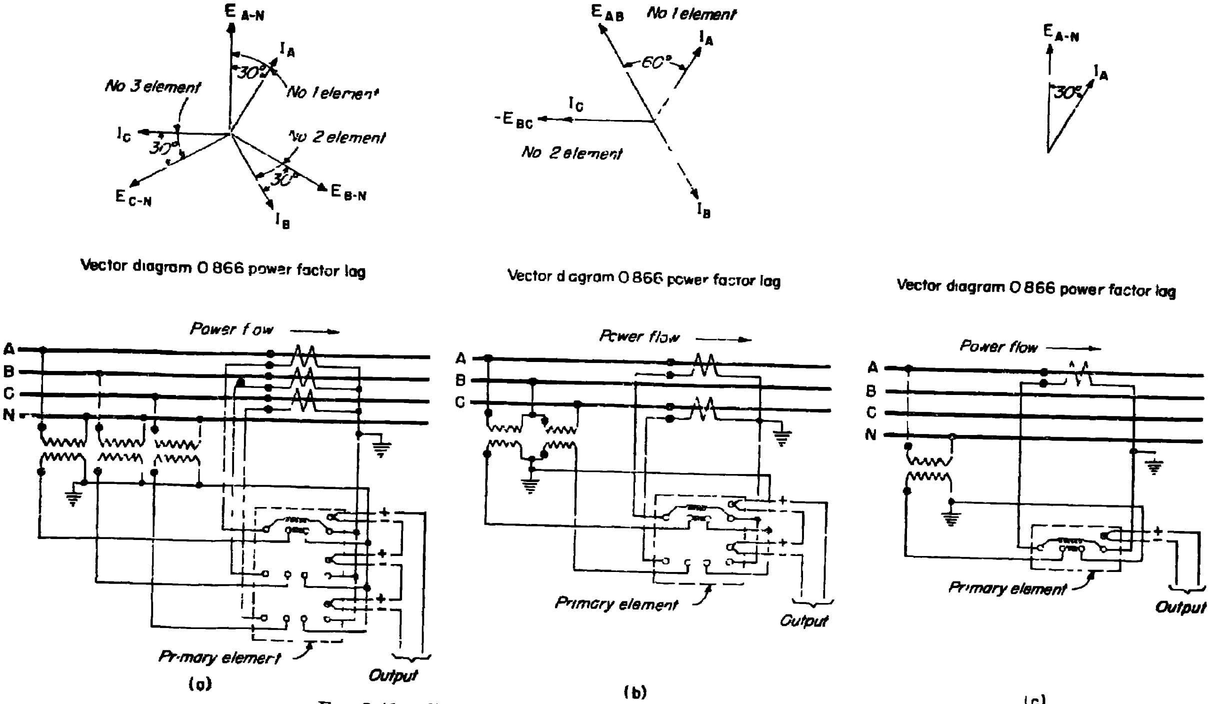

Fig. 8-49 Connections for measurement of three-phase power.

The currents in phases 1 and 3 react with their respective voltages, and the current in phase 2 is reversed and reacts with the potentials of phases 1 and 3.

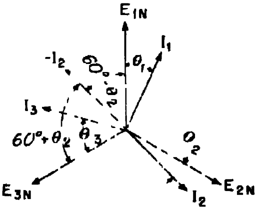
The metering can be expressed as follows:

$$\text{Metered phase 1 power} = E_{1n}I_1 \cos\theta_1 \tag{4}$$

$$\text{Metered phase 3 power} = E_{3n}I_3 \cos\theta_3 \tag{5}$$

$$\text{Metered phase 2 power} = E_{1n}I_2 \cos(60^\circ - \theta_2) + E_{3n}I_2 \cos(60^\circ + \theta_2) \tag{6}$$

If the voltages are equal in magnitude, then as far as magnitude is concerned we can write $E_{1n} = E_{3n} = E_{2n}$, and Eq (6) reduces to $E_{2n}I_2 \cos\theta_2$. The total for the three phases is the sum of the power measured on the individual phases which in this case is correct for total three-phase power.



Vector diagram

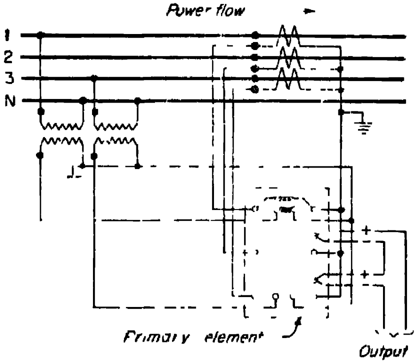


Fig. 8-50. Two and one-half-element metering.

Reactive Volt-ampere Measurement. As in the measurement of a-c watts there is considerable latitude in the connections which may be employed in the measurement of reactive volt-amperes, but the method which is used universally for the measurement of reactive volt-amperes on three-phase circuits is that of cross phasing the potential circuits with respect to the current circuits. This cross phasing may be accomplished merely by connecting the voltage coils across the phases opposite to that in which the current coil is connected as shown by Fig. 8-51*a* and 8-51*b* or by using phasing transformers as shown by Fig. 8-52*a* and 8-52*b*. The latter method, which is most generally employed, has the advantage of greater accuracy but is somewhat more complicated.

Unfortunately, there is no method available for accurately metering reactive volt-amperes of a three-phase circuit when both currents and voltages are unbalanced. A detailed analysis of the errors is beyond the scope of this section. The errors arising from unbalanced load conditions are most readily determined by the use of symmetrical components. This is covered in a very comprehensive manner by A. E. Knowlton.[1]

Power-factor Measurements. Power-factor meters at the present time are most generally used in connection with the metering of industrial loads. (On power systems power-factor meters have been, to a large extent, replaced by kvar meters.) Power-factor meters are (1) accurate only on balanced loads, (2) primarily for use on circuits where the power flow is in one direction, and (3) their sensitivity decreases as the current flow decreases. Crossed-coil electrodynamometer type of meters are used quite generally for measuring power factor. They usually employ two potential circuits and one current circuit.

Note.- Registration must be multiplied by 0.577

(a) (b)

FIG. 8-51. (a) Reactive volt-ampere measurement of three-phase, three-wire circuit using cross phasing. (b) Reactive volt-ampere measurement of three-phase, four-wire circuit using cross phasing.

A method employing a thermal converter, which is connected in the same manner as a two-element wattmeter, measures the ratio of the millivolt outputs of the two elements. The connections of the primary element and the recorder for measuring the ratio of the millivolt output is shown by Fig. 8-53.

The output of the element 1 is proportional to $EI \cos (\theta + 30°)$, and the output of element 2 is proportional to $EI \cos (\theta - 30°)$. When θ is zero (unity power factor), the outputs of the two elements are equal (balanced load conditions assumed), and the ratio of the two outputs is unity. Thus the recorder balances at its midpoint. This mid-point on the scale is marked unity power factor. When the power factor is 0.5 lag, θ is 60 deg, and the output of element 1 is zero. Thus the recorder moves to the high end of the scale which is marked 0.5 power factor—lag. When the power is 0.5 lead, the conditions of output are reversed, and the recorder moves to the low end of the scale which is calibrated 0.5 power factor—lead. At intermedi-

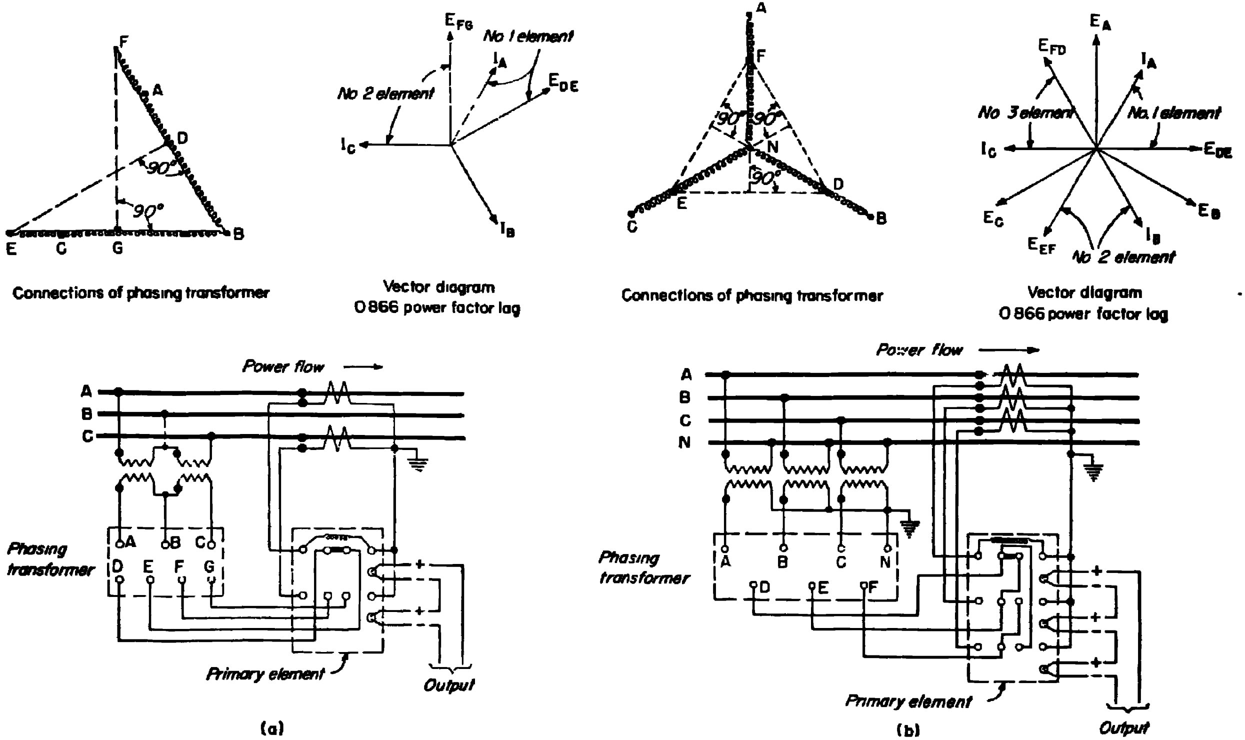

FIG. 8-52. (a) Reactive volt-ampere measurement on three-phase, three-wire circuit using phasing transformers. (b) Reactive volt-ampere measurement on three-phase, four-wire circuit using phasing transformers.

ate values of power factor the recorder balances at intermediate points along the scale.

Alternating-voltage and -current Measurements. For the measurement of alternating voltage or current any of the primary elements listed for a-c measurements under Primary Elements Used for Graphic Measurements can be used. They all produce a squared scale for both voltage and current.

The thermal type of primary element offers certain advantages in that its output can be connected directly to a full metallic telemetering channel without the use of auxiliary equipment. It also offers certain advantages when it is desired to record several voltages and or currents on a single chart which is commonly done by means of a multiple-point recorder.

TELEMETERING PRINCIPLES

The systems most commonly used for the telemetering of electric power and related quantities may be classified as follows:

1. Direct-current Systems
   a. Current
   b. Voltage
2. Impulse Systems
   a. Time duration
   b. Frequency
   c. Impulse matching

Direct-current Systems. The system of telemetering which employs direct current as a translating means may take several different forms. The systems employing this translating means produce the necessary d-c voltage so as to cause a direct current to flow in a telemetering channel. This current is maintained at a definite ratio with the primary quantity being measured. The current corresponding to full-scale reading varies from 5 to 30 ma depending on the manufacturer.

The transmitting principle with all systems is such that changes in the circuit resistance through which the current flows and also changes in supply voltage to the power supply are automatically compensated.

The Esterline-Angus long-distance recorder, the General Electric Company torque-balance transmitter, and the Leeds and Northrup Company current-balance transmitter are typical of current-balance transmitters.

The first two enumerated above employ grid-controlled vacuum tubes to produce the required telemetering current. The torque-balance transmitter (Fig. 8-54) consists of an optical system, a lamp, two photoelectric tubes, and two three-element vacuum tubes. The restraining element, through which the telemetering current flows, sets up a torque opposing that of the operating element. If these two torques are not equal, the suspension on which the mirror is mounted will turn to a new position and decrease the light on one photoelectric tube and increase the light on the other. The photoelectric tubes by means of their light-sensitive characteristics will bias one three-element tube to conduct less current and will bias the other to conduct more. The difference in these two currents is the current which flows in the telemetering channel and also the restraining element. When the torque of the restraining element equals that of the operating element, the mirror remains stationary in the position required. The system is suitable for operating with a zero-center wattmeter. The polarity of the telemetering current will reverse with a reversal of power flow through the wattmeter.

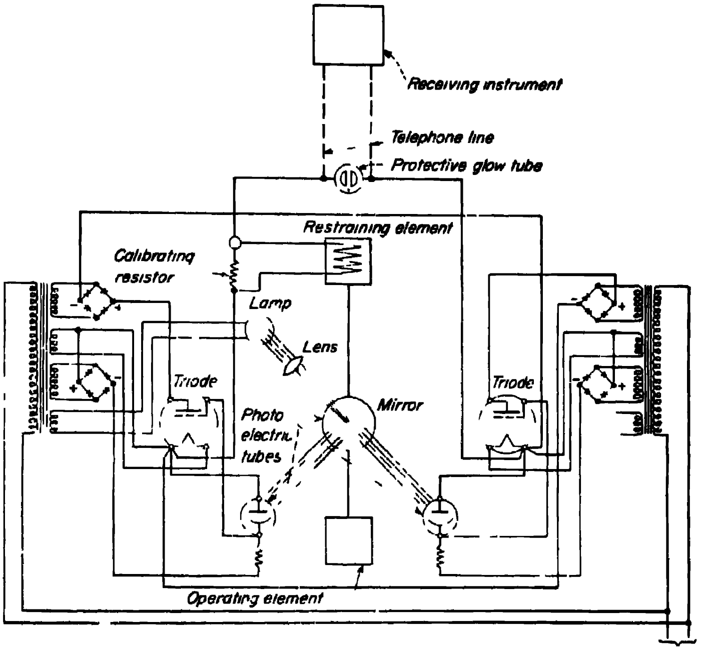

Fig. 8-54. Torque-balance transmitter.

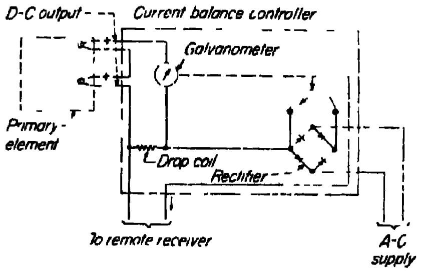

Fig. 8-55. Current-balance transmitter.

The Leeds and Northrup Company current-balance transmitter (Fig. 8-55) uses a Lincoln thermal converter as a primary element. The d-c output of the thermal converter is compared with the voltage across a "drop" coil which is connected in series with the telemetering circuit so that the d-c voltage across this coil is proportional to the current flowing in the telemetering channel.

Any difference between the thermal converter and "drop"-coil voltages will be detected by the galvanometer and by means of the mechanical (Micromax) amplifying system will vary the voltage, which sets up the telemetering current, until a balance is achieved. Thus, a definite relation is maintained between the thermal-converter output and the telemetering current.

Any number of receivers may be connected in series with the d-c system so that the same reading may be obtained at widely separated locations. The receivers may be recorders of the milliampere or potentiometer type, or an indicating milliammeter may be used when a record is not desired.

The d-c system is used with metallic circuits up to 100 miles in length and has certain advantages when the noise level of the circuit is high. It is readily apparent that the noise voltage across the receiver terminals is the product of the current produced in the loop telemetering channel by the noise voltage and the receiver resistance. The receiver resistance is usually in the order of a few ohms so that the noise voltage across the receiver is only a small fraction of the total noise voltage in the circuit. For example, if the total telemetering-channel resistance is 1,000 ohms and the receiver resistance is 10 ohms, only 1 per cent of the noise voltage appears across the receiver terminals.

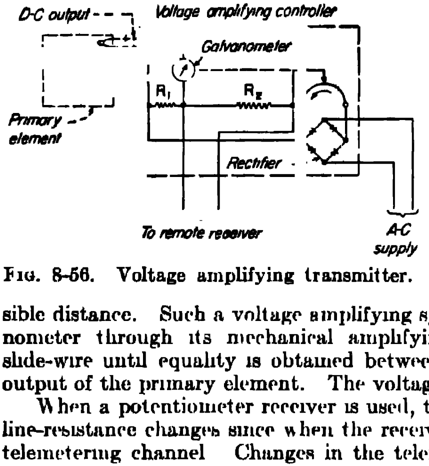

FIG. 8-56. Voltage amplifying transmitter.

Direct-current Voltage Systems. Direct-current voltage systems use a d-c voltage, usually of small magnitude, as a translating means. The d-c voltage system usually employed, where the distance does not exceed 20 to 30 miles and no unusual noise voltages are encountered, is that employing a thermal converter as the primary element and a potentiometer recorder as a receiver.

When distances are greater than noted above, a voltage amplifying system can be used to extend the permissible distance. Such a voltage amplifying system is shown in Fig. 8-56. The galvanometer through its mechanical amplifying system adjusts the contact of the slide-wire until equality is obtained between the voltage across R_1 and the voltage output of the primary element. The voltage amplification obtained is R_2/R_1.

When a potentiometer receiver is used, the voltage system is also independent of line-resistance changes since when the receiver is balanced no current flows over the telemetering channel Changes in the telemetering-channel resistance due to temperature variations affect only the sensitivity and not the inherent accuracy of the system.

Slow-rate Impulse Systems. *Time Duration.* Several telemetering systems utilizing the length of impulse in a cycle repeating at constant intervals are now in general use.

These are typified by the Builder's Iron Foundry Chronoflo system, The Leeds and Northrup Company Micromax Ballistic system, and the Bristol Company Metameter system.

The principle employed in the Chronoflo and Metameter systems utilizes the time between successive impulses as well as the length of the impulse. It is evident that, for the constant telemetering cycle, if the impulse become longer, the time between impulses becomes shorter and vice versa. The transmitter (Fig. 8-57) consists of cam, synchronous motor, rocker bar and magnet, and cam shoe and arm.

In operation, the cam rotates at a constant speed making a complete revolution in 15 sec (1-min or 4-sec cycles are used for some services). The cam-shoe arm swings in a plane parallel to the face of the cam and rides between the cam and the rocker bar. As the leading edge of the cam engages the cam shoe, the rocker bar is moved forward, carrying the magnet away from the mercury switch and causing the switch contacts to close.

Since the cam-shoe arm is positioned by the measuring element, the length of time that the cam shoe rides on the cam, and consequently the length of time that the switch is closed, will vary in accordance with the quantity measured.

The receiver (Fig. 8-57) consists of a relay, magnetic "up" and "down" clutches, synchronous-motor clutch drive, and pen-arm positioner. The motor, running continuously, drives the clutch gears in opposite directions. When the two-wire signal circuit from the transmitter is closed, the relay is energized and in turn closes the circuit which energizes the "up" clutch, and the pen-arm positioner travels outward as long as this clutch is engaged. Conversely, when the circuit from the transmitter is open, the relay is deenergized, thus energizing the "down" clutch, and the pen arm positioner moves inward. Once each cycle, therefore, the pen (or pointer) is accurately and positively positioned to the correct reading.

If the frequency of the supply to the transmitter and receiver are the same value, there is no inherent error in the telemetering system. If the frequency applied at the transmitter is higher than that of the receiver, the receiver will be proportionately insensitive. When the frequency at the receiver is higher than that at the transmitter, the receiver will oscillate or hunt around the correct reading proportional to the difference of the frequencies.

The Leeds and Northrup Company Micromax Ballistic system of telemetering operates on a 2.4-sec cycle. The transmitter consists of Micromax potentiometer-type load recorder which generates impulses proportional in length to the transmitter reading.

The receiver consists of a standard Micromax balancing mechanism operating in conjunction with a ballistic galvanometer, hence the name Micromax Ballistic system of telemetering.

The receiver measuring circuit (Fig. 8-58) takes the form of a bridge which is supplied from a rectified d-c source. The bridge form of circuit makes the measurement independent of drifts in the voltage supply.

The relay contact F_1 is closed by the transmitter and remains closed for a time equal to the length of the transmitter impulse. The closure of F_1 charges capacitor C through the high resistance R.

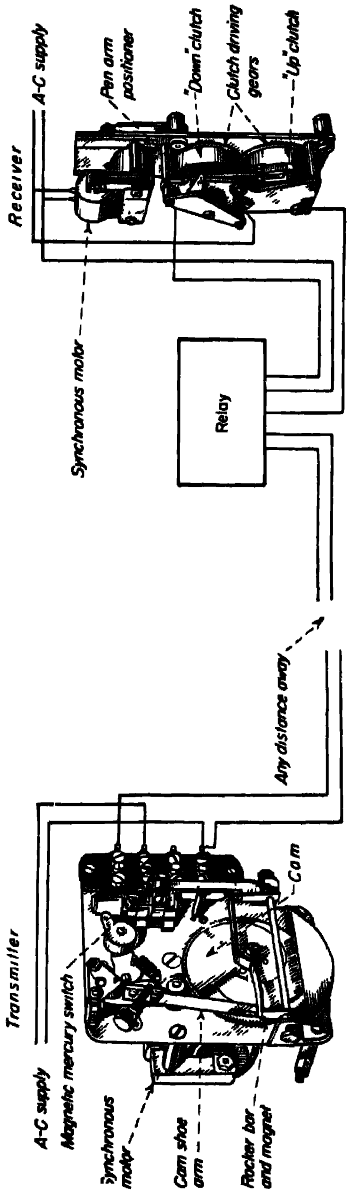

Fig. 8-57. Chronoflo telemetering system.

The voltage across the capacitor at the end of the transmitted impulse, which bears an exponential relation to the length of the impulse, is measured ballistically by the closure of interrupter I_1. If the capacitor voltage differs from that obtained from the slide-wire at the point of contact, the galvanometer receives a ballistic "kick" when interrupter I_1 closes. Immediately after the galvanometer deflects, the Micromax mechanism clamps the galvanometer pointer when it has deflected to its maximum position and moves the recorder slide-wire—pen moves with the slide-wire—to a position where the two voltages are equal. If there is no further change in the length of the transmitter impulse, subsequent closures of I_1 will not cause the galvanometer to deflect since the capacitor and the slide-wire voltage at the contact point are equal.

After the voltage of the capacitor has been measured, the capacitor is discharged by the shorting interrupter I_2 so that the capacitor starts the next charging cycle from zero voltage. The time constant of this RC circuit is approximately ten seconds so that for the maximum length of impulse—approximately two seconds - the capacitor voltage is still on the more linear part of the exponential charging curve The effect of this small departure from linearity is eliminated by shunting a portion of the slide-wire by means of resistor R_1.

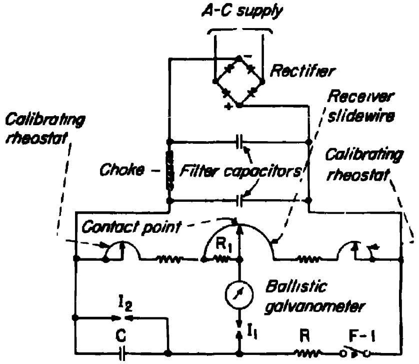

FIG. 8-58. Micromax Ballistic telemetering receiver circuit.

Means are provided for automatically synchronizing the receiver with the transmitter so that the interrupters close at the correct point in the telemetering cycle. This synchronizing means also permits the operation of this telemetering system when the frequency at the transmitter and receiver differ by as much as 2.4 cycles. Under these abnormal frequency conditions the receiver record will be displaced with respect to the transmitter but will otherwise faithfully reproduce the transmitted quantity.

Impulse Matching. A type of telemetering in which both the transmitter and receiver generate impulses proportional to their respective readings is typified by the Bailey Company Synchro-meter and the Leeds and Northrup Company type-MI telemetering.

The "Synchro-meter" (Fig. 8-59) consists of a transmitter and a receiver which are operated from power sources having the same frequency so that the cams C_1 and C_2 have the same time cycle. The contacts at the transmitter are pivoted at points C and M so that, as the quantity being measured increases, the upper contact moves upward, and the lower contact must consequently move up farther to close these contacts. Thus the time of contact is later in the cam cycle. The receiver operates in essentially the same manner except that its upper contact is positioned with the pointer of the receiver. If the transmitter and receiver have the same reading contacts, M_r and M_t will close simultaneously it is assumed for the moment that the cams are synchronized as regards phasing in the cycle—and close both shading-coil circuits of the induction motor with the result that the receiver does not move. As the receiver cam advances in its cycle, the mercury switch is opened before contacts M_r and M_t so that it is not necessary for these contacts to break any current. If the transmitter reading decreases, contacts M_t will close before contacts M_r and close the circuit of one shading coil of the induction motor, causing the receiver to decrease its reading. When contacts M_r close, they will close the circuit of the second shading coil of the induction motor, and the motor stops. The movement of the receiver is thus proportional to the difference in the readings of the transmitter and receiver. When the transmitter reading increases, contacts M_r close first, causing the receiver reading to increase. As noted in the foregoing, the cams must be correctly phased in the cycle. This is accomplished by means of an auxiliary circuit which, by interrupting the feed to the receiver cam motor, causes the receiver cycle to be retarded until it coincides in place with the transmitter cycle. The auxiliary circuit requires a third wire between the transmitter and receiver.

The type MI telemetering of the Leeds and Northrup Company operates on the same principle, but only a single circuit is required between the transmitter and receiver. The difference in the start of the impulses is used for synchronizing, and the difference at the end of the impulses is utilized for balancing the receiver.

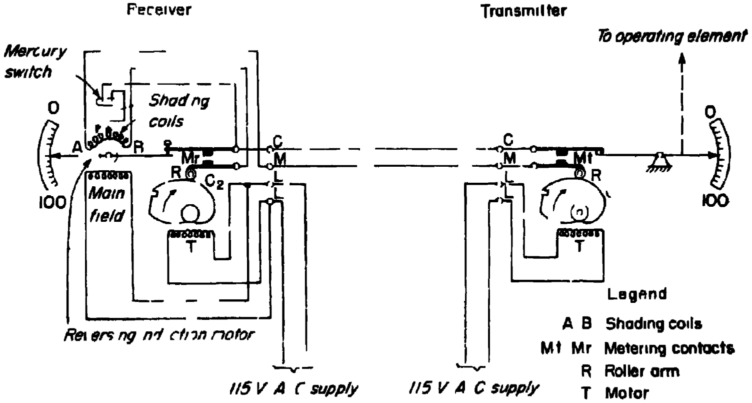

Fig. 8-[illegible]. Synchro-meter telemetering system.

These systems of telemetering are not affected by frequency variations when the frequency is the same at both the transmitter and receiver. The type MI telemetering system is arranged to produce a faithful record of the transmitted quantity—although slightly displaced—when the frequencies differ by an amount as great as 2.5 cycles.

High-rate Impulse Systems. High-rate impulse systems are generally understood to be telemetering systems which send from ten to approximately two hundred impulses per minute.

The Westinghouse system of impulse telemetering which operates over a range of 40 to 200 impulses per minute is an example of this type of telemetering.

The transmitter consists of a conventional polyphase induction disk watt-hour meter carrying on the upper end of its shaft a commutator similar to that used on a d-c watt-hour meter. Alternate bars of the commutator are connected to a slip ring. In order that the receiving equipment does not have to operate down to zero impulses and also to take care of installations where power flow may be in either direction, a synchronous motor drives a brush around the commutator, making and breaking in the circuit which sends out the impulses. When the watt-hour meter is running, the rate of impulses is proportional to the algebraic sum of the speeds of the brush and meter. When the watt-hour meter is standing still, a so-called "base rate" of impulses is generated which is proportional to the synchronous motor speed.

The receiver uses the principle of releasing a constant quantity of electricity for each impulse. These charges are smoothed out into a steady meter reading by a smoothing circuit. The receiver is constructed as two units, one containing the glow-tube constant-voltage device, relay, and capacitors and the other the indicating or recording instrument. The schematic diagram is shown in Fig. 8-60.

The impulse operates the relay which transposes the leads to the 0.2-uf capacitor on a 90-volt d-c circuit. Since the capacitor is discharged and recharged in the opposite direction, the total charge represented by a change in relay position is 36 microcoulombs. The smoothing circuit consists of a choke coil in series with the meter and a condenser and copper-oxide rectifier in series, shunting the coil and meter. The impulse of current from the operation of reversing the condenser passes through the rectifier in the forward direction and is stored in the large capacitor from which it flows into the meter through the rectifier in the backward direction. The action of the rectifier in the charging of the capacitor is to stretch out the discharging time over what can be obtained with an ohmic resistor.

The choke coil serves mainly to reduce the ballistic kick given the meter pointer when an impulse is received. The receiving meter is designed with a very strong field which permits a high cemf to be developed with small motion and further serves to reduce pointer pulsations. The glow tube UX-874 is used to keep the voltage constant for charging the capacitor.

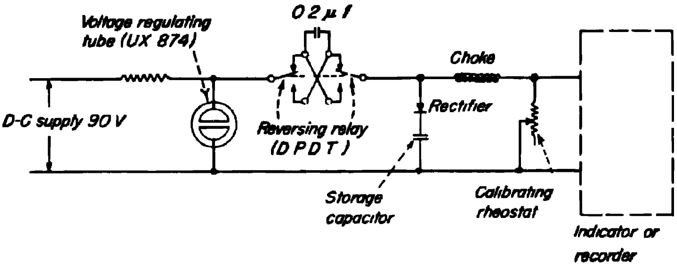

Fig. 8-60. High-rate impulse telemetering receiver.

Telemetering Systems Using Frequency as a Translating Medium. Frequency as a translating medium for telemetered data offers excellent possibilities for high-speed telemetering systems. A frequency system can be considered as an extremely high-rate impulse system. The use of an oscillator as a frequency source permits the rate of impulsing to be changed smoothly and, for the most practical considerations, instantaneously to a new value. If the primary measuring element which changes the oscillator frequency is fast, there is little delay in getting the change in frequency to the remote receiver.

With a continuously balancing type of receiver it is entirely possible to reduce the over-all response of the telemetering system to less than ½ sec.

The idealized system should have the following characteristics:

1. The frequency used should be between 20 and 100 cycles, and the band width should be in the order of 20 per cent of the base frequency used. For example, a range of 20 to 25 cycles or 80 to 100 cycles would be ideal from the standpoint of carrier-current transmission. Frequencies of this order take up very little space in the frequency spectrum, which is becoming more crowded as time goes on. Frequencies in this range also have the advantage of low attenuation when used on telephone circuits.

2. The receiver should, to a high degree, be independent of changes in the wave form which appears at its input terminals.

3. Variations of 40 db (100:1) in the amplitude of the voltage input to the receiver should not cause appreciable errors.

4. The speed of response of the components which constitute the telemetering system should be such that the over-all response does not exceed ½ sec. The use of a frequency lower than 20 cycles means that delay must be incorporated into the receiver, which shows up the response of the system.

5. The telemetering system should be independent of ambient temperature changes.

Some of the disadvantages of frequency telemetering systems employed in the past were:

1. The use of too high a frequency for translation
2. The use of too wide a band of frequencies
3. Insufficient stability as regards ambient temperature changes
4. Errors introduced by wave-form changes
5. Errors due to voltage variations

DIRECT-CURRENT TEIEMETERING CHANNELS

All telemetering systems which employ either direct current or voltage as a translating medium require a full metallic circuit. In special cases the earth may form the return conductor. This, however, is the equivalent of a metallic conductor. In all cases the insulation of the telemetering channel should be as good as the standards required in telephone practice

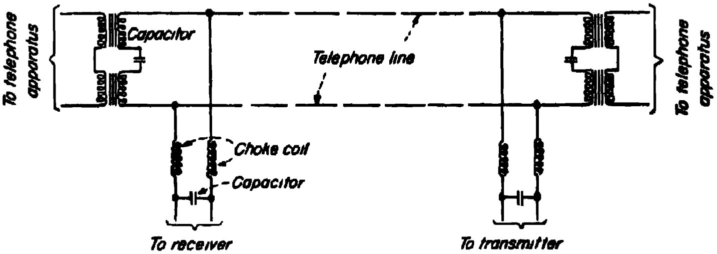

FIG. 8-61 Composite telephone circuit for telemetering.

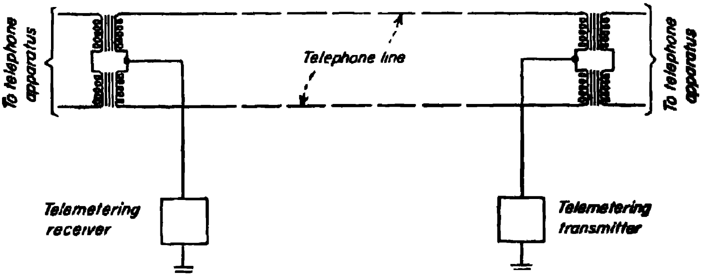

FIG. 8-62. Simplexed telephone circuit for telemetering.

The distance over which a reading may be telemetered is limited, from a practical standpoint, only by the cost of the telemetering channel. Telemetering readings for a distance of 100 miles is common practice.

Direct-current Voltage Systems. For all d-c *voltage* systems of telemetering which operate either on a few millivolts or several volts, a full metallic, ungrounded, circuit is essential. The circuit should also be balanced within commonly accepted limits.

Under special conditions it may be possible to use a composite circuit. The circuit as shown in Fig. 8-61 is typical.

Direct-current Systems. For direct-*current* systems the circuits described under Direct-current Voltage Systems may be used, and in addition, under certain conditions, a single wire with ground return or a simplexed telephone circuit as shown in Fig. 8-62 may be used.

In connection with d-c telemetering circuits it should be understood that the *most* *reliable and interference-free readings* are obtained when a twisted pair in lead cable, which is not simplexed or composited, is used as the telemetering channel.

IMPULSE-TELEMETERING CHANNELS

Impulse telemetering may be used with any circuit which will pass an alternating current. The circuit may be of the metallic type completed through a magnetic circuit or a dielectric circuit. This means that, in addition to the circuits which are used for d-c telemetering, lower grade metallic circuits as well as carrier-current circuits may be used for transmitting the telemetering impulses.

With carrier-current channels, which in most cases use existing high-tension lines for transmission, the cost of the transmission circuit is not a factor. Consequently, the transmission of telemetering signals a distance of 300 or 400 miles is not uncommon.

FACTORS AFFECTING CHOICE OF TELEMETERING SYSTEMS

The factors of reliability and over-all cost (channel plus telemetering equipment) determine largely whether direct current or impulse telemetering is used.

Reliability. Direct-current systems of telemetering are inherently more reliable than impulse-telemetering systems. In its simplest form a d-c telemetering system may have as its transmitter a thermal wattmeter whose d-c millivoltage output is connected directly to the telemetering channel Thus there are no moving parts and no auxiliary supplies required at the transmitter. The receiver consists of a standard potentiometer recorder.

An impulse system of telemetering, in its simplest form, consists of a primary measuring element which actuates a contacting device with the consequent wear on the contacting device and relays. Also one or more auxiliary power supplies is required for the operation of the system. In general, the receiving recorder for impulse systems is more complicated than that used with the d-c systems.

Since the d-c system has fewer moving parts than the impulse system, the order of reliability is higher.

Telemetering Equipment Costs. The cost of equipment required for d-c telemetering systems is less than that for a comparable impulse system so that, if the telemetering equipment were the primary cost, the d-c system would be used exclusively This cost, however, is usually not a very great item. The cost of the telemetering channel usually dictates the type of telemetering system used

Telemetering Channels. In metropolitan areas where the distances possibly do not exceed 20 to 30 miles, it is impractical to use anything but telephone lines to bring the telemetering signals to the system operator's office since this is usually located centrally in the area. In general, the generating stations and interchange points radiate in all directions from the system operator's office so that a separate telemetering channel is required for each point. Consequently, the d-c system of telemetering is usually used because of lower first cost and higher reliability. If it were desired to transmit a multiplicity of readings between a generating station and the system operator's office, the use of carrier frequency on the telephone cables, in conjunction with impulse telemetering, might be economically justified depending on the basis used for computing the channel rental.

When the telemetering is not in a congested area, the problem generall, resolves into equating the cost of the carrier frequency and the impulse-telemetering equipment to be used over existing high-tension circuits to that of the rental of a telephone channel and the cost of the d-c telemetering equipment. The factor of reliability should be given proper weighting in this comparison.

AUTOMATIC INTEGRATION OF GRAPHIC METER RECORDS

In many instances an integration of the quantity being recorded at the receiving end of a telemetering system is required. Also in some installations the integration of the total of several of the telemetered quantities as recorded on a totalizing recorder is necessary. Several methods, both mechanical and electrical, have been extensively used for this purpose.

An electrical method of integration commonly employed consists of a d-c retransmitting slide wire mounted on the recorder (Fig. 8-63) which operates in conjunction with an equivalent watt controller to produce an a-c wattage which is proportional to the recorder reading. As the d-c millivoltage of the retransmitter changes, it causes the galvanometer of the equivalent watt controller to deflect, and by means of the mechanical amplifying system of the controller the alternating current to the current element of the thermal wattmeter is varied until its d-c output balances that set up by the retransmitting slide wire. A conventional single-phase induction-disk watt-hour meter has its current coils in series and potential coils in parallel with the thermal wattmeter. Thus the watts imposed on the watt-hour meter are the same as those on the thermal wattmeter, and in turn the watt-hour meter load is proportional to the position of the retransmitting slide wire. The watt-hour-meter registration is thus an integration of the recorder chart or, to be more exact, is an integration of the electrical load being telemetered. The watt-hour meter, when equipped with contacts, operates a demand meter in the conventional manner.

Fig. 8-63. Integrating circuit for telemetered reading.

A typical mechanical type of integrator (Fig. 8-64) has a pivotally mounted member 1 which is rotated at constant speed around 6 as a center. Member 1, when in its lowered position as shown in Fig. 8-64, permits knife edge 11 to engage the toothed gear 8 and causes it to rotate with 1 in a clockwise direction until the projection 12 touches a fixed pin (not shown) and lifts assembly 1. When the assembly is lifted, the flipper 10, owing to its spring action, assumes a position whereby assembly 1 and the knife edge 11 are lifted and the toothed gear 8 is disengaged, and there is no further rotation of 8. It should be noted that the flipper 10 rotates with assembly 1. As the flipper rotates further it comes in contact with notch 14 on the bakelite disk 7. When the flipper drops into notch 14, it assumes the position shown, and the toothed gear 8 is engaged. The position of notch 14 is governed by the reading of the recorder. The movements of toothed gear 8 are summed up on a dial (not shown),

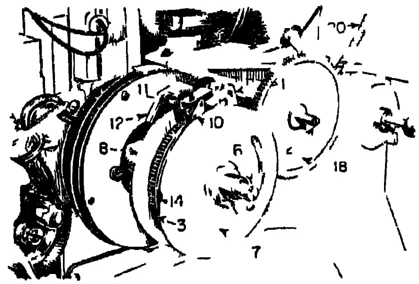

Fig. 8-64. Mechanical integrator for telemetered reading.

and thus the dial reading is an integration of the quantity being measured. Contacts for the operation of demand meters are mounted on an extension from the dial shaft.

TELEMETERING APPLIED TO AN INTERCONNECTED SYSTEM

Local and remote graphic power metering for a typical interconnected electric-power system may incorporate several types of primary elements and methods of transmission (Fig. 8-65).

FIG. 8-65. Typical installation of telemetering on an electric power system. System operator's office not designated.

The equipment at generating station A consists of a torque-balance transmitter whose d-c output current operates a local "station generation recorder," and in series with this is the 50-mile telephone line and a "station A generation recorder" located at the system operator's office. The station generation recorder at station A operates a self-synchronous transmitter (Selsyn) which in turn causes the large dial indicators driven by the self-synchronous receivers to assume the same positions as the transmitter. The use of these indicators gives the boiler and turbine rooms an instantaneous indication of any change in the station load-recorder reading.

The telemetering equipment for generating station B performs the same functions as that of station A. The difference is in the method of making the measurements. The thermal wattmeter develops a d-c potential which is measured by the local recorder. This local recorder retransmits a d-c potential—of the order of 1 volt—to the station B generation recorder located at the system operator's office.

The telemetering equipment for station C does not provide any record at the generating station. In this instance the output of the thermal wattmeter is connected directly to the telephone line and is measured by the station C generation recorder at the system operator's office.

Station D is shown to consist of two generators with the output of the thermal wattmeter of each generator recorded on a separate instrument, and thus a record of each generator output is provided. The d-c outputs of the retransmitting circuits of these two recorders are connected in series so that the station D generation recorder at the system operator's office records the sum of the two generator loads.

The interchange with system X is transmitted to the system operator's office by impulse telemetering over a carrier-current channel. The output of the thermal wattmeter is recorded at the point of interchange, and the impulses generated by this recorder are received over the carrier-current channel for the operation of "X interchange recorder" located at the system operator's office.

The method of the measurement of the interchange with system Y is the same as described for station C.

At the system operator's office a record of the output of each generating station is provided as well as a separate record of the interchange of systems X and Y. Thus the dispatcher knows at all times the conditions prevailing at the several generating stations and interchange points.

The summation of the outputs of the several generating stations by means of retransmitters on the individual recorders provides a record of total system generation.

The algebraic summation of the two interchange recorders furnishes a record of the net interchange with adjacent power systems. The net-interchange recorder is provided with a mechanical-type integrator with demand contacts. From this information the system operator can determine not only instantaneous values but integrated values as well. He also has an indication, by means of the demand meter, as to how well he is holding the demand to contract values.

The algebraic sum of the total system generation and net-interchange recorders supplies the system operator with a record of the total load on his system.

CONCLUSIONS

The ramifications of local and remote power measurements are many and varied as pointed out in this discussion. It will suffice to state that the many methods available permit the metering and combining of the quantities to solve almost any problem which exists in the field of local and remote graphic power metering

STEAM-TURBINE GENERATORS*

BY CHARLES B. SMITH, B.S., B.M.E.

Turbine Specialist, Turbine Division General Electric Company Lynn, Massachusetts

INTRODUCTION

Of all the electrical generating capacity which exists in the United States (over 70 million kva) approximately 65 per cent consists of steam turbine generators of which Figs. 8-66 and 8-67 are representative. Of the remainder approximately 33 per cent is represented by hydraulic power using water-wheel turbines, and but 2 per cent is available from the use of diesels, gas engines and reciprocating steam engines. As a consequence, power-plant engineers are almost certain to come into contact with steam turbine generators and a knowledge of the basic principles for the application, operation and maintenance of these units will simplify the engineer's task and assist him in maintaining efficient and continuous operation of his plant. This subsection is devoted to a presentation of these fundamentals primarily as they

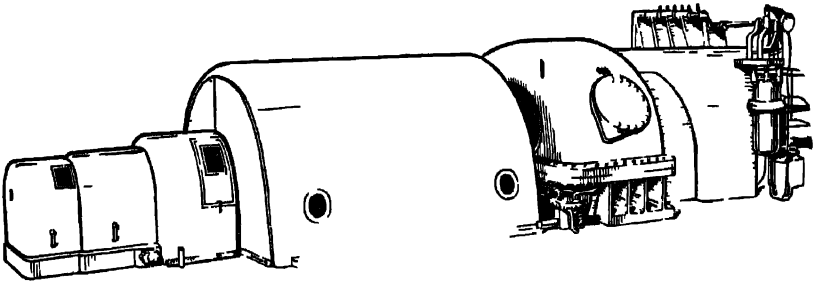

Fig. 8-66. A 7,500-kw steam turbine generator.

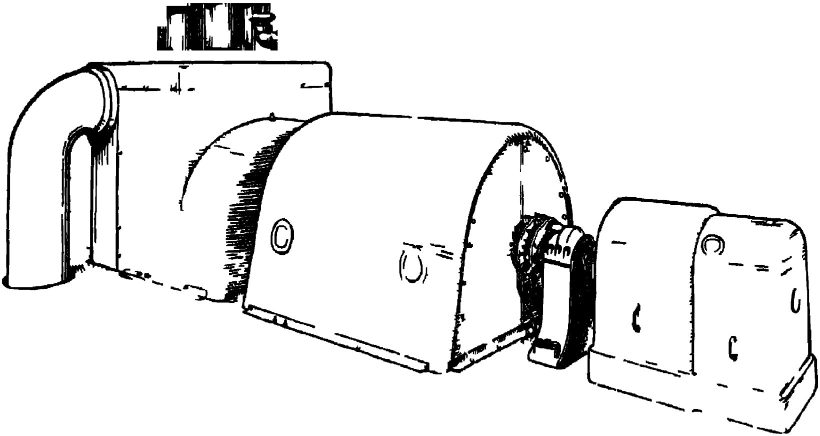

Fig. 8-67. A 1,000-kw noncondensing automatic extraction turbine generator.

---

* Superior numbers refer to specific references listed at the end of this subsection.

apply to units ranging in capacity from 75 to 15,000 kw, but they apply in general to steam-turbine generators of any capacity

APPLICATION OF STEAM-TURBINE GENERATORS

Turbines

Types of Turbines. Steam turbines may be broadly classified into two types:

1 Condensing (exhaust pressure less than atmospheric)

2 Noncondensing (exhaust pressure atmospheric or higher)

Condensing turbines, illustrated by Fig 8-68*a*, convert a higher percentage of the available energy in the steam into useful work and thus for the same initial steam conditions give greater power output than a noncondensing turbine per pound of fuel consumed Condensing turbines, however, usually furnish no steam for heating or other industrial use. The heat remaining in the exhaust steam is ordinarily discarded to the condenser cooling water and serves no useful purpose

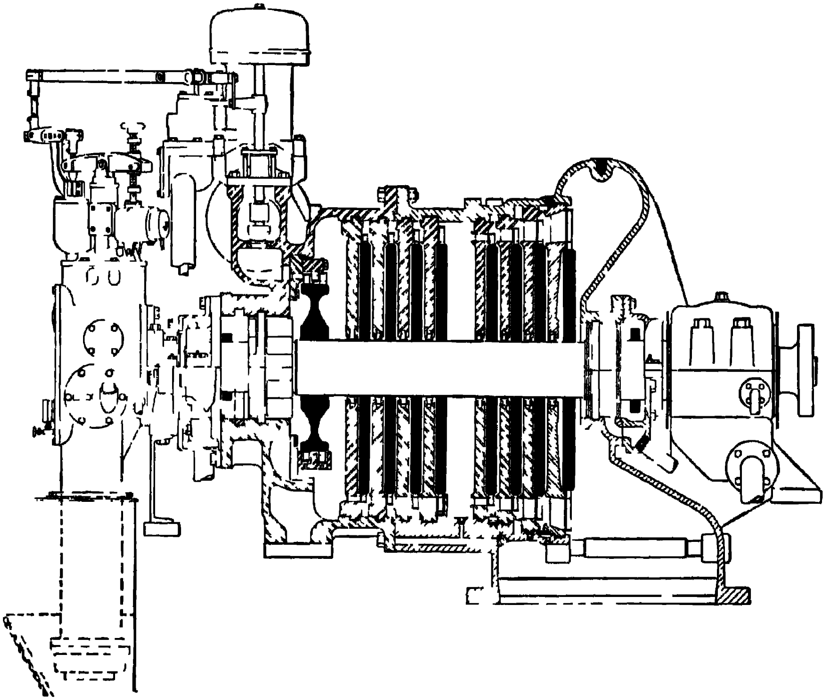

FIG 8-68*a* Straight condensing turbine.

Noncondensing turbines, represented by Fig 8-68*b*, although making less use of the available energy in the steam for electrical power generation, are generally designed so that the exhaust steam is at a pressure and temperature suitable for heating or other industrial use. Thus, the heat remaining in the exhaust steam serves a useful purpose and is not charged to the turbine as a loss In such a system, the electrical power generated may be considered a by-product of the industrial process for which steam is supplied

Condensing and noncondensing turbines may be subdivided further into extraction turbines of either the nonautomatic or automatic type Turbines of the nonautomatic-extraction type similar to Fig 8-68*c* provide steam at pressures varying with

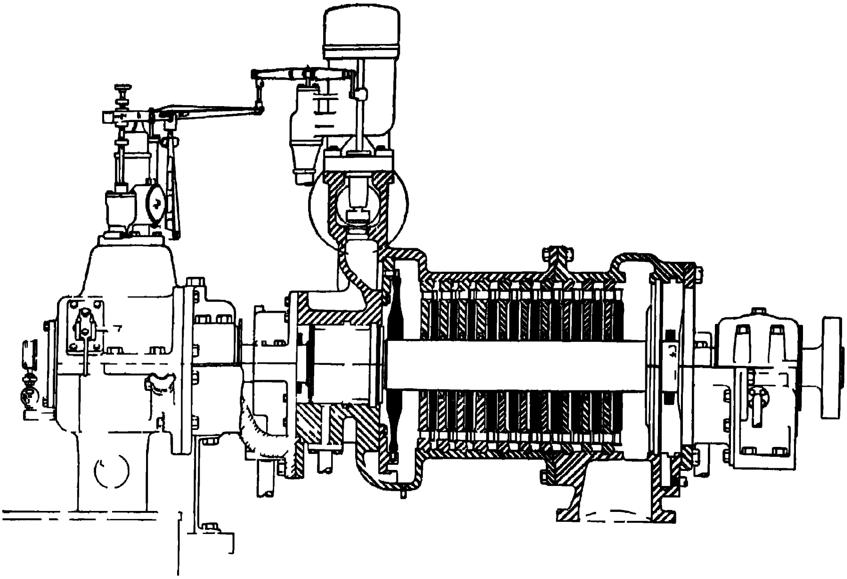

FIG. 8-68b Straight noncondensing turbine

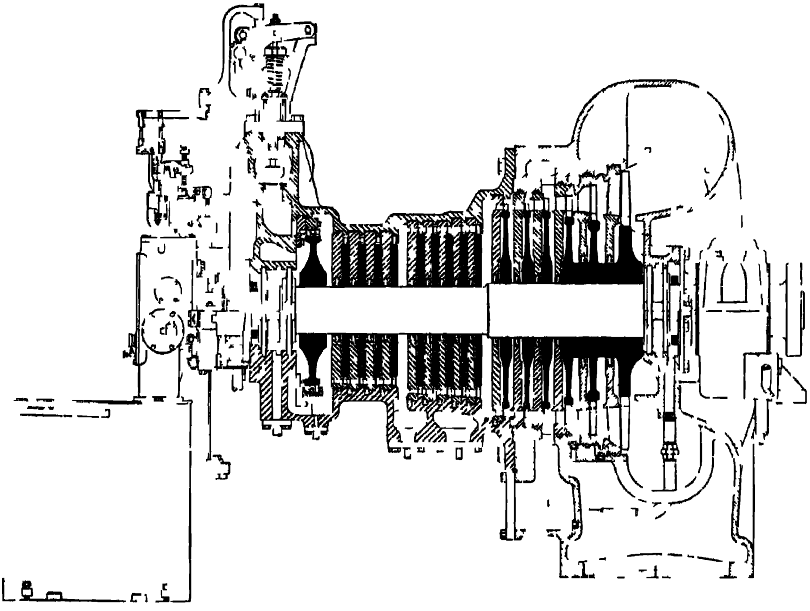

FIG. 8-68c Nonautomatic-extraction condensing turbine.

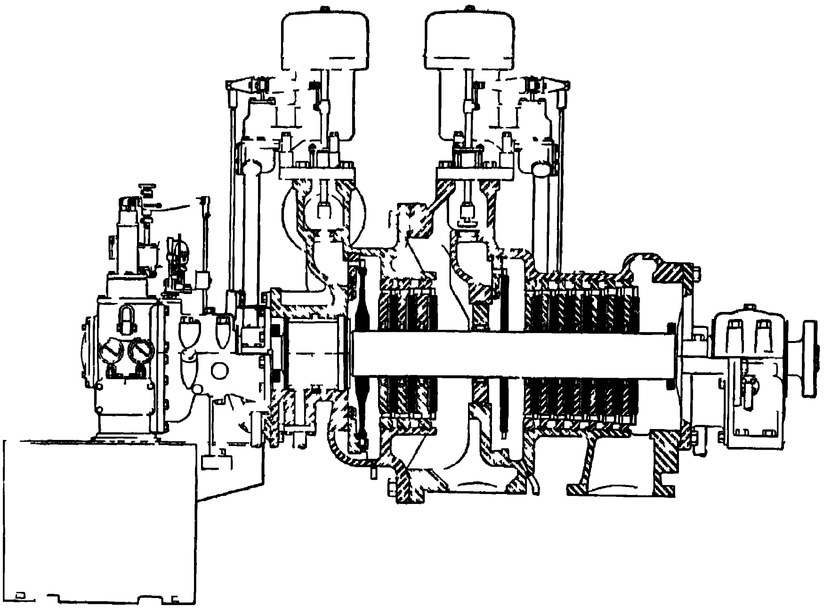

Fig. 8-68d. Single automatic-extraction noncondensing turbine.

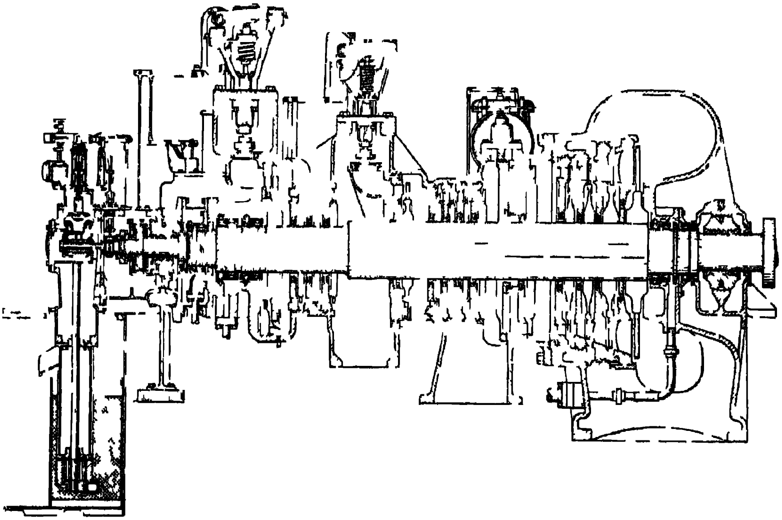

Fig. 8-68e. Double-automatic-extraction condensing turbine.

load, usually for feed-water heating as described later, but also for other industrial purposes where the quantity of steam required is comparatively small. Automatic-extraction units with either one or two extraction openings, as shown in Figs. 8-68d and 8-68e, usually furnish process steam at a constant pressure over the rated load range of the set. If the unit is noncondensing, the exhaust flow may also be used for process steam. If, however, the extraction-process steam flow is not sufficient to carry the electrical load requirements of the plant, the exhaust end of the turbine may be made condensing, and the additional steam required to carry the electrical load is passed to the condenser.

Standard Ratings. Standard ratings, in kilowatts, for both a-c and d-c turbine-generator sets are listed in Table 8-34. Units of larger rating are also available.

Table 8-34. Standard Kilowatt Ratings for Turbine-generator Sets

A-c sets			D-c sets		
10	125	1,500	10	125	1,500
15	150	2,000	15	150	2,000
20	175	2,500	20	200	2,500
25	200	3,000	25	250	*
35	250	3,500	30	300	
50	300	4,000	40	400	
60	350	5,000	50	500	
75	400	6,000	60	750	
100	500	7,500	75	1,000	
	700	10,000	100		
	1,000	11,500			
		12,500			
		15,000			

* Larger ratings can be obtained by coupling generators in tandem.

Pressure and Temperature Ranges. Turbine prices are generally increased in steps as the initial pressure and temperature are increased. For turbines rated 10 to 400 kw, the standard pressure and temperature steps are usually as shown in Table 8-35.

Table 8-35. 10- to 400-kw Turbines

Standard inlet pressure, psig	*Standard inlet temperature, deg F*
250 and lower	500 and lower
251 400	501–600
401 600	601 750
	751–825

Table 8-36. 500- to 7,500-kw Turbines

Standard inlet pressure, psig	*Standard inlet temperature, deg F*
101 250	500 and lower
251 400	501 750
401–600	751-825
601 900	826 900
901 1 500	901-950

For turbines rated at 500 to 7,500 kw, the standard pressure and temperature steps are usually as shown in Table 8-36.

For turbines rated at 10,000 kw and larger, the pressure and temperature steps (condensing and noncondensing) are usually as shown in Table 8-37.

In general, pressure and temperature are considered independently for pricing purposes, and the price of the turbine is based on the upper limit of the inlet pressure and temperature group in which it falls, *i.e.*, a turbine designed and constructed for normal operation and most efficient performance with a given inlet pressure and temperature will also be designed and constructed so as to be satisfactory for operation with minor changes at the maximum pressure and temperature of the group above in which it falls and will be priced accordingly. Thus, a 4,000-kw turbine to be purchased for operation with 375 psig 800°F total temperature steam at the throttle would be priced the same as a turbine purchased for operation with 400 psig 825°F total temperature steam at the throttle and would be constructed so as to be satisfactory for continuous operation at these upper limits with but minor changes to the steam-path parts such as new valves, valve seats, and first-stage nozzle plate.

Table 8-37. 10,000-kw and Larger Turbines

Standard inlet pressure, psig	*Standard inlet temperature, deg F*
450 and lower	750 and lower
451 650	751 825
651-850	826 900
851 1,450	901 950
	951-1,000

Steam Performance. Turbine-generator-set performance is generally quoted in terms of steam rate. The steam rate is the pounds of steam that must be supplied to the turbine inlet per kilowatthour of generator electrical output. The throttle flow, in pounds per hour, equals the product of the electrical output being delivered by the generator and the steam rate at that load.

The approximate full-load and half-load steam rates of condensing and noncondensing, nonautomatic-extraction, 60-cycle, a-c turbine-generator sets may be obtained by multiplying the theoretical steam rate[1] by factors obtained from Figs. 8-69 and 8-70.

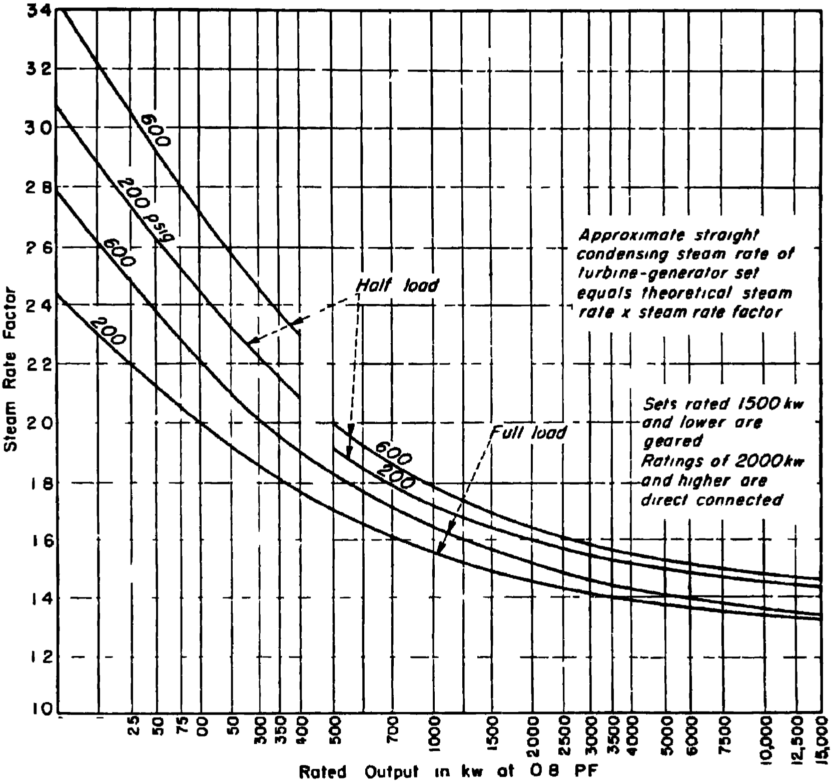

Fig. 8-69. Approximate steam-rate factors for condensing, nonautomatic-extraction, 60 cycle, a-c turbine-generator sets.

The steam rates of 50-cycle and 25-cycle a-c sets and of d-c sets will be approximately 3 to 10 per cent greater than those for the correspondingly rated 60-cycle a-c sets

Feed-water Heating. When required, turbines, either condensing or noncondensing, will be furnished with openings for the nonautomatic extraction of steam for feed-water heating or for any required industrial use such as the operation of an evaporator.

The number of openings which will be furnished without a price increase is as shown in Table 8-38.

Table 8-38

Rating of set, kw	*Number of openings*
10–400	None
500–1 500	1
2,000–3,500	2
4,000–7,500	3
10,000–15 000	4

The flow which may be extracted is limited to 15 per cent of the nonextraction throttle flow at any given load from one opening or a total of 30 per cent of the nonextraction throttle flow at any given load from two or more openings, except for machines rated 10,000 kw and larger where the uncontrolled extraction flow may equal 35 per cent of the throttle flow at any given load. A price addition will be made for quantities of extraction steam in excess of these amounts or for more openings than are shown by Table 8-38.

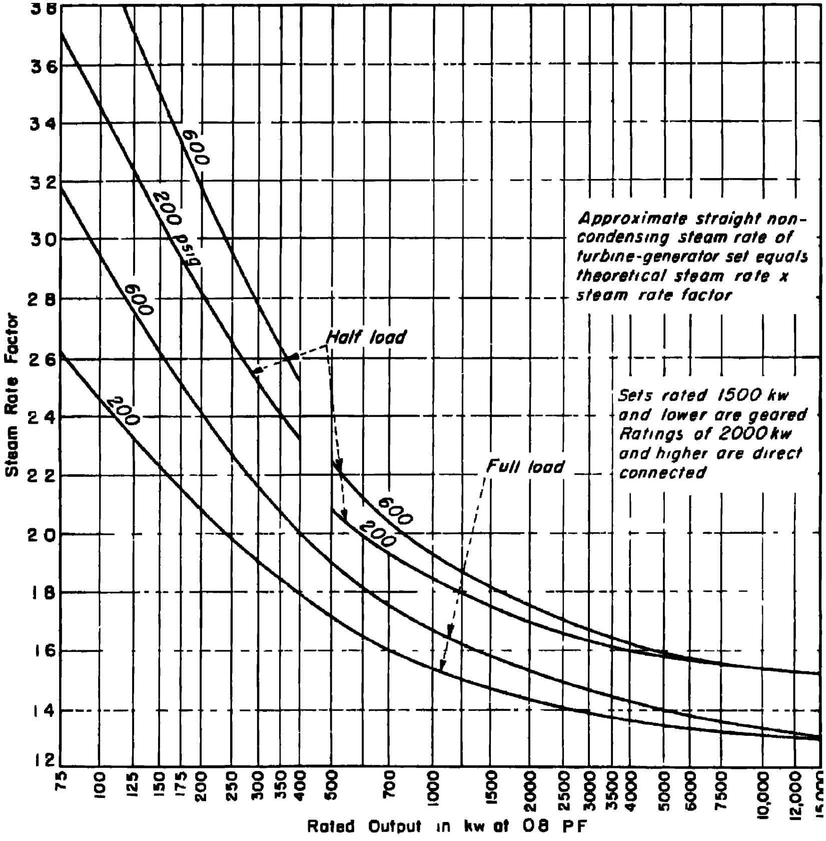

FIG. 8-70. Approximate steam-rate factors for noncondensing, nonautomatic-extraction, 60-cycle, a-c turbine-generator sets.

When steam from power-plant auxiliaries is not available for feed-water heating, the approximate fuel saving which may be made by extracting from the main turbine will be approximately as given by Fig 8-71.

Figure 8-72 gives a means of finding the approximate optimum turbine-flange pressures for feed-water heating extraction with any turbine inlet pressure and any number of heaters.

To use this chart, (1) enter with the turbine inlet pressure as the horizontal coordinate and go vertically to the line labeled with the number of feed-water heaters desired. (2) Draw a straight line from the point obtained in (1) to the ¾ load condenser pressure in inches of mercury absolute. (3) Where this line crosses the heaters designated on the coordinate, read the respective approximate ideal turbine-flange pressures for extraction to the feed-water heaters.

The turbine manufacturer may be allowed to deviate several per cent (say 10 to

20 per cent or more) from the ideal extraction pressures with little effect on the fuel savings resulting from feed-water heating extraction.

Turbine Governing. The control arrangement with which a turbine generator is equipped is generally dictated by the requirements of the application, i.e., by the service and results intended. Fundamental safety devices such as an overspeed trip (Fig. 8-73) are common to all types.

The control of speed and the control of steam pressure are the two most common functions of turbine controls.

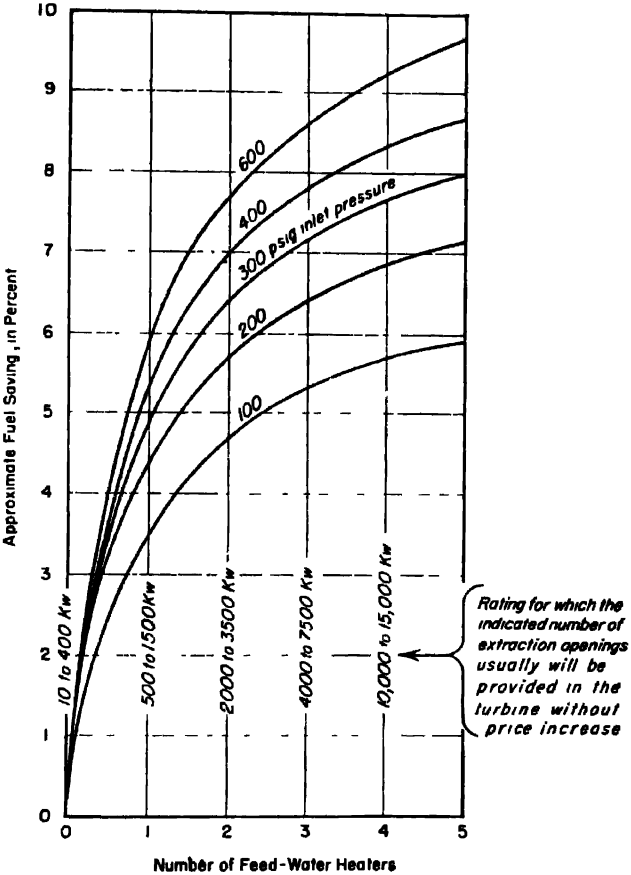

Fig. 8-71. Approximate fuel savings resulting from the use of feed-water heaters.

On very small turbines, particularly if exceptionally accurate control is not required, the speed or the pressure-sensitive element itself may be used to operate the steam-control valves as illustrated in Fig 8-74. On larger turbines and where more accurate control is required, the relatively small forces available in the speed or pressure-sensitive elements must be amplified to provide positive operation of the steam control valves. Amplification of forces is generally accomplished by the use of relays comprised of a pilot valve which regulates fluid-pressure supply and discharge on a power piston of ample capacity to operate the control valves. Figure 8-75 is representative of such a control arrangement. The governor element supplies only

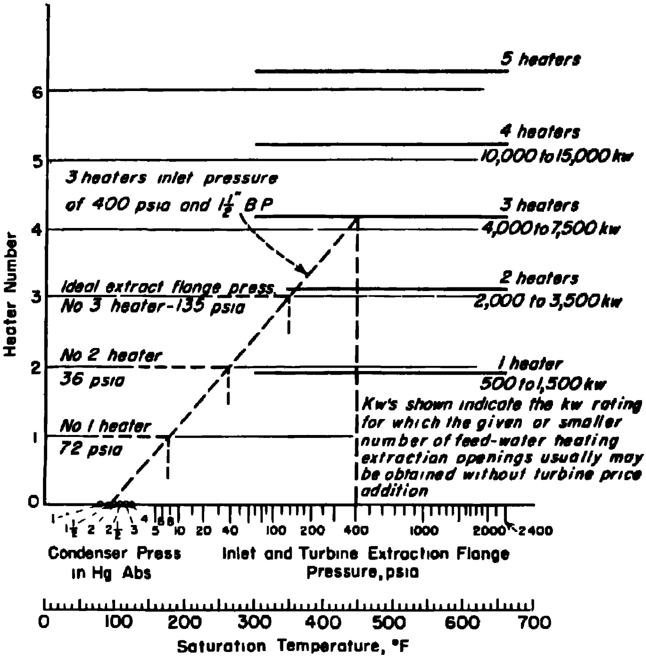

FIG. 8-72 Chart for obtaining approximate ideal-extraction turbine-flange pressures for feed-water heating extraction.

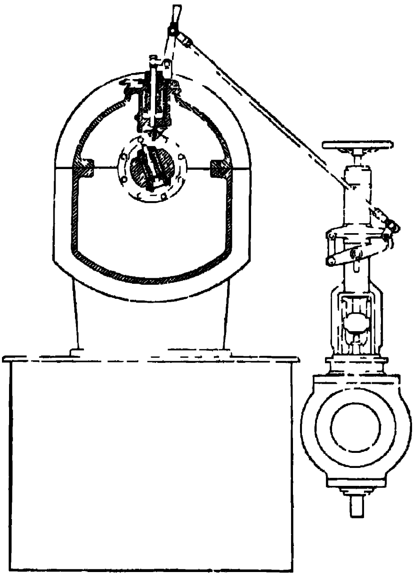

FIG. 8-73. Emergency-governor and throttle-trip arrangement.

the small forces required to position the pilot valve, and the large forces are obtained from the fluid-pressure supply. Oil at the proper pressure from the turbine's own oil system is most generally used as the operating medium. Other operating mediums, such as steam, are used successfully.

Governor Regulation. The speed or pressure (whichever is being controlled) variation permitted by the governor, as load is added or subtracted, is known as the "governor regulation."

Speed-governor Regulation. Speed-governor regulation is generally not over 2 per cent speed change for one-half rated load change or not over 4 per cent for rated load change.

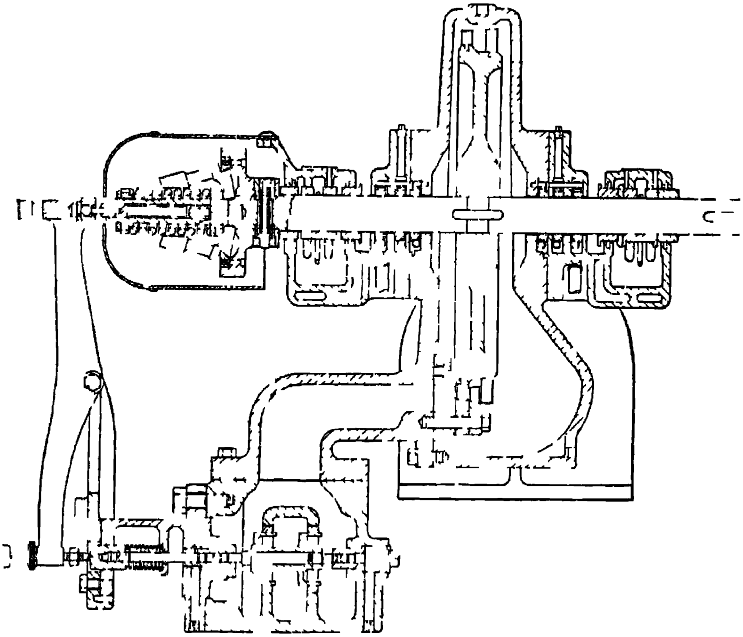

FIG. 8-74. Direct-acting speed-governor control of valve gear.

Speed governors are occasionally equipped with correctors or compensators (Fig. 8-76) which, as the name implies, correct for the speed change inherent in the regulation and give in actual practice substantially zero regulation. It is possible to operate only one such unit on a system at a time with its corrector in service. Such a unit absorbs all system-settled load changes except as load may be redistributed among units by the operators, and all other speed-controlled units operate at substantially base load.

Pressure-governor Regulation. Pressure-governor regulation is generally of the order of not over 4 per cent pressure change for a total change in the controlled steam flow. These governors (Fig. 8-77) also are frequently equipped with correctors or compensators. When so equipped, stability is enhanced by a governor with a broad basic regulation and with sufficiently fast corrector action to produce over-all control within acceptable limits.

If the entire steam flow to a turbine is under the control of a pressure governor, the generated load is determined only by steam demands, and the speed must be controlled by other a-c generating units electrically in parallel. The speed governor would generally be set as a preemergency governor and would interfere with the steam flow only on an abnormal rise in system speed.

Pressure governors are used to control exhaust pressure, extraction pressure, or inlet pressure, as the case may be Exhaust-pressure governors are generally used to balance turbine steam flow against process-heating steam demand, thus passing through the turbine only that steam required for process and thereby generating whatever power may result Likewise, initial pressure governors may be used to pass through a turbine whatever steam may be generated in a waste heat process Initial pressure governors are also frequently used to unload turbines automatically and thereby reduce boiler flow on high pressure boilers upon dropping of the boiler pressure for any reason

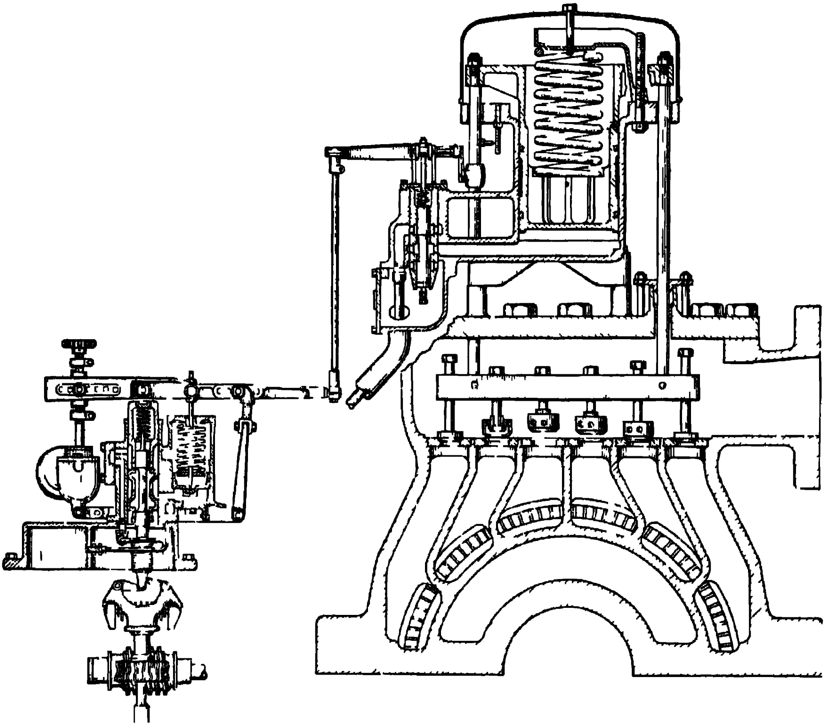

Fig. 8-75 Oil relayed speed-governor control of valve gear

Combined Speed and Pressure Governing On automatic-extraction type turbines many combinations of the functions of speed and pressure control occur depending on the service intended

When speed and extraction pressure are controlled simultaneously, the speed and pressure controls are frequently interconnected in such a way that changes caused by one do not require that major corrections be made by the other Thus, Fig 8-78 diagrammatically indicates how a change in the position of the speed governor will automatically reposition the three control valves in the same direction (towards the wide open or the closed position depending upon whether electrical load is being added or subtracted) and thus prevent a major disturbance in the pressure at the automatic-extraction openings due to the change in total steam flow through the turbine In this way, variations within the governor regulation are reduced to a minimum

Likewise, a decrease in the extraction-flow requirements at either of the extraction

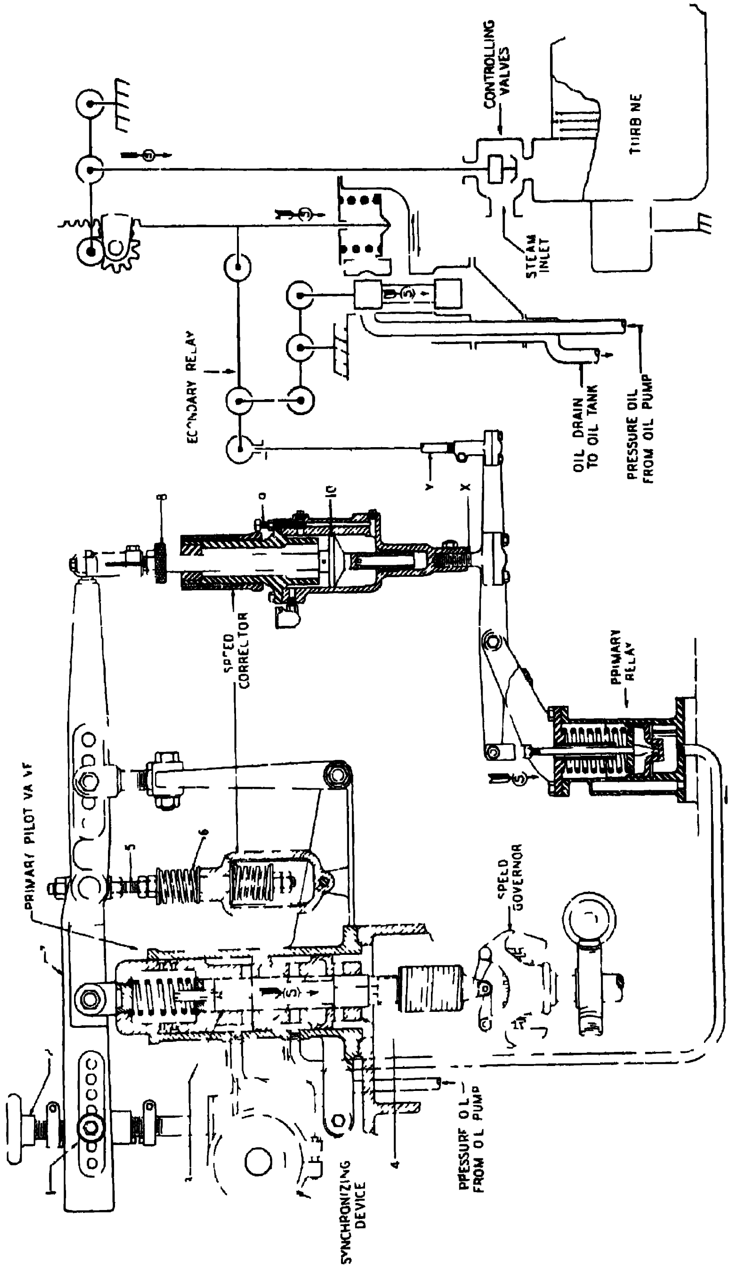

FIG. 8-76. Application of speed corrector to an oil-relayed speed-governing system.

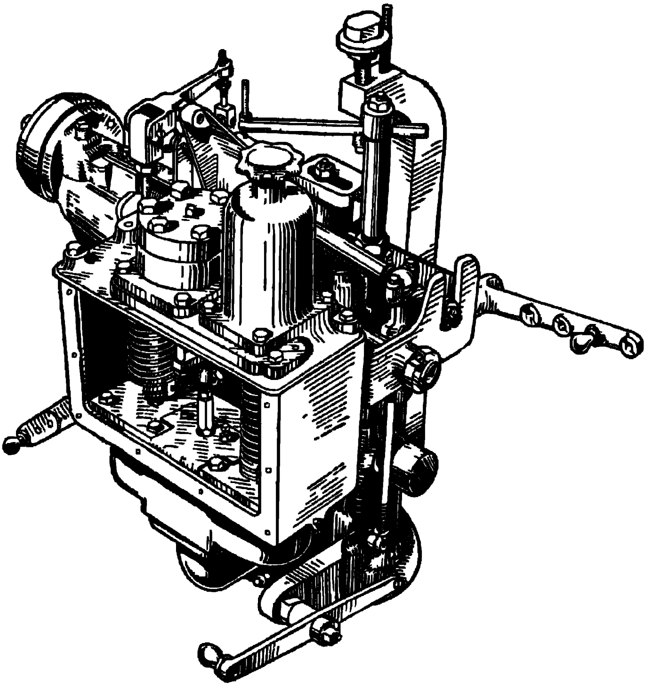

Fig. 8-77 Pressure governor

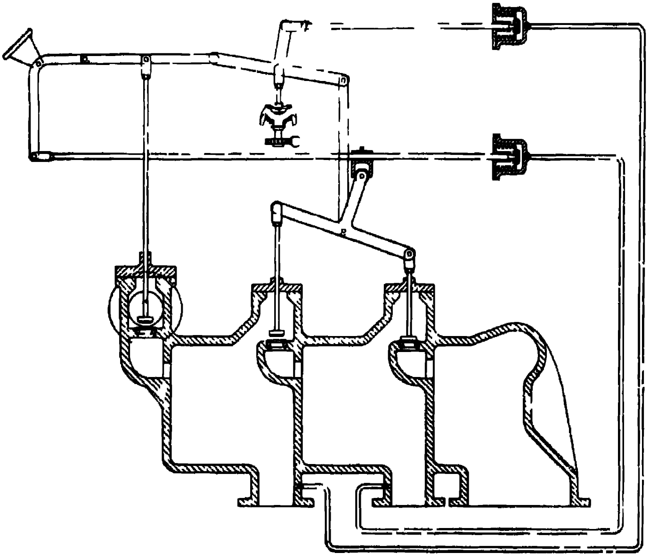

Fig. 8-78 Schematic arrangement for the simultaneous control of speed and extraction pressures

points will tend to raise the pressure at the automatic-extraction opening effected and thus activate the pressure governor which, as indicated in Fig. 8-78, will move the control valve (or valves) ahead of the extraction point in the closed direction and move the control valve (or valves) after the extraction point in the open direction. Thus, although the amount of steam passing through the turbine up to the extraction opening involved is decreased and hence the power output of that section is less, additional steam is passed through the turbine below the extraction point, and the power output in this section is increased correspondingly. Thus the loss of power in one section is offset by the gain of power in the other, and as a consequence little or no change in speed results. Upon an increase in extraction-flow requirements, the operation is similar but in the opposite order to that indicated.

The simultaneous control of speed and the extraction pressure at two automatic-extraction or admission openings is not uncommon.

Generators

Turbine-driven generators (Fig. 8-79) are available in sizes from less than 10 to over 100,000 kw, and single units have been built for ratings as high as 165,000 kw.

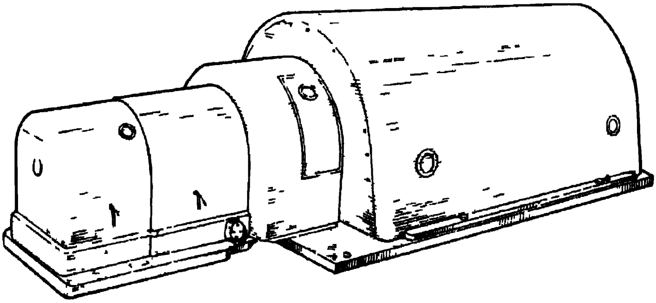

Fig. 8-79. Sixty-cycle, synchronous, a-c turbine generator.

The following description applies to units from 75 to 15,000 kw, inclusive, representing the sizes encountered in most industrial plants and in all but the larger central stations.

Types of Generators. In the size range from 75 to 15,000 kw, a-c generators are all of the revolving-field type and are generally furnished in either of two general types, as regards generator speed, as shown in Table 8-39.

Table 8-39

Kw rating	Type	Poles	Generator speed	
			60 cycles	50 cycles
75–1,500	Geared	6	1,200 rpm	1,000 rpm
2,000–15,000	Direct connected	2	3,600 rpm	3,000 rpm

The six-pole generators are of the so-called "salient-pole" type (Fig. 8-80), while the two-pole units are of the "round rotor" or nonsalient pole type (Fig. 8-81) required by the higher speed of operation. A six-pole generator can be built for ratings greater than 1,500 kw if necessary.

Geared-type six-pole generators are air-cooled and are generally furnished with open-type ventilation. Two-pole direct-connected generators from 2,000 to 11,500 kw are air-cooled and are generally made totally enclosed with air coolers mounted in a recirculating ventilating system. Air coolers may be mounted above or below the floor line as desired (Fig. 8-82). Generators 15,000 kw and above are generally hydrogen-cooled.

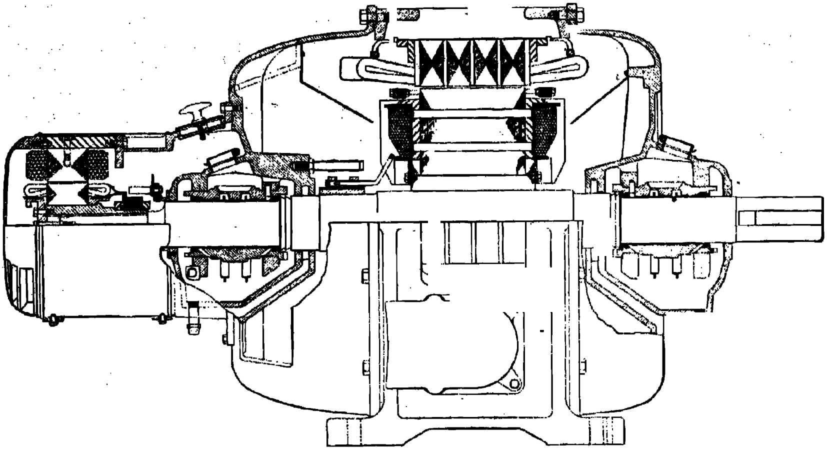

FIG. 8-80. Six-pole, "salient-pole," totally enclosed generator.

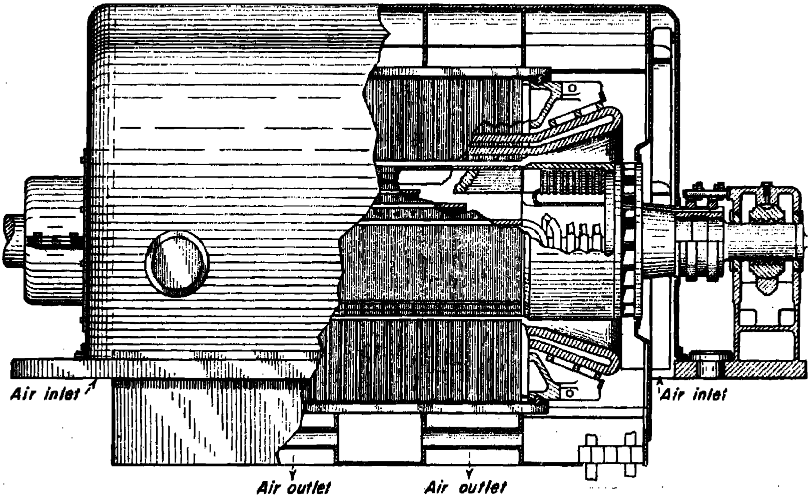

FIG. 8-81. Two-pole, "round-rotor," totally enclosed generator.

Standard Voltages. Standard terminal voltages of a-c generators in the size range from 75 to 15,000 kw are as shown in Table 8-40.

Table 8-40

Kw rating	*Standard voltages*
75–400	240; 480; 600; 2,400
500–1,500	480; 600; 2,400
2,000–7,500	2,400; 4,160; 5,000
10,000–15,000	6,900; 11,500; 12,500; 13,800; 14,400

Turbine-driven d-c generators are always of the geared type with standard speeds and voltages as listed in Table 8-41.

Table 8-41

Kw	Speeds, rpm		
	125 v	250 v	600 v
150 400	1 200	1 200	
500	750	900	900
750		900	900
1,000		750	750
1,500		514	514
2,000		750*	750*
2,000		360	514
2,500		750*	750*
2,500		. ...	514
3,000		514*	514*
4 000		360*	514*
5,000			514*

* Two generators coupled in tandem.

These generators are of the open type, air-cooled. They are also available for $^{125}/_{250}$ volts three-wire in each rating where 250 volts is standard.

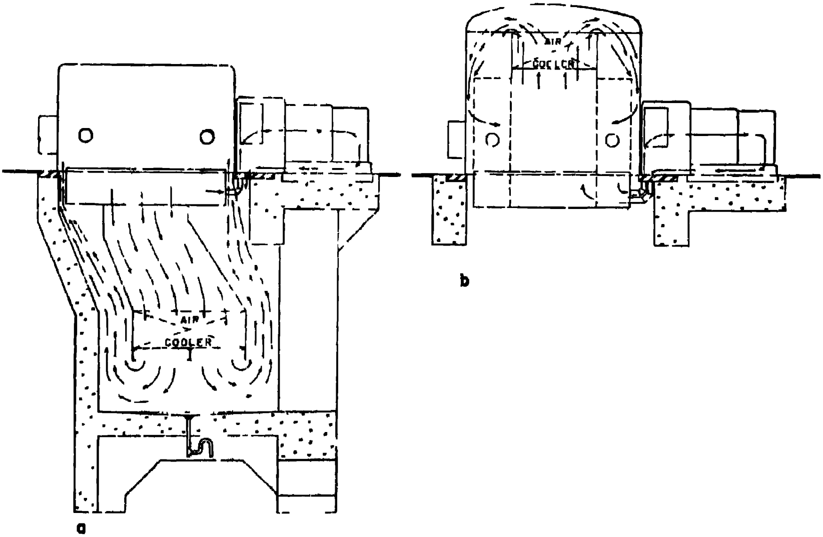

FIG. 8-82. Air-cooler arrangements: (a) cooler mounted in duct work below generator; (b) cooler mounted in top of generator housing.

Standard Characteristics. Present accepted standards for turbine-driven generators are contained in the following publications:

General Standards for Rotating Electrical Machinery—ASA, C50 (1943).[2]

Preferred Standards for Large 3,600-RPM Turbo-generators—AIEE, 601 (1945);[3] AIEE, 602 (1945).

NEMA Turbine-generator Recommended Practices NEMA Publication[4] No. 41-66 (1941).

Some of the main features of these standards are listed in Table 8-42 for convenience. For further details, refer to the standards themselves.

These standards apply to generators operating at altitudes of 3,300 ft or less. Generators designed for standard temperature rises at altitudes greater than 3,300 ft are generally built in oversize frames. Generators designed for 0.70 power factor or for short-circuit ratios higher than listed in Table 8-42 are also generally built in oversize frames.

Table 8-42

Kw	Power factor	Type	Ventilation	Short-circuit ratio	Excitation voltage	Temp. rise above 40°C	
						Armature	Field
75–400	0.80	Salient pole	Open	No standard	125	50°C thermometer	60°C (resistance)
500–1,500	0.80	Salient pole	Open	0.80–0.85	125	50°C thermometer	80°C (resistance)
2,000–7,500	0.80	Round rotor	Totally enclosed	0.80–0.85	125	60°C resistance-temp. detector	80°C (resistance)
10,000–15,000	0.80	Round rotor	Totally enclosed	0.90	250	60°C resistance-temp. detector	80°C (resistance)
11,500* and 15,000*	0.85	Round rotor	Totally enclosed	0.80	250	60°C resistance-temp. detector	85°C (resistance)

* AIEE-ASME preferred standard units.

Exciters

Direct-connected shunt-wound, self-excited exciters (Fig. 8-83) with direct-acting voltage regulators in the exciter field are standard for generators from 100 to 10,000

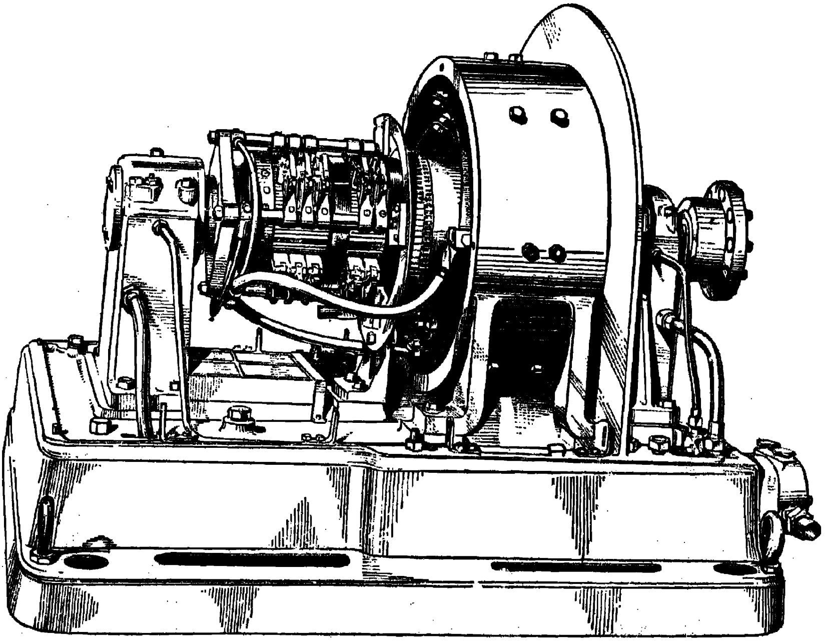

FIG. 8-83. Direct-current, shunt-wound, self-excited, 3,600-rpm exciter.

kw Above 10,000 kw the standards call for a direct-connected main exciter, shunt-wound and separately excited and a compound-wound pilot exciter (Fig 8-84) with hand or automatic control of the main exciter field

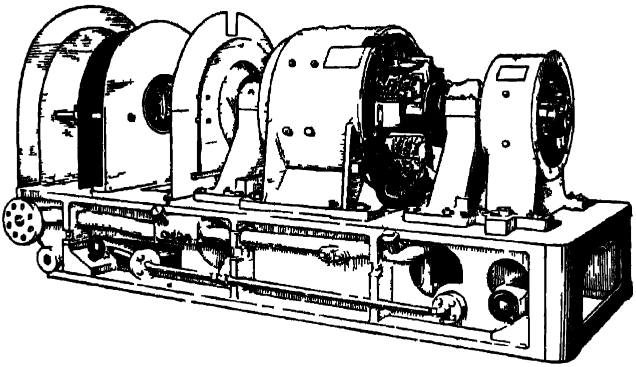

Fig 8 84 Main and pilot exciters

Accessories

For efficient and reliable operation a steam turbine generator unit is supplied with certain standard features and accessories These items vary somewhat with unit rating but the following tabulation is representative of the equipment furnished

Condensing and Noncondensing Steam Turbines (except low pressure—those with 20 psig or lower inlet pressure)

1 Steam strainer with removable element

2 Combined trip and throttle or stop valve actuated by an overspeed governor The action of the emergency governor is transmitted to the valve either through a mechanical linkage or a fluid oil relay system (Fig 8 85)

3 Overspeed governor entirely independent of the normal speed-regulating governor

4 Multiple automatic normal speed governing valves (see Fig 8-75 under Governing)

5 Speed regulating governor to control the position of the normal-speed governing valves through the medium of a relay-controlled hydraulic-valve-operating mechanism (see Fig 8 75 under Governing)

6 Oil pump mounted upon or positively driven from the unit to provide oil for the valve-operating mechanism and lubricating oil to each bearing of the unit except ring-oiled generator and exciter bearings on geared units To protect the pump from damage, a strainer is usually located at the suction passage of the pump

7 Oil reservoir of sufficient capacity for the unit requirements

8 Oil cooler of sufficient size to remove the heat absorbed in the oil and keep the bearing discharge oil temperatures at approximately 140 to 160°F when the cooler is supplied with cooling water at a temperature specified by the purchaser but not exceeding 95 F These are either of the single- or double-pass type with the water flowing through the tubes and the oil directed by baffle plates around the tubes

9 Steam-driven auxiliary oil pump (Fig 8-86) with an automatic starting device actuated by a reduction from normal oil pressure in the system This control device is usually an oil pressure positioned diaphragm which regulates the inlet valve to the driving turbine

10 Oil-pressure trip mechanism or its equivalent to stop the flow of steam into the turbine should the oil pressure in the system drop to too low a value

11 Oil piping connecting all integral parts of the turbine-generator-unit oiling system except piping between the turbine unit and the oil cooler (and between the

turbine unit and auxiliary oil pump) Oil piping will be of steel and will have welded or flanged connections

12 Vibrating-reed or electric indicating tachometer or frequency meter calibrated in rpm to indicate the turbine speed

13 Necessary operating gauges with gauge board or other suitable mounting (Fig 8-87) Only when gauges or gauge boards are mounted on the unit will gauge pipings be included

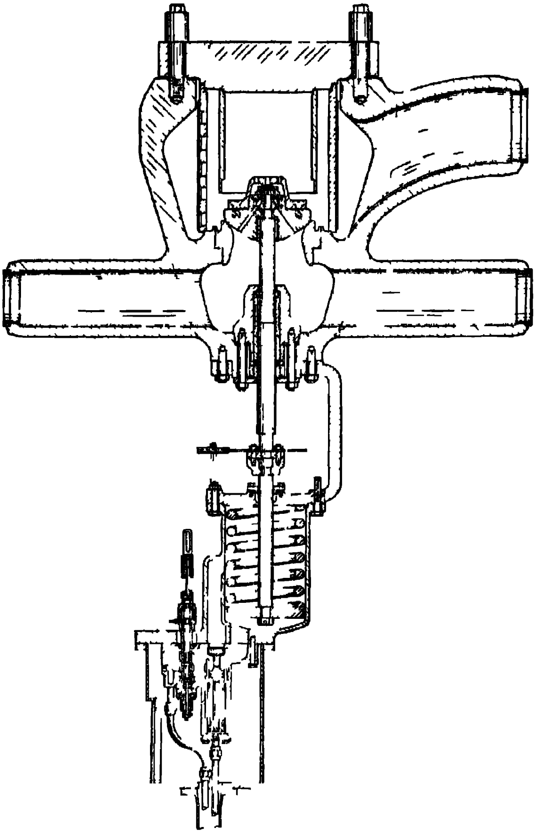

Fig 8-85 Trip stop valve

Standard gauge equipment includes

a Steam gauges for determining
Initial pressure
First-stage pressure
Exhaust pressure

b Oil-pressure gauges—usually one reading bearing pressure and the other governor oil pressure

c Gland-water pressure gauges if the glands are of the water seal type

14 Gland-steam condenser or condensers (when the gland design requires their use) but not including piping between the unit and such gland condensers Sometimes a wet vacuum-pump arrangement is provided These systems serve to prevent gland-steam leakage into the bearing housings and the turbine room To eliminate

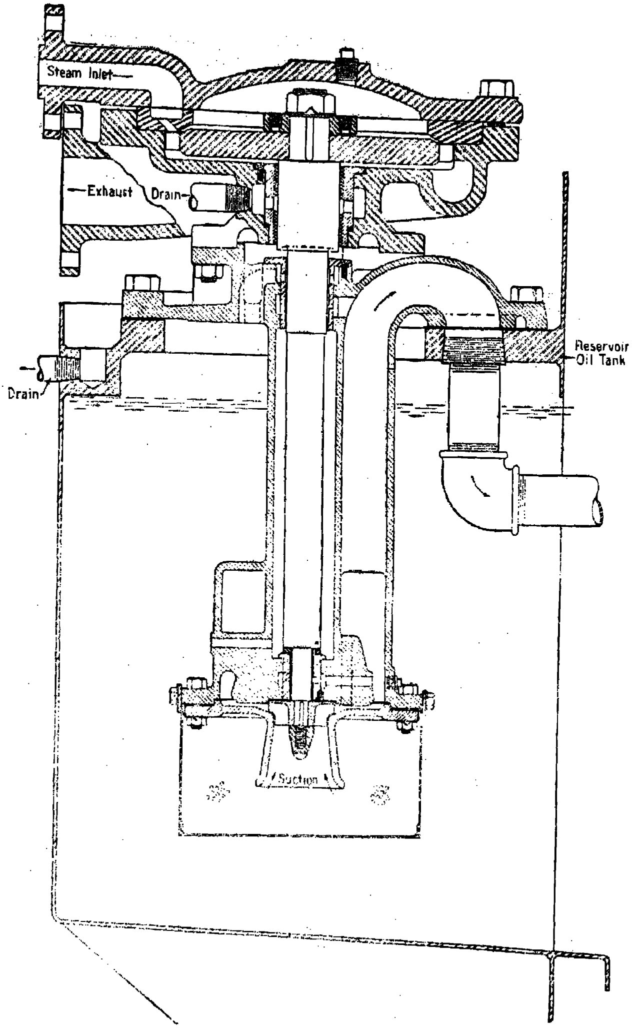

FIG. 8-86. Steam-turbine-driven auxiliary oil pump.

manual adjustment of the sealing steam with changes of load, some manufacturers also provide automatic steam-seal regulators.

Automatic-extraction Turbines. Automatic-extraction turbines normally include all the features and accessories listed for condensing and noncondensing steam turbines together with the following additional features and accessories:

1. Extraction-pressure gauge
2. Automatic device for controlling the pressure of the extracted steam by varying the flow of steam to the lower pressure stages of the turbine
3. Interconnection between the speed governor and extraction control, either mechanical or hydraulic
4. Automatic nonreturn valve for each automatic-extraction outlet, with trip actuated from the overspeed governor, usually through an oil relay

Low-pressure Turbines (those with 20 psig or lower inlet pressure). Low-pressure turbines usually include all the features and accessories listed for condensing and noncondensing steam turbines with the following exceptions and additions:

1. Omit steam strainer.
2. Instead of combined trip and throttle valve, substitute a simple trip valve in low-pressure steam supply line, actuated by overspeed governor (gate or throttle valve not included).
3. A single governor valve may be substituted for multiple automatic valves.

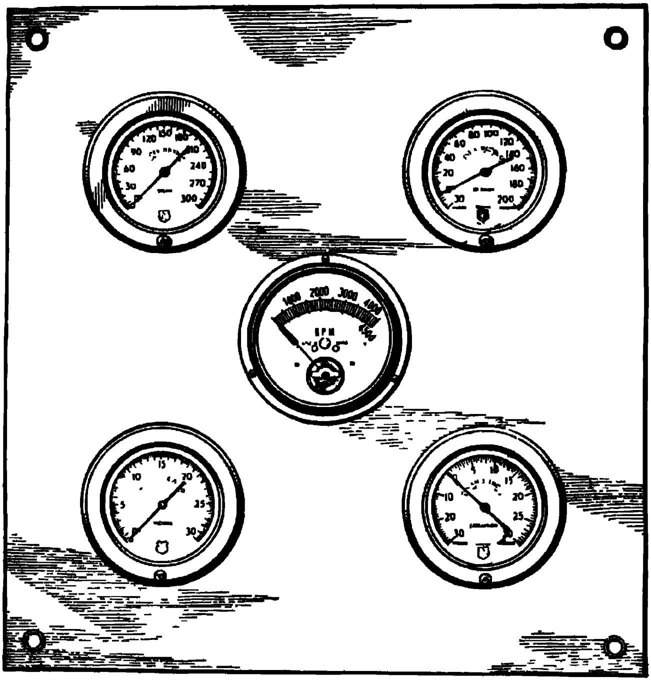

FIG. 8-87. Turbine gauge board.

Mixed-pressure Turbines. In general, mixed-pressure turbines include all the features listed for condensing and noncondensing steam turbines, with the exception of the steam strainer on l-p inlet. Furthermore, they have the following additions:

1. Low-pressure steam gauge
2. Device to control the pressure in the lower pressure steam line by varying the low-pressure steam flow through the turbine
3. Interconnection of l-p governor valve to speed governor and to high-pressure governor valves.
4. Simple trip valve in low-pressure steam line actuated by overspeed governor (gate or throttle valve not included when lower pressure is 20-lb gauge or less)

Reduction Gears. Gears are of the helical type and specially designed for high-speed continuous service. They are of the totally enclosed, forced-flood lubricated type and include the following features and accessories:

1. Complete lubricating system as outlined under Condensing and Noncondensing Steam Turbines, Item 11.

Generators and Exciters. 1. Field-discharge resistor.

2. Embedded temperature detectors in stator windings for 1,500 kw and above.

3. Field wound for 125 volts up to 2,500 kw. Above 2,500 kw, field wound for either 125- or 250-volt excitation.

4. Exciter-field rheostat, hand operated up to 7,500 kw and motor operated above 7,500 kw.

General Accessories—Unit as a Whole. In accordance with present practice, the following unit features and accessories are usually furnished:

1. Wrenches for all special bolts and nuts (standard wrenches not included)
2. Soleplates or base plates as necessitated by the particular turbine and generator design
3. Couplings
4. Turbine-rotor lifting gear, if necessitated by the particular turbine design

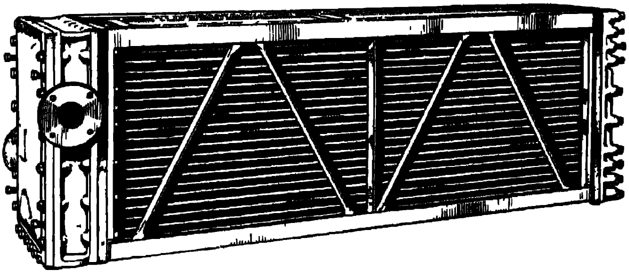

Fig. 8-88. Generator-surface air cooler.

Special Accessories. Certain other accessories, not normally furnished as standard equipment, are desirable for safe and efficient operation. These include generator air coolers (Fig. 8-88), designed for mounting either in duct work below the generator or on top of the generator within the housing of the generator, generator-temperature indicator, thermometers, and positive-type nonreturn valves for uncontrolled extraction lines where there is a possibility of reverse steam flow of sufficient volume to overspeed the turbine. If required, most turbine manufacturers can furnish this equipment.

Over-all Dimensions and Weights

Some concept of the approximate over-all size and weight of a turbine-generator set is usually of value for preliminary station layouts Table 8-43, together with Figs 8-89 *a*, *b*, and *c*, indicates such data for straight condensing units and is sufficiently accurate for estimating purposes. Automatic-extraction units will tend to be somewhat larger - approximately one foot in length—and noncondensing units will be slightly shorter.

Foundations

This material outlines a few general suggestions which may prove helpful in the design and construction of the foundation for a turbine-generator set and which experience proves are very frequently overlooked in the initial design of the structure.

Types of Foundations. Of the several different foundation types from which to choose, ranging from plain massive concrete construction to the other extreme of an entirely structural-steel construction, general practice seems to indicate that foundation construction of the reinforced-concrete type fills the requirements of simplicity in design and construction, necessary amount of rigidity, fair accessibility, and economy of space at a reasonable cost. As a consequence, the following comments are confined mainly to this type of construction, a typical example of which is shown in Fig. 8-90.

Provision for Proper Clearance. Although it appears self-evident, too much attention cannot be given to providing clearances necessary to prevent interference between the turbine parts, especially piping and flange connections and the foundation. For the sake of appearance such parts are usually located below the level of the operating floor. Chipping and burning operations on a completed foundation are too frequently unpleasant and costly indications that this detail was overlooked.

Table 8-43

Rating, kw	Approximate dimensions: Length, With exciter	Approximate dimensions: Length, Without exciter	Approximate dimensions: Width	Approximate dimensions: Above-floor height	Generator, rpm	Outline sketch	Weight, lb

Loads and Deflections. Turbine manufacturers' outline prints usually indicate the dead load and the vacuum load which must be supported by the foundation,

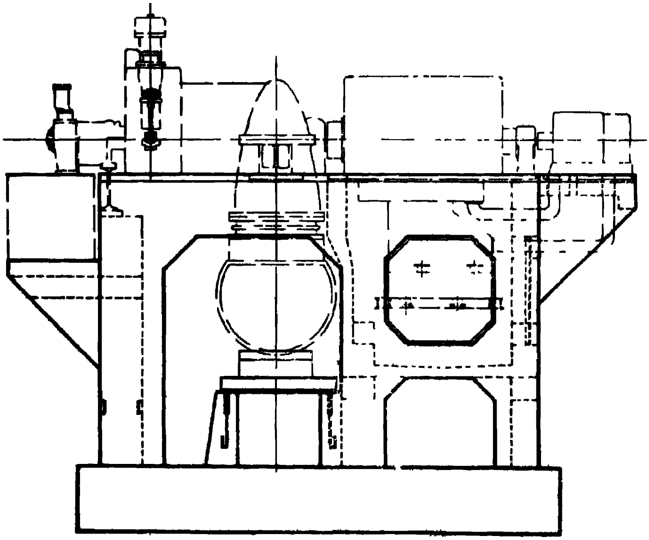

Fig. 8-89. Turbine-generator foundation.

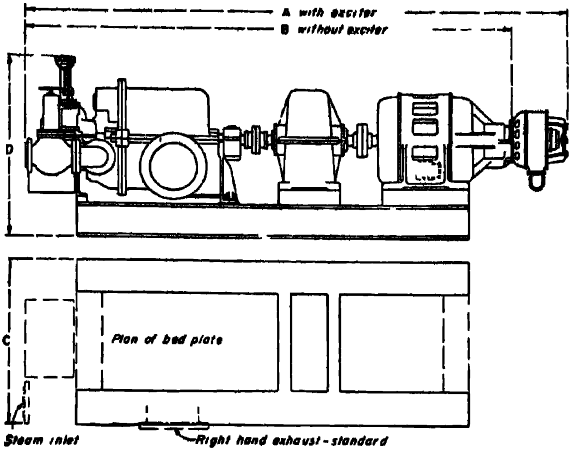

Fig 8-90a. Outline, 60-cycle geared units.

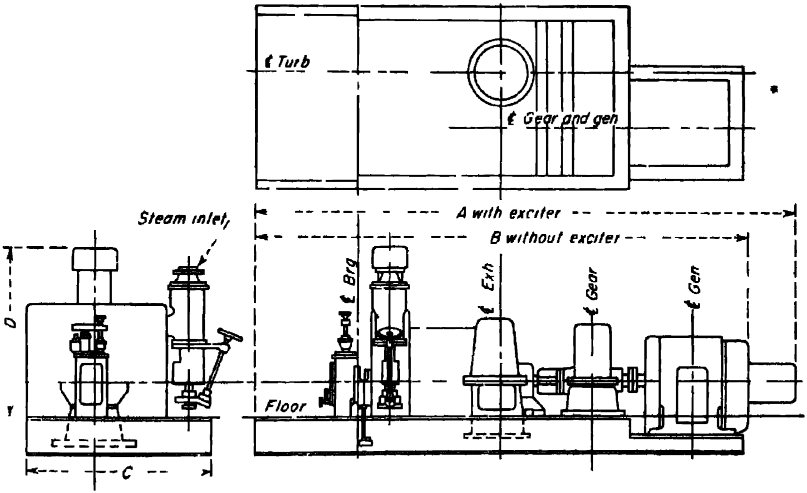

Fig. 8-90b. Outline, 60-cycle geared units.

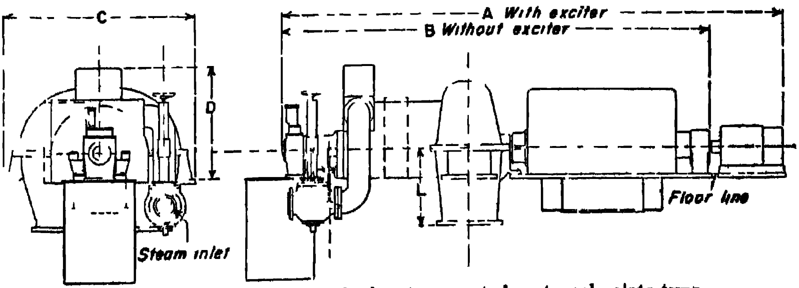

Fig. 8-90c Outline, 60-cycle direct-connected units, sole-plate type.

together with the points of application of these loads. However high-speed machines such as turbines have a live-load characteristic which should be allowed for in the design of a foundation. It is good practice to consider this factor as an impact load and figure it as an additional load which is equivalent to one-half the dead and vacuum load as applied at the various loading points on the foundation and which should be added to the dead and vacuum load to determine the total foundation loading.

Since serious operating difficulties result when a turbine-generator set is misaligned, deflections rather than unit stress are selected as the criterion of strength for the structure. For main supporting beams, the maximum deflection based on the above total loading consisting of dead load, vacuum load, impact load, and the weight of the beam itself should not exceed 0 020 in., and the closer this deflection approaches zero, the better. To provide horizontal rigidity, cross bracing and column reinforcement should limit the horizontal deflection at the foundation deck to not over 0.020 in., based on a force equivalent to one-half the total dead load acting in a horizontal direction at the center of the turbine shaft and at right angles to the axis of the shaft, parallel to the foundation deck.

Vibration. Since the vibration of the unit will be transmitted through the entire structure on which the set rests, it is recommended, as a means of limiting the transmission of the unit's vibration, that its foundation be separated from the station floor or any other part of the building structure. Because of resonant frequencies, almost imperceptible vibrations in the foundation structure itself may be amplified to decidedly objectionable proportions in interconnected adjacent structures. This is especially true for galleries or any other overhanging construction supported from the foundation.

***Subbase.** The subbase under the foundation should be sufficiently rigid to prevent local settling of any part of the foundation structure. Such settlement causes misalignment of the turbine, and vibration and rubbing difficulties may result. Separate footings for each column should be considered only where the foundation footings can be extended down to bedrock. Where this is not possible, a study of the soil may indicate that a reinforced-concrete mat will give the desired support.

Concrete Mixture. A concrete mixture of 1:2:4, based on using only the best material throughout, is usually adequate for these foundations. If poured during cold weather, necessary protection against freezing should be provided, and in all cases, proper setting time should be allowed before applying load. To secure the benefits of a first-class design, careful workmanship is a necessity in the construction of the foundation.

OPERATION OF STEAM-TURBINE GENERATORS

The installation of a turbine-generator unit represents a large plant investment To protect this financial outlay and to avoid unnecessary unit outages, care and precaution should be exercised in the operation of these sets Although turbine construction is inherently sturdy, efficient, and reliable, operation of these units depends on the maintenance of comparatively small clearances between the stationary and rotating parts. As a consequence, definite precautions should be observed in the starting, stopping, and normal operation of these sets.

Turbine manufacturers usually provide instruction books for the turbines which they build. When such data are available, reference should be made to them for detailed operating instructions. However, in the absence of such specific information, the procedures enumerated below can be used. While the instructions tabulated apply primarily to condensing units, they can also be used for noncondensing and automatic-extraction turbines by including several minor variations.

Turbine-generator Starting Procedure— Condensing Turbines (Fig. 8-91)

1. Open all casing drain valves.
2. Open drain ahead of throttle valve to drain condensate from the main, and then slowly open stop valve ahead of the throttle valve.
3. Start auxiliary oil pump, check oil pressure, and look for oil flow through bearing-sight flows.

4. Check level in oil reservoir.
5. Establish circulating-water flow through the condenser.
6. Start condenser air pumps.
7. Start condensate pump.
8. When drain ahead of throttle valve blows clear, open the throttle valve sufficiently to start the turbine rotor revolving, and then quickly shut off by
9. Tripping the emergency hand control to check its operation.
10. Listen for rubbing or internal noise within casing, using a metal rod or other listening device.
11. If no rubs are evident, reestablish steam flow and bring rotor speed up to about 10 to 15 per cent of the normal speed rating. Maintain about one hour to warm up rotor and casing evenly as soon as rotor is rolling steadily.
12. Close all casing drains or transfer to traps to increase vacuum as much as possible.

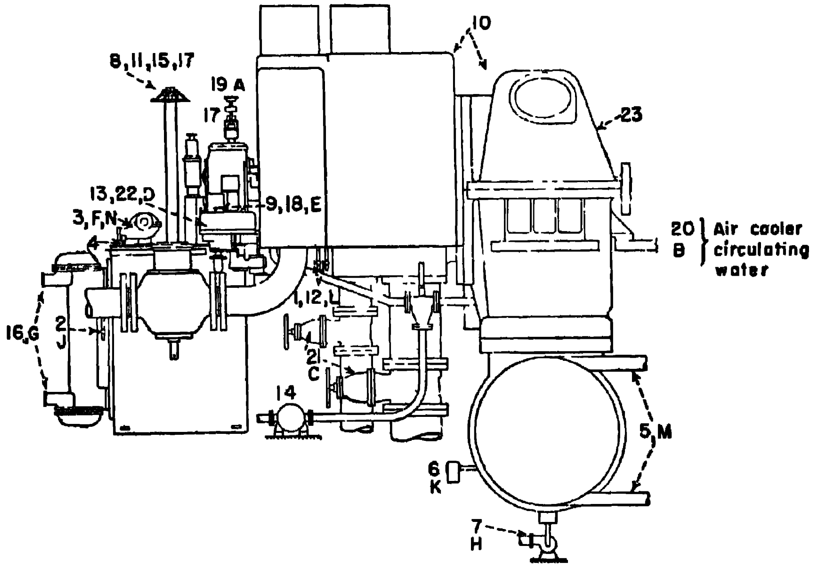

FIG. 8-91. Turbine starting and shutdown procedure.

13. Open packing-drain valves and admit sealing steam to the high-pressure and low-pressure shaft packing boxes using steam-seal regulator if turbine is so equipped. If water-sealed, admit water as required.
14. Start packing-drain condensers or vacuum pumps.
15. Gradually increase the speed to normal rated speed. If any abnormal vibration or noise is experienced at any time during acceleration, decrease the speed to 10 per cent of normal and continue the warm-up period until no difficulty is encountered during acceleration. Do not force a turbine to speed.
16. When the temperature of the oil leaving the bearings reaches 140°F, start the circulation of water to the oil cooler so as to maintain the temperature of the oil leaving the bearings between 140 and 160°F.
17. As the turbine approaches rated speed, observe to see that the governor takes control. When the turbine is operating under the control of the governor, open the throttle valve wide.
18. Trip the emergency device and see that the throttle valve closes promptly. Then reset the tripping device, open the throttle valve, and again bring the turbine up to rated speed.

19. Excite the field, synchronize the generator, connect it to the system, and apply about 20 per cent of normal load.

20. Start the water circulating in the generator air cooler if installed.

21. Open bleed-line valves and place heaters in operation.

22. Adjust high-pressure and low-pressure seals for operating condition, if necessary.

23. After exhaust hood has become cool, apply additional load as desired.

Turbine-generator Shutdown Procedure—Condensing Turbines (Fig. 8-91)

A. Gradually diminish the load to zero, disconnect the unit from the line, and remove the generator field excitation.

B. Shut off the water to the generator air coolers.

C. Close bleed-line valves, and take heaters out of service.

D. Close steam or water supply to high-pressure and low-pressure shaft packing.

E. Close the throttle valve by manually tripping the emergency device.

F. Check to see that the auxiliary oil pump starts as oil pressure falls

G. Shut off the water to the oil coolers.

H. Shut down condensate pump.

J. Close the stop valve ahead of the throttle valve, and open the drain ahead of the throttle valve.

K. To protect against internal corrosion, keep the condenser air pumps operating for about twenty minutes. Then shut down.

L. Open all atmospheric drains

M. Shut down condenser circulating-water pumps.

N. Keep auxiliary oil pump in operation until bearings are cool.

Special Procedures

Noncondensing Turbines. For noncondensing turbines, the same procedure applies except that condenser operations are naturally omitted. Turbines designed to exhaust against high back pressure may be brought to normal speed at no load when exhausting against atmospheric pressure. Before placing the unit on the line, the back pressure is raised to normal by gradually closing the atmospheric-relief valve and gradually opening the exhaust-line valve. As the back pressure is increased, the throttle valve is opened further to maintain speed until ultimately the turbine governs on the speed governor and the throttle is open wide.

Where it is necessary to start the turbine on high back pressure, the following starting procedure is recommended so as to avoid drawing an excessive amount of steam from the system.

1. Have oil pressure on the governing apparatus and bearings.
2. Turn the synchronizing handwheel so as to close the controlling valves.
3. Have the back pressure on the turbine.
4. Open the throttle valve wide.
5. Gradually open the controlling valves by means of the synchronizing handwheel until the rotor of the turbine starts turning.
6. As soon as the rotor starts to turn, regulate the rate of acceleration by opening or closing the controlling valves by means of the synchronizing handwheel.
7. When the governing speed is reached, synchronize the generator and connect it to the system.
8. If the unit is governed by a back-pressure governor, turn the synchronizing handwheel to the high-speed stop position.

Automatic-extraction Turbines. In placing automatic-extraction turbines on the line, they are brought up to speed and loaded first as straight condensing or noncondensing machines, as the case may be, and then the extraction valves are put in operation. Order of procedure is reversed for shutting down.

Routine Operation

Once a turbine-generator set has been connected into the system, normally very little attention is required during its operation. However, as precautionary measures, the following routine operational checks are recommended.

As with any other high-speed rotating equipment, bearing-discharge-oil temperatures and shaft vibration should be checked. Changes from normal values should be investigated for the cause of the variation. Higher oil temperatures may mean clogged oil passages or loss of cooling water.

Inlet- and exhaust-steam conditions should be observed and maintained as close as possible to normal. Stage-shell pressure should be noted in connection with electrical load. Any marked variation in these pressures,[6] if it cannot be explained by a change in operating conditions, may be an indication of plugging in the nozzles or buckets. The various safety devices should be operated occasionally to ensure their being available for use in an emergency. Generator temperatures should be read to ascertain whether or not the generator is being cooled properly.

These routine checks are quickly and easily made and serve to inform the operator as to the proper functioning of his equipment.

MAINTENANCE OF STEAM-TURBINE GENERATORS

Every turbine operator is confronted with the necessity of having his equipment available for use for the maximum percentage of time. To obtain this goal, it is desirable not only to follow established operating procedures as outlined under Routine Operation but also to follow a systemized method of planned inspection and overhaul. Such maintenance reduces outages, guards against hazardous operation, and aids in securing maximum possible steam economy from the unit. The following material contains suggestions which may be helpful in expediting the inspection and overhaul of steam-turbine generators.

Planning Preliminary to Overhaul

To reduce the outage time to a minimum, careful planning prior to the overhaul should be undertaken. Inspection data such as instruction books, drawings, governor-setting diagrams, and previous inspection records should be reviewed and studied. A tabulation of past operation difficulties to be corrected during the overhaul should be made up. Tables or charts on which can be recorded any measurements or notes giving information concerning the condition of the various elements should be prepared in advance. Any repair parts to be installed should be cleaned, inspected, and checked to see that no parts are damaged or missing. Rigging, blocking, tools, and special equipment required for the overhaul should be obtained and placed in first-class condition. Also, to secure the maximum possible benefit from the overhaul program, it is recommended that a competent field-service representative be obtained from the turbine manufacturer to supervise the work. This preliminary planning, if carefully done, will effectively decrease the time the unit will be out of service for overhaul.

Accurate Records

If the records of the parts inspected are to be useful in determining the deterioration rate of the various parts, and this is an important factor in the scheduling of future overhauls and in the ordering of replacement parts, the necessity of making careful and accurate records cannot be overemphasized. Photographs, wax impressions, templates, and sketches are all useful in obtaining accurate and lasting records. Such data when sent in to the turbine manufacturer assist in determining the proper replacement material and also aid in making recommendations for repairs. Many inspection reports contain only the inspector's opinions or conclusions and fail to include the basic facts. Such reports fail to provide valuable records of actual conditions. There is no substitute for accurate facts.

Turbine

Experience has indicated the potential troubles to be looked for in inspecting turbine generators and their accessories. Some suggestions which may prove helpful are enumerated below. Maintenance of the turbine is discussed first.

Steam-path Parts. The steam-path parts consisting of the nozzles and buckets or the blading should be examined carefully for the accumulation of deposits, erosion, corrosion, and cracks. An accurate record of the condition of these parts can be obtained by dimensional measurements and by the use of templates, wax impressions, and photographs. The location of plugged or corroded sections should be recorded. Samples of the deposits should be taken for laboratory analysis which may indicate means of eliminating further deposits or the development of a method for removing the deposits without having to open the turbine. The use of coarse sand blast for cleaning the steam-path parts is not recommended as this method produces rough surfaces which increase steam consumption Coarse sand blasting also produces sharp edges from which cracks may start, and there is also the danger of cutting away valuable metal in an attempt to remove hard deposits. Cleaning with a fly ash blast or fine sand (24 mesh or finer) (Fig. 8-92) or hand scraping is preferable to the use of coarse sand blast. Cleaning pays dividends in improved steam economy and in the reduction of the thrust load.

After the steam-path parts are cleaned, they should be examined minutely for erosion and small cracks. Erosion of nozzles and buckets or blading produces sharp corners or notches having high stress concentration which may result in the starting of cracks. Therefore, these sharp eroded portions should be removed and the edges smoothed and polished. Cracks or flaws in the blading may be discovered by a visual inspection with the aid of a small mirror similar to a dental mirror. Imperfections can be indicated by chalk marks and also recorded in writing. Another method is to apply penetrating oil such as kerosene to the cleaned blades, wipe off the excess oil, and then paint them with whiting If any cracks exist, the kerosene usually stays in the cracks and as soon as the whiting is dry the penetrating oil in the cracks will show through the whiting coat as a yellow streak. A magnetic particle test[9] may also be used to examine the buckets and nozzle blading when these parts are made of a magnetic material.

FIG. 8-92. Cleaning turbine blading with a fly ash blast.

Wheels, Rotors, and Shafts. Since the rotating parts of a steam turbine are relatively highly stressed at speed, it is important that these parts be cleaned down to bare metal so that any defects such as cracks will be disclosed. Tests for cracks should be made by either the "kerosene-whiting" method or the magnetic particle test previously mentioned under steam-path parts Wheels should be checked for movement on the shaft, cracks at the keyway, and sharp edges at the equalizer holes. The sound of each wheel when tapped with a hammer should be noted. A dead-sounding wheel is not necessarily a defective one, but a careful investigation should be made of any wheel having a dead sound if it previously had a bell-clear sound when tapped with a hammer, as such a change indicates a change in the solidity of the rotor assembly. Loose or cracked wheels often sound dead. Before any welding is attempted on any rotating parts of a turbine, the manufacturer should be consulted. Welding, improperly done, can set up internal stresses and also change the structure of the metal and cause cracks which may progress to failure.

Rough or pitted journals should be stoned, ground, or turned, depending upon the extent of the surface damage. If a suitable lathe is not available, this work can be done with the rotor in the unit. Figure 8-93 shows a No. 2 journal being ground with the rotor in place, using temporary bearings at the oil-deflector fits and driving the rotor by means of a motor belt drive on the shaft coupling. Figure 8-94 shows the setup for grinding a No. 1 bearing journal. If it is found necessary to true up a coupling face, great care should be taken in preparing the setup for doing this work. The rotor should be blocked so that it cannot move axially. To check the coupling face after machining or grinding, an indicator should be placed at a point directly opposite the point where the cutting tool is mounted. If the indicator is placed in the tool post where the cut is taken, it will usually indicate zero under any condition, whereas if the indicator is mounted directly opposite the tool post, it will indicate a runout double the actual runout if there was any axial movement of the rotor during the machining. This check should be made on all coupling faces being faced either with the rotor in its bearings or with the rotor in a lathe. Very often coupling faces are improperly machined in a lathe because the lathe-spindle thrust runs out, which causes a slight axial movement of the rotor. Coupling faces should be machined flat to 0.001 in. concave. Coupling faces must not be convex if good operation is expected.

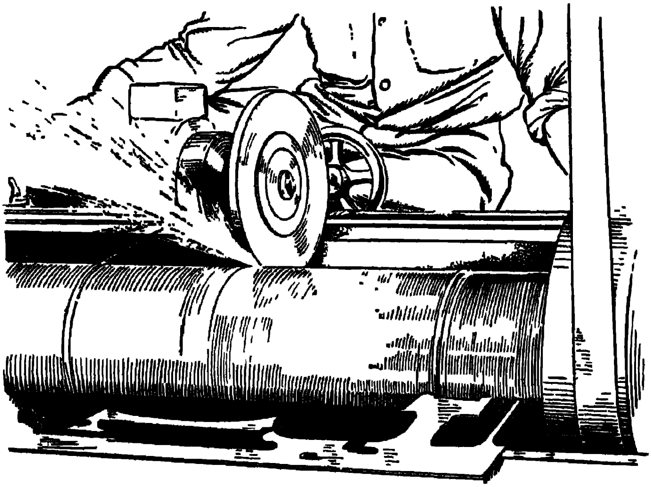

FIG. 8-93. Grinding a main journal.

Bearing Linings and Thrust Bearing. The bearing linings should be examined for wear. The clearances between the journal and the bore of the bearing should be measured and recorded. The clearance in the bearing can be measured either by shims or by lead wire. Bearing linings are usually manufactured with a vertical clearance over the shaft of 0.0013 in. per in. of shaft diameter. If the rotor is in good balance with no tendency to vibrate, rebabbitting may not be necessary until the vertical clearance has become 0.0025 in. per in. of shaft diameter. Records of past performance will usually indicate the allowable bearing clearance.

The babbitt surfaces should be inspected for cracks, high spots, and separation from the bearing shell. Cracking and separation may be caused by vibration in the rotating parts and if found will necessitate rebabbitting. High spots in the babbitt surface should be scraped down lightly to form a uniform bearing surface.

The thrust bearing maintaining the axial position of the rotor in relation to the casing should always be examined. The condition of the babbitt surface should be noted, and the clearance of the bearing should be readjusted to that specified by the manufacturer. Usually this clearance runs from about 0.006 to 0.012 in. depending upon the size and type of bearing.

Shaft Packing. The shaft packings of steam turbines usually fall into one of three classes—the labyrinth type, carbon ring, or water seal, or in some cases combinations of these types. These shaft seals should be examined for wear. The packing clearances recommended by the manufacturer should not be reduced, or vibration trouble may be encountered. By careful machining, worn packing can often be reconditioned. If the shaft-packing fits are found to be pitted or eroded, turning or grinding will recondition the surface. The packing must then be refitted. Where metal-spray equipment is available, shaft-packing fits can sometimes be satisfactorily repaired thereby maintaining the original shaft diameter at the packing fit, but the manufacturer should be consulted for his recommendations on this procedure.

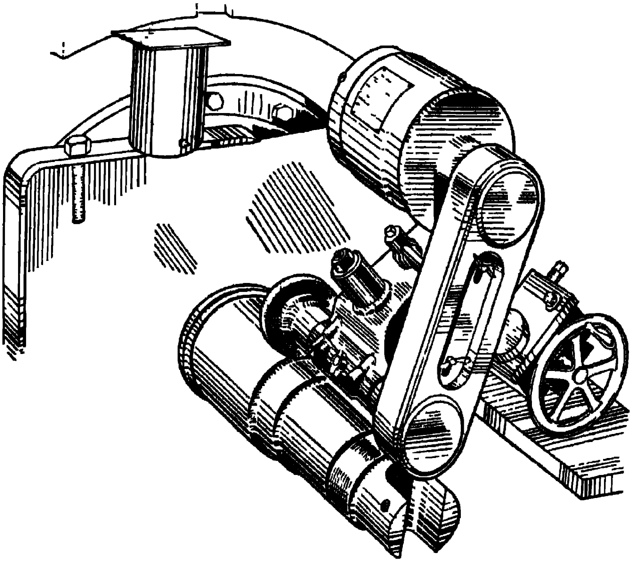

FIG. 8-94. Setup for reconditioning a No. 1 bearing journal by grinding without removing the rotor from the casing.

Casing Erosion. Where casing erosion is experienced, it is usually caused by the accumulation of a high moisture content in the expanding steam. The tiny droplets of water hurled from the rotating blades with a high velocity impinge against the casing and wear away the surface. If possible, the initial superheat of the steam should be increased or the turbine manufacturer should be consulted as to the possibility of adding moisture separators to the casing to remove this moisture which not only causes casing erosion but also reduces the steam economy of the unit.

Repair of the eroded surface can be made either by welding or by the insertion of filler strips or patch plates. Welding, if possible, is usually the less costly process, but caution must be exercised to avoid casing distortion during welding. Where the casing is steel, repair can be made by welding up the eroded portion. On a cast-iron casing it is usually necessary to machine down the surface and install patch plates to repair steam joints, although it may be possible to effect repairs by bronze or monel welding. Erosion elsewhere can be restored with metal spray of a noncorrosive material or by covering the worn spot with patch plates so that future wear will be on the plate which is replaceable. In all cases of serious erosion or corrosion it is advisable to determine the casing thickness by making a template of the contour which can be checked against the drawing dimensions by the manufacturer.

Lubrication System. Cleaning of the lubrication system is an important item in the overhaul work. It is a hard, tedious task to clean an oil system properly, but it is worth while. A clean lubrication system results in longer oil life, reduces sludge, and helps prevent corrosion or rusting of parts. If any part of the lubrication system requires painting, be sure the proper paint is used. And, equally important, the surface must be properly prepared, or the paint may come off with disastrous results. The oil supplier should be consulted for information on cleaning solvents and painting of lubrication systems. A partly cleaned system is a hazard as sludge or dirt from the dirty section may be dislodged and block lubrication.

The main oil pump usually of the positive-displacement gear type and driven at reduced speed through a worm-gear drive should be carefully inspected for proper alignment and wear of the moving parts. The bearing and guide-bushing clearances should be checked against the manufacturer's recommendation. The pump-casing clearance and the wear of the pump gears should be recorded. The condition of the driving worm on the turbine shaft and of the driven gear on the pump shaft should be noted and a careful alignment made of these parts.

The auxiliary oil pump, usually of the centrifugal-type driven by a steam turbine should be given an inspection similar to that described for the main oil pump.

Governor and Valve Gear. The various bushings and pins on the governor and the connecting valve gear linkage should be examined for excess clearance and the condition of the parts recorded. Those showing abnormal wear should be replaced so as to ensure proper functioning of the governor system.

Generator

During the overhaul of a turbine generator the most important points to check on the generator are the condition of the insulation, cleanliness of the whole unit, and mechanical condition of the rotating parts.

Insulation. After disassembling the generator the exposed parts of the windings should be inspected for dirt, oil, grease, carbon dust, or other deposits. Dry dirt should be removed with a vacuum cleaner or by carefully blowing out with dry compressed air. Oil or other gummy deposits should be cleaned off with carbon tetrachloride. If the varnish is damaged, the windings should be revarnished with air-drying varnish.

Before reassembling, the insulation resistance of all windings should be measured with a Megger. Readings of insulation resistance should also be taken at regular intervals between overhauls, using the same or a duplicate Megger each time and recording the temperature and atmospheric conditions under which the readings are taken each time. A record should be kept of these readings to note any unexplained sudden drop in resistance or a gradual decrease with time. When the resistance drops to one-tenth or less of the original value when the machine was clean and new, it is time to consider taking the machine out of service for repair.

The insulation of rotating parts should be inspected as far as possible to note any cracks or mechanical breaks in the tape, collars, etc. In the case of round-rotor generators, it may be advisable to remove the retaining rings, or end bells, if there is any suspicion of mechanical breaking of the coil insulation underneath.

It will not be possible to get any direct visual inspection of the slot portions of the rotor coils on round-rotor generators or of the slot portions of armature coils on any machines. Reliance must be placed in the insulation-resistance readings to check the condition of these parts of the generator.

Air Passages. In addition to checking the cleanliness of the windings themselves, the air passages in the generator should be carefully inspected. These include the air ducts in the stator core, air passages in the frame, holes in the centering rings on round-rotor machine, air spaces under the rotor-coil ends, ventilating slots or holes in the rotor core, etc. All such passages should be blown out carefully with compressed air (free from moisture), and oil or gummy deposits wiped off the surfaces with carbon tetrachloride where they can be reached. The same attention should be given to fan blades and rings.

Any unusual amounts of dirt or unusual oil or other deposits should be investigated to see if air seals, oil deflectors, and brushes are properly fitted during operation.

Rotor Parts. Rotors should be examined for tightness of wedges, bolts, and screws. Any surface cracks or flaws should be noted. Risers on d-c armatures should be checked for breakage or other damage such as overheating. Signs of burning at the wedges on round-rotor a-c generators should be looked for as an indication of unbalanced current loading.

Retaining rings and fans should be examined carefully for any signs of cracks or flaws. Retaining rings that fit over wedges or cores should be particularly inspected for signs of localized heating or burning in the tips due to unbalanced circuit loading Retaining rings and fan fits should be checked for tightness as well as for tightness of locking screws, etc.

Collector Rings and Brush Rigging. The active surfaces of collector rings should be inspected, and any evidence of threading or grooving, unusual wear, or unusual deposits or coatings should be noted. These may give an indication of poor brush fitting or operation at wrong brush pressure or with wrong brushes. The diameters of the rings should be checked to make sure the safe wearing depth is not exceeded. The rings should be trued up, cleaned, and polished if necessary.

The collector insulation should be cleaned off, checked for cracks or other damage, and revarnished if necessary. Leads should be inspected for tightness of joints and for cracks or signs of overheating

Brush rigging should be checked for tightness of bolts, studs, connections, etc. The condition of stud insulation, washers, etc , should be examined and these parts replaced if necessary. Dirt and gummy deposits should be removed Brushes should be inspected for fit on rings or commutator, chipped or cracked brushes should be replaced, and the freedom of movement of brushes in holders checked. Brush pressure should be set at the value recommended by the manufacturer.

Exciter

In general the same points should be checked on a d-c generator or direct-connected exciter during overhaul as on a-c generators.

Insulation. The cleanliness, insulation resistance, and mechanical condition of the armature and field windings of an exciter should be checked and repaired in the same way as for an a-c generator. A more thorough visual inspection of the windings can usually be made on d-c machines, and full advantage should be taken of this fact.

Most modern turbine generators are equipped with direct-connected exciters which are totally enclosed and ventilated by air from the main unit. A filter is provided to prevent the return air from the exciter from carrying carbon dust from the brushes into the main generator air circuits. The condition of this filter should be periodically checked, and it should be replaced when the resistance to air flow through it becomes double that of a new clean filter. Any unusual deposits or collections of dirt or oil inside the housing should be investigated. The exciter should be carefully cleaned out after sanding or stoning the commutator or fitting brushes.

Windings and Connections. It should be made certain that all electrical connections are tight. The windings, risers, bolts, etc., should be checked for evidences of overheating or mechanical failures, such as cracks, etc. In particular, it should be made sure that the binding wire on the armature is not disturbed or damaged.

Commutator. The commutator surface should be examined for blackening or rough spots, high mica between bars, amount of wear, etc. Ordinarily, the commutator will require only occasional cleaning off with a piece of canvas or other nonlinting substance. Oil should not be used. In severe cases of burning or roughening, it will be necessary to stone or even to turn down and regrind the commutator.

Brushes and Brush Rigging. The brush rigging and holders should be cleaned off. Defective insulating studs, washers, or yokes should be replaced. Bolts, screws, connections, etc., should be tightened if necessary. Brushes should be checked for fit on the commutator. Chipped, cracked, or worn brushes should be replaced. Free movement of the brushes in the holders should be checked. Position of the brush yoke should be checked to see that it has not shifted from the original position. Brush pressure should be set on individual brushes at the value recommended by the manufacturer.

Accessories

The various protective devices such as relief valves, nonreturn valves, and oil-pressure regulator should be given an operation test before being placed in service, and a record should be made of the test.

The throttle trip valve should be tested for smooth and easy operation. If any sluggishness is noted, the parts should be cleaned thoroughly and the defect remedied. A sticky throttle valve is a hazardous operating condition.

The tubes of the oil cooler and the generator-surface air cooler should be inspected for plugging and leaks. The oil-cooler tube bundle is usually removable and may be cleaned by slushing in a commercial metal-cleaning solution. The manufacturers of such cleansing solutions furnish comprehensive instruction for their use. Normally only the water side of the air cooler requires cleaning, and in the majority of instances, such cleaning can be done with rubber plugs and compressed air or other standard methods used for cleaning condenser tubes. If the air side of the tubes becomes dirty, it is necessary to remove the sections and clean them with water or a solution of washing soda as previously mentioned. An alternative method is to apply through the tube bundle an air blast saturated with carbon tetrachloride.

During the inspection period, it is also desirable to clean and recalibrate all flow meters, pressure gages, and thermometers. Replacements, if necessary, should be obtained to ensure safe operation.

GAS TURBINES*

BY DR. J. T. RETTALIATA

Consultant to Allis-Chalmers Manufacturing Co., Milwaukee, Wisconsin,
Dean of Engineering, Illinois Institute of Technology,
Chicago, Illinois

HISTORICAL

The gas turbine has a history traceable to the period preceding the birth of Christ. Hero[1,4] of Alexandria, in 130 B.C., is credited with the first device that could be included in the category of gas turbines. The medieval "smokejack,"[2,5] similar to a windmill, could also be considered a form of gas turbine.

In 1791, Barber[3] of England obtained a patent on a machine which, while of primitive design, contained the essential features of a modern gas turbine. In 1808, Dumbell,[4] also of England, patented a device which was a prototype of the "explosion" type of gas turbine.

The first serious attempt at achieving a practical gas turbine occurred in 1872 when Stolze[6] of Germany built a machine which appeared to be of advanced design. Tests conducted on the unit were unsuccessful, however.

During the years 1903 to 1906, the Société des Turbo-moteurs,[6,7] in Paris, experimented with gas turbines and produced a unit that operated under its own power. While the machine obtained a thermal efficiency of only less than 3 per cent, it was probably the first combustion gas turbine to produce useful output.

In 1908, Karavodine,[5] in Paris, built a small gas turbine which operated on an explosion cycle with open combustion chamber, similar to the German V-1 "buzz bomb" used during the Second World War. The thermal efficiency of the Karavodine machine was very low, although the turbine allegedly operated satisfactorily.

Also in 1908, Holzwarth[8] began the development of his explosion type of gas turbine and is reputedly continuing this work at the present time. Notwithstanding the long period of experimentation, reports infer that there are only several Holzwarth turbines operating in the world today. Stodola has concluded that a thermal efficiency of 13 per cent is the highest obtained up to 1927 on tests of turbines of this type.

Despite a development period extending over two millenniums, the gas turbine did not achieve commercial significance until the third decade of the twentieth century. The main obstacles confronting the early investigators were twofold. (1) The then-existent materials were incapable of withstanding the elevated temperatures necessary to produce suitable cycle efficiencies. (2) The compressors available at the time did not possess adequate efficiencies so as to make the cycle feasible.

These difficulties have been surmounted by recent metallurgical and aerodynamic advances. Utilization of the required high temperatures is accomplished with the superior materials now available, and a highly efficient axial-flow compressor has resulted from progress in fluid research.

OPERATING PRINCIPLES

Practically all present-day gas turbines operate on a cycle wherein combustion occurs essentially at constant pressure instead of at constant volume, as in the case of the Holzwarth turbine. Those operating on the former cycle are referred to as "combustion gas turbines." Of these, the majority are of the "open"-cycle type wherein air is continuously taken in from the atmosphere and exhaust gases from the turbine are discharged back to the atmosphere. There are other gas-turbine cycles in existence which are referred to as "closed" cycles because the working medium is not expelled from the system but rather is continuously recirculated. This type will be discussed under Closed Cycles for Gas Turbines. All subsequent comments will refer to open-cycle units unless specifically designated otherwise.

---

* Superior numbers refer to specific references listed at the end of this subsection.

Simplicity is one of the distinguishing features of open-cycle machines. Absence of the many diverse appendages characteristic of previous types has undoubtedly contributed to the commercial success which they have attained. Basic constituents of a combustion-turbine unit are a gas turbine, compressor, combustion chamber, and fuel equipment. Supplementing these with a generator, lubrication system, control apparatus, and a means for starting completes a power plant significant primarily because of its lack of the veritable myriad of auxiliaries necessary for steam-plant operation. Furthermore, since its working medium, air, is universally available and because water is not required in its operation, the basic gas-turbine plant enjoys the added unique advantage of being independent of geographical location.

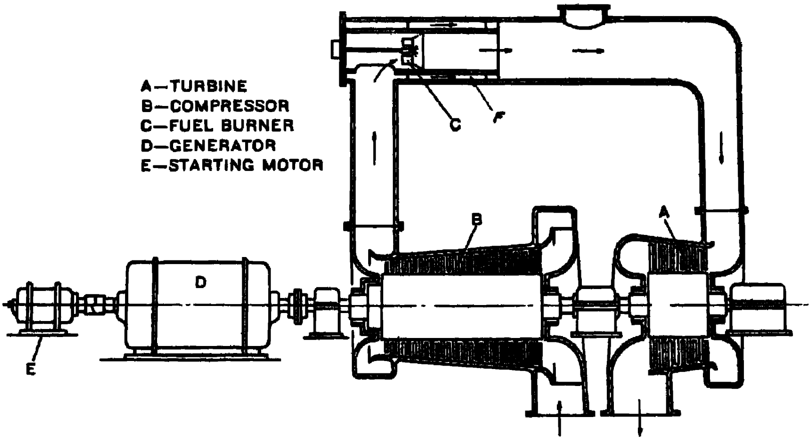

Fig. 8-95. Section through combustion gas-turbine–axial-compressor unit.

The arrangement of a modern combustion gas-turbine unit is depicted in Fig. 8-95. Air from the atmosphere is compressed in a multistage axial-flow compressor *B*, driven by a reaction-type gas turbine *A*. Liquid or gaseous fuel injected at *C* is burned with part of the air discharged from the compressor; the remaining, and greater, part flows through the annular space *F* and, upon emerging, mixes with and cools the products of combustion to a suitable turbine-inlet temperature. Expansion of this gas to atmosphere in the turbine produces more power than that required to effect compression of the air, and the excess power is supplied to a generator *D*. For starting purposes, a motor *E* is provided to bring the unit up to approximately 25 per cent of normal running speed, beyond which the turbine is capable of driving the compressor unassisted.

A speed governor, regulating the fuel supply and thereby the turbine-inlet temperature, affords the necessary control equipment. If a designated overspeed is exceeded, an emergency governor actuates a valve, causing the gas to by-pass the turbine. Balance pistons are not required since the axial thrusts of the turbine and compressor, being equal and opposite in direction, are effectively neutralized through the solid coupling connection. A thrust bearing is provided, however, to absorb any slight axial unbalance that may inadvertently exist.

The axial-flow type of compressor, as shown in Fig. 8-95, is believed to be the most desirable for gas-turbine units, principally because of its higher efficiency. Other types, however, have also been used. Gas turbines have been built with positive-displacement compressors of the Lysholm type. In most instances, centrifugal compressors have been employed in aircraft jet-propulsion gas turbines, although many axial compressors have been used for this service too.

DESIGN FEATURES

Turbine. Since the gas turbine in the prime mover size range has been in successful operation for only a relatively short period, its applications have been necessarily limited and of a special nature.

The principal commercial application in this country has been in oil refineries employing the Houdry process, a catalytic cracking method of manufacturing high-octane gasoline. Air, discharged from the axial compressor after being used in the process to reactivate a catalyst, is returned to the turbine as a high-temperature gas which, upon expansion, produces power to drive the compressor. The excess power is furnished to the generator. In this arrangement no combustion chamber is required since the process itself acts in this capacity after the sequence of operations in the cycle has been established.

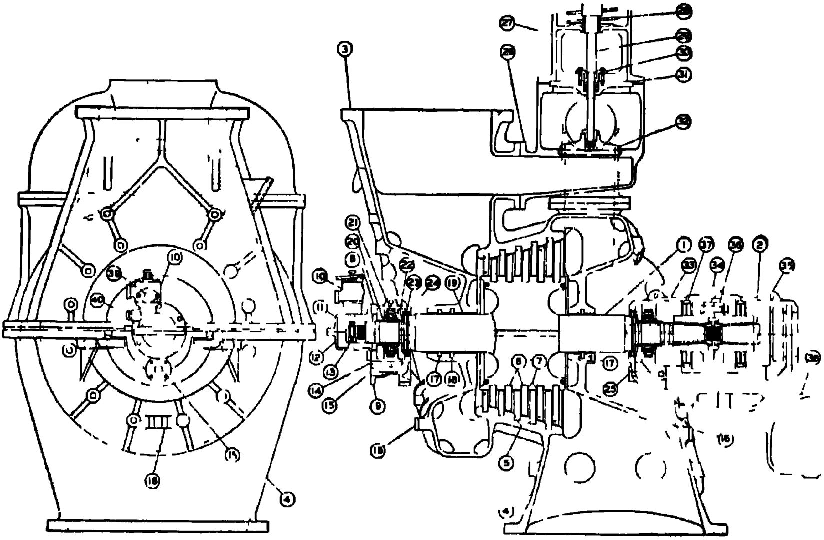

FIG. 8-96. Section through 40,000-cfm gas turbine.

As the pressure drop through the process is appreciable when compared with the maximum-cycle pressure, the net power developed is not so great as that which could be produced if a conventional combustion chamber were employed. The depreciation in useful power can be condoned in this particular instance, however, as the primary function of the gas-turbine unit is the furnishing of compressed air to the process, and any excess power may be considered a by-product. The use of the gas turbine in this application contributes to the economic justification of the Houdry process.

The oil-refinery gas turbines were originally designed and manufactured by Brown-Boveri[9] and Company of Baden, Switzerland, which has done much pioneering development work in the gas-turbine field. Most of the Houdry units, however, have been built by Allis-Chalmers,[10] at first to Brown-Boveri designs under a license arrangement, but later to modified designs after expiration of the license several years ago.

To fulfill the air requirements of various installations embodying the application of the Houdry process, units having compressor capacities of 16,000, 23,000, 40,000, and 60,000 cfm have been constructed. Since the Houdry units are representative, in general, of gas turbines operating on the basic open cycle, one of them will be used for illustrative purposes so that design features can be described. A section through the gas turbine for a 40,000-cfm unit is shown in Fig. 8-96. Neglecting the numerous details, reference will be made only to the major parts.

A solid chromo-nickel-steel forging comprises the turbine spindle 1 on whose periphery are inserted five rows of reaction blading 6, to be described more fully later.

The turbine casing, split on the horizontal center line, is cast of carbon-molybdenum steel. The gas inlet passage 3 and exhaust passage 4, both located in the same vertical plane, are cast integrally with their respective cylinder halves. Five rows of reaction cylinder blading 5 are inserted in grooves machined in the casing. A by-pass connection 26 joins the inlet and exhaust regions through a valve 32 operated by an emergency governor 10 when overspeed conditions exist.

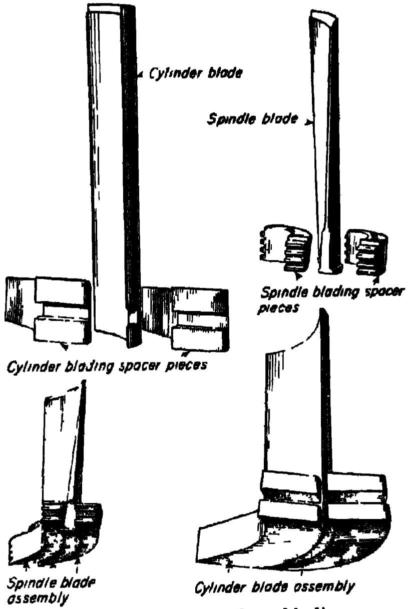

Fig. 8-97. Gas-turbine blading.

Labyrinth glands 19 are provided to prevent leakage of gas to atmosphere where the turbine-spindle ends emerge from the casing. To reduce gas leakage further, sealing air from the compressor discharge is injected at a suitable point 17 in the glands.

Roller bearings 21 are shown, however, these would be of the sleeve type in a machine designed for power purposes only. Some of the later Houdry units also have sleeve bearings. A solid coupling 36 joins the turbine spindle 1 with the rotor 2 of the axial compressor.

The turbine cylinder and spindle blades with spacer pieces are shown in Fig. 8-97. The tapered and twisted spindle blades, milled from 19 per cent chromium–9 per cent nickel steel containing small amounts of tungsten, molybdenum, titanium, and columbium, are securely held in place by the engaging of the upset end of the blade with the serrated spacer pieces. The cylinder blades, made of the same material, are fastened in their grooves by the engaging of a projecting ring in the groove with a slot in the blade and the close-fitting spacer pieces. Later designs have an integral root blade.

Compressor. A sectional view of the axial compressor used on a 40,000-cfm unit is shown in Fig 8-98 The forged-steel rotor 1 consists of a shaft end having a hollow cylinder for the spindle proper on which the rotating blades 6 are mounted and a drum with the other shaft end The hollow cylinder is shrunk onto the drum and locked

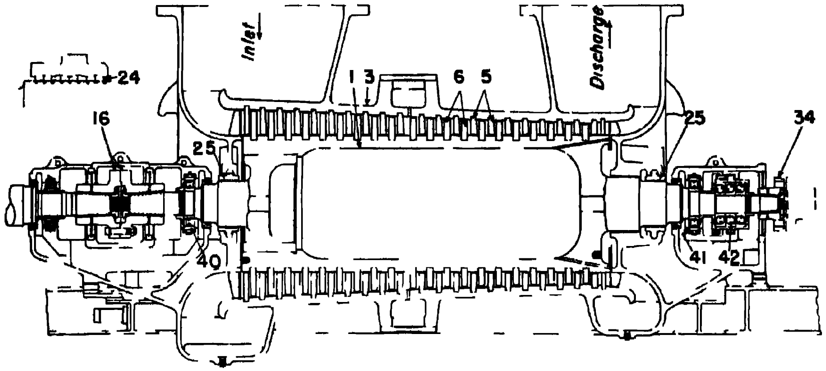

FIG 8-98 Section through 40 000-cfm axial compressor

The cast-iron casing 3 is horizontally split with intake and discharge openings are directed vertically upward and cast integrally with the upper half The stationary blading 5 is inserted in grooves machined in the inner periphery of the cylinder

Where the shaft ends pass through the casing, labyrinth sealing glands 25 are provided These glands consist of radially projecting fins 24 on the shaft which rotate with close radial clearance in grooves in the casing 25 The turbine glands are similarly constructed

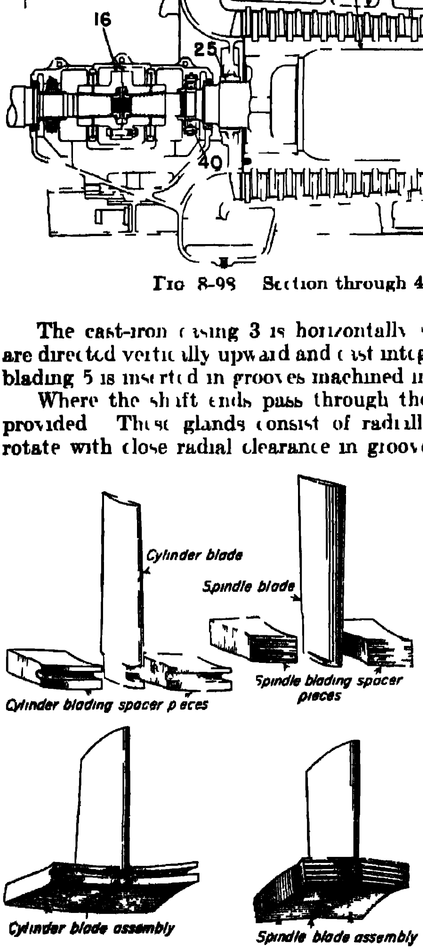

FIG 8-99 Axial-compressor blading

Roller bearings 40 and 41 are shown, but as in the case of the turbine, a power unit would be designed with bearings of the sleeve type A ball thrust bearing 42 absorbs any slight axial thrust that may exist In a power unit this thrust bearing would be of the Kingsbury type

The solid coupling 16 transmits the driving torque of the gas turbine to the compressor The excess power of the unit is supplied to the generator through a gear connected to the coupling end 34

The cylinder and spindle blading used in the axial compressor is shown in Fig 8-99. Since high temperatures are not involved, 5 per cent nickel steel is used as blading material Root fastenings similar to those described for the turbine, are depicted, but later designs have a one-piece blade construction where the root is integral with the flow-passage part of the blade The blades have airfoil cross sections, as aerodynamic requirements dictate such contours in order to produce a high-efficiency axial compressor

Combustion Chamber. When used as a power-producing unit, the gas turbine would have a combustion chamber located between the compressor discharge and the turbine inlet. The chamber is essentially a cylindrical pipe with a fuel-burner element located in the end near the compressor.

After removal from the combustion chamber proper the burner is shown in Fig. 8-100. Louvers, with provision for external adjustment, assure a suitable apportionment of the air discharged from the compressor so that the correct quantity enters the burner for combustion purposes. The remaining air flows through the annular passage defined by the combustion chamber wall (not shown) and the steel liner. Deflectors located in this passage impart a whirling motion to the air, creating a turbulent condition which produces a thorough subsequent mixing with the products of combustion emerging from the central portion of the liner.

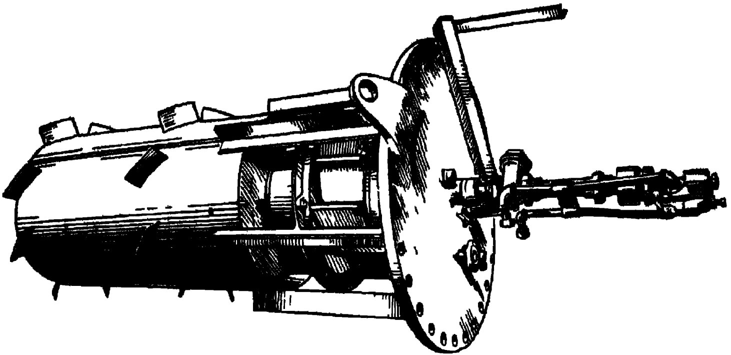

Fig. 8-100. Fuel-burner element.

Assembly. A partially assembled 23,000-cfm gas-turbine axial-compressor unit is shown in Fig. 8-101. Mounted on a common base plate, the six-stage turbine at the left is directly coupled to a 21-stage compressor at the right. This unit, operating at 6,000 rpm, is geared to an 1,800-rpm generator not shown. Lashing wires installed in the first stationary and last two rotating blade rows in the turbine increase the vibrational frequency and reduce the bending stresses in the blades. Roller bearings and labyrinth sealing glands may be clearly seen.

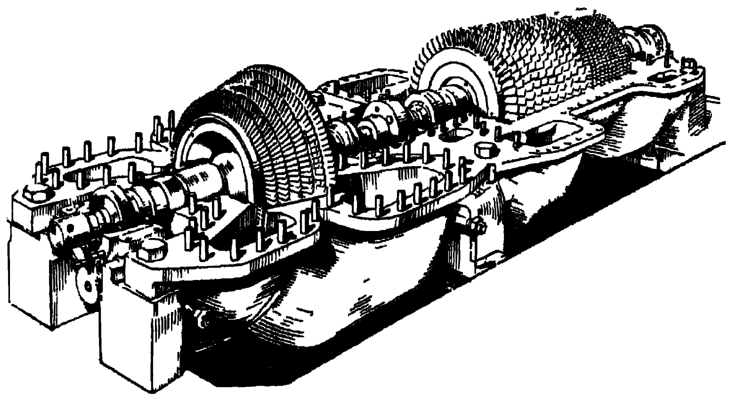

Fig. 8-101. Partially assembled 23,000-cfm gas-turbine–axial-compressor unit.

Except for the installation of the combustion chamber, a completely assembled 40,000-cfm gas-turbine axial compressor unit is shown in Fig. 8-102. This machine

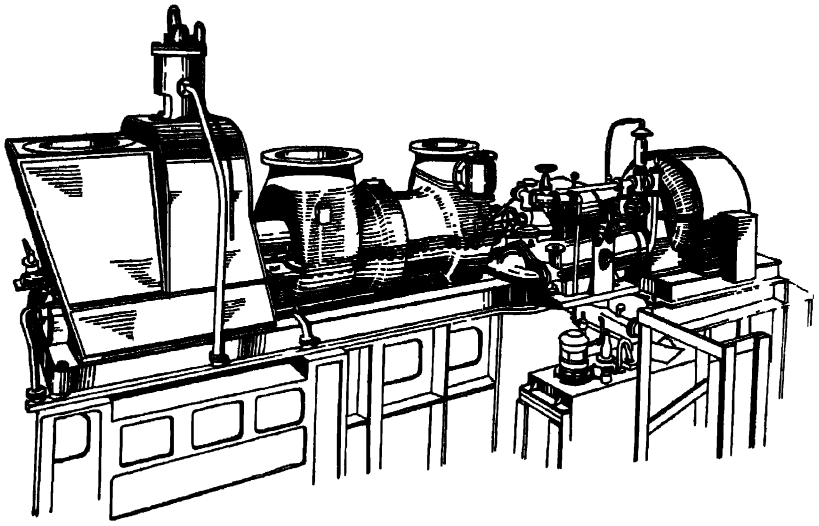

FIG. 8-102. Allis-Chalmers gas-turbine–axial-compressor unit of 40,000 cfm cap

would have a net coupling output of 2,600 hp when operating on 1200°F gas at the turbine inlet.

PERFORMANCE CHARACTERISTICS

Basic Cycle (Cycle A). The performance of a gas-turbine unit depends, among other factors, upon the type of cycle adopted. The basic cycle shown in Fig 8-95 is reproduced schematically in Fig. 8-103 and designated as cycle A. The thermal efficiency of this cycle is given in Fig 8-104 as a function of pressure ratio for various turbine-inlet gas temperatures from 800 to 1600°F. The performance data presented in Fig 8-104 and subsequent Figs. 8-106, 8-108, 8-110, and 8-112 are based on a turbine efficiency of 86 per cent, a compressor efficiency of 84 per cent, a combustion efficiency of 98 per cent, a compressor intake temperature of 60°F, and mechanical losses of 0.5 per cent in the turbine and also in the compressor.

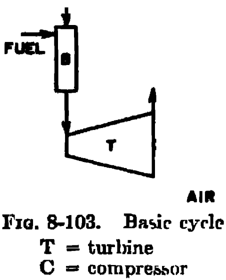

FIG. 8-103. Basic cycle (cycle A).

T = turbine

C = compressor

B = combustion chamber

In those cycles employing regeneration, the heat-exchanger surface is 5 sq ft per coupling hp, and the over-all heat-transfer coefficient from gas to air is 10 Btu/(hr) (sq ft)(deg F). Where intercooling is used, the surface of the intercooler is 1.5 sq ft per coupling hp, and an over-all water-to-air coefficient of heat transfer of 20 Btu/(hr) (sq ft)(deg F) is taken. The performance calculations for all the cycles account for the pressure drops occurring in the various elements.

In all cases the thermal efficiency is defined as the ratio of the useful output at the coupling to the energy required from the fuel, each expressed in appropriate units

Referring to Fig. 8-104 it can be seen that the thermal efficiency improves with increasing gas temperature at the turbine inlet. It will also be noted that the higher temperatures require an increase in cycle pressure ratio in order to achieve maximum thermal efficiency As will be observed later for all cycles, the efficiencies are enhanced by the use of elevated temperatures, and, similarly, such temperatures necessitate higher pressure ratios for optimum conditions to exist.

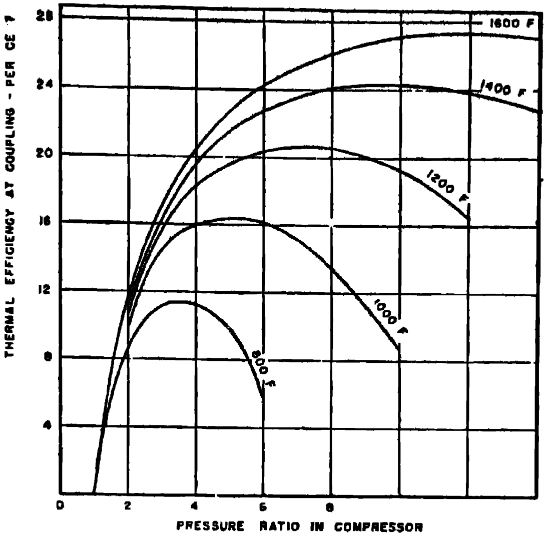

FIG. 8-104. Thermal efficiency of basic cycle.

Regenerative Cycle (Cycle B). In order to improve the efficiency, cycle A can be modified from the basic form into a regenerative type by the addition of a counterflow heat exchanger as shown by cycle B in Fig. 8-105. With such an arrangement the turbine exhaust gas is used to preheat the compressor-discharge air before entry of the latter into the combustion chamber. Figure 8-106 shows the efficiency of this kind of cycle, and the improvement effected by the heat exchanger is readily apparent. At 1200°F, for example, the maximum thermal efficiency is 28.4 per cent, representing an increase of 38 per cent over the corresponding efficiency of cycle A at the same temperature. It will be noted that, in addition to increasing efficiency, the heat exchanger also has the effect of reducing the value of the pressure ratio for the point of maximum efficiency. Regenerative heating by this method influences all cycles similarly.

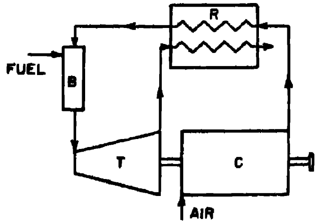

FIG. 8-105. Regenerative cycle (cycle B).

T = turbine
C = compressor
B = combustion chamber
R = regenerator

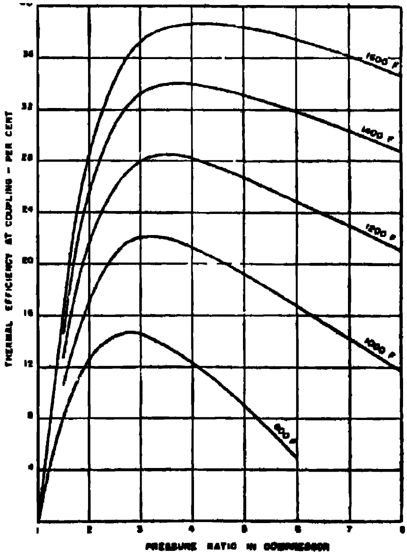

FIG. 8-106. Thermal efficiency of regenerative cycle.

Regenerative Cycle with Reheating (Cycle C). A still higher efficiency cycle can be obtained by incorporating a reheat turbine, as shown by cycle C in Fig. 8-107. In this system, instead of the expansion occurring uninterruptedly in the turbine as in cycle B, the motive fluid is withdrawn at an intermediate point and heated externally until its temperature corresponds to the value at the turbine inlet. It is then reintroduced into the turbine where it expands to the exhaust pressure. For optimum conditions, the reheat point should be selected so that the work done by the portions of the turbine before and after the reheat belt is approximately equal. A comparison of Figs. 8-106 and 8-108 will show the benefit of reheating. It can be seen that reheating has an effect

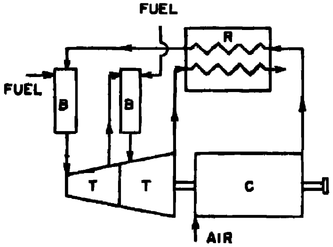

FIG. 8-107. Regenerative cycle with reheating (cycle C).

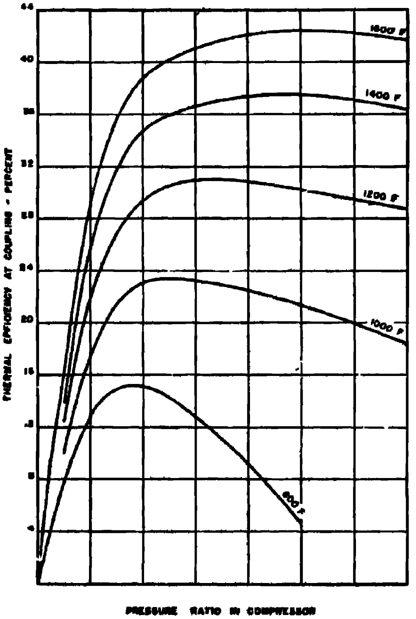

FIG. 8-110. Thermal efficiency of regenerative cycle with intercooling.

counter to that of regeneration in that optimum results occur at higher pressure ratios.

Regenerative Cycle with Intercooling (Cycle D). Another method of augmenting the performance of cycle B is to incorporate an intercooler in the compression part of the cycle and thereby reduce the power required by the compressor. Thus the air from the atmosphere is partially compressed and then cooled indirectly by water in a counterflow heat exchanger, after which it undergoes its final stage of compression. This combination is shown as cycle D in Fig. 8-109. The performance characteristics of cycle D are given in Fig. 8-110. As in the case of reheating, when compared with cycle B, the introduction of intercooling increases the pressure ratio associated with maximum efficiency conditions.

Regenerative Cycle with Reheating and Intercooling (Cycle E). When all the aforementioned elements are used in a gas-turbine cycle, best results in the way of thermal efficiency are obtained. Cycle E, employing such a combination, is depicted in Fig. 8-111 The thermal efficiencies of the cycle at various temperatures and pressure ratios are given in Fig. 8-112. The added refinements of reheating and inter-

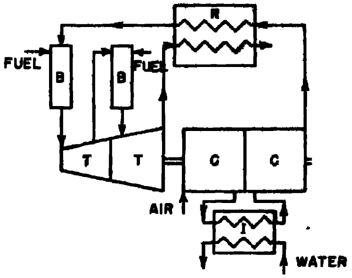

FIG. 8-111. Regenerative cycle with reheating and intercooling (cycle E).

I = intercooler

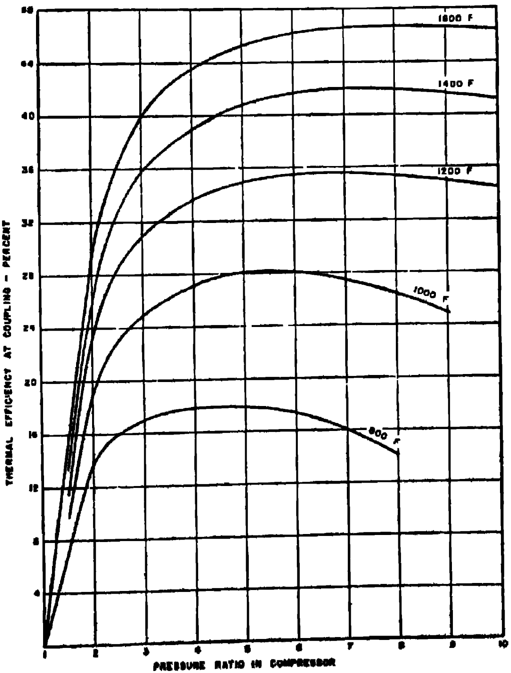

FIG. 8-112. Thermal efficiency of regenerative cycle with reheating and intercooling.

cooling have, as in the case of cycles C and D, moved the point of maximum efficiency to ever higher pressure ratios. Flatter efficiency characteristics have also resulted.

Comparison of Cycles. The maximum efficiencies have been plotted in Fig. 8-113 as a function of temperature for all the aforementioned cycles so that a comparison can be readily made. The increase in thermal efficiency with higher turbine-inlet temperatures is readily apparent. Because of such beneficial results obtained with the use of elevated temperatures, there is a real incentive for metallurgical advances so as to develop superior alloys to operate in the upper regions of temperature.

While all cycles improve with increased turbine-inlet temperature, it will be noted by comparing cycles A and B that the single modification showing the greatest relative gain is the addition of the heat exchanger to the basic cycle. From this observation it can be concluded that the most obvious manner in which to improve fuel consumption is to employ a heat exchanger, as it is a comparatively inexpensive piece of equipment with relatively low maintenance.

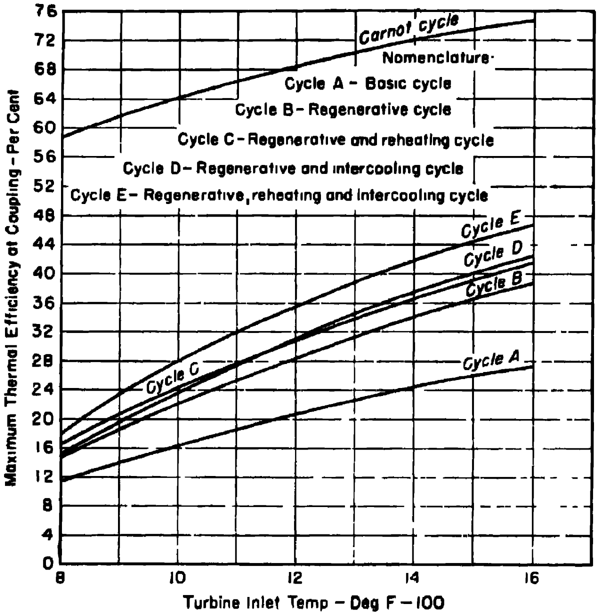

FIG. 8-113. Maximum thermal efficiency of various cycles.

Reference to Fig. 8-113 will reveal that the rate of improvement occasioned by higher temperatures increases as additional elements are embodied in the cycle. Thus a given increment in temperature benefits the more complex cycles to a greater extent than the others. For the conditions selected, reheating and intercooling both show about the same average gain when applied individually to the regenerative cycle.

The Carnot efficiency, representing the maximum possible attainment of any cycle between given temperature limits, is also shown on Fig. 8-113. Notwithstanding all the refinements incorporated in cycle E, it is still lacking to a considerable degree when compared with the ideal reversible Carnot cycle at a given temperature In the limiting case, however, with infinite surface in the regenerator and an infinite number of reheating and intercooling points, cycle E will then be theoretically reversible and will have the same efficiency as the Carnot cycle between any given temperature levels. The magnitude of the difference between the actual cycle E and the

Carnot is a measure of the departure of the performance of the various cycle components from ideal conditions.

In the foregoing cycles, it was intended to show the effect on performance of a change in the cycle by adding a single element at a time, starting with the basic cycle. In each cycle where it is used, the regenerator has the same surface for a given output and the same coefficient of heat transmission. This also applies to the intercooler. Thus the various cycles are directly comparable when determining the effect of the respective elements since corresponding components are based on the same conditions.

As a result of this premise, therefore, the regenerator and intercooler effectivenesses are different for each cycle and temperature. Effectiveness is defined as the ratio of the change in temperature of the heated or cooled air and the difference between the highest and lowest temperatures occurring in the heat-exchange process. As an illustration, the effectiveness of the regenerator in cycle B with a turbine-inlet temperature of 800°F is 77 per cent, while in cycle E at 1600°F, it is 90 per cent. Similarly, the intercooler effectiveness of cycle E at 1600°F is higher than for cycle D at 800°F.

In all cases it is the same size regenerator or intercooler, but in the more complex cycles the effectiveness is higher because of the reduced quantity of motive fluid being handled per unit output. Consequently, a smaller and less expensive heat-exchange element may be used in one of the more elaborate cycles than in the simpler ones for the same efficiency.

This procedure of using the same heat-exchange elements in different cycles is the most efficacious manner in which the effect of the cycle itself can be demonstrated. If, in addition to altering the cycle, the same effectiveness of the heat-exchange apparatus had been retained instead, then the datum points would be incompatible, and any comparisons would be rendered illusory.

While the foregoing discussion utilized five different cycles for illustrative purposes, it should be understood that a variety of other cycle combinations is possible, and each may have certain distinct advantages. Regardless of the type of open cycle adopted, however, it will employ several or all of the elements contained in the cycles just discussed Furthermore, in a given cycle one or more units of the same element may be used in order to accomplish a particularly desired effect. Several other open-cycle arrangements will be discussed under Gas-turbine Applications

Specific Fuel Consumption. Figure 8-114 shows the minimum specific fuel consumption, in pounds per brake horsepower-hour, of cycles A to E, inclusive, and of the Carnot cycle when oil is used as a fuel. It was obtained by converting the thermal-efficiency curves of Fig. 8-103 to a specific fuel consumption basis, assuming the fuel oil to have a lower heating value of 17,800 Btu per lb. Reference to Fig. 8-114 will reveal the obvious improvement in performance resulting from the adoption of elevated temperatures. Above 1200°F the specific fuel consumption of the more elaborate cycles is in the range of the diesel engine, while the fuel cost will be considerably less because of the cheaper grade of fuel which the gas turbine is capable of utilizing.

Since in open-cycle gas turbines the products of combustion pass through the turbine blading, such machines have usually been considered as suitable primarily for employing only liquid fuels so as to reduce the solid particles in the motive fluid to a minimum. However, the Locomotive Development Committee,[11] under Bituminous Coal Research, Inc., is at present conducting tests whose promising results indicate the practicability of using pulverized bituminous coal as a gas-turbine fuel. This application will be discussed in more detail under Gas-turbine Applications.

With coal fuel, Fig. 8-115 gives for cycles A to F, inclusive, and the Carnot cycle the minimum specific fuel consumption as a function of turbine-inlet temperature. A bituminous coal having a lower heating value of 12,500 Btu per lb has been selected. Above 1200°F the fuel rate for the regenerative cycles is comparable with that obtainable in modern central steam stations.

Fuel Costs. Also in Fig. 8-114 is given the fuel cost, in cents per brake horsepower-hour, for a fuel oil having an API gravity of 16, a cost of 4 cents per gal, and a density of 8 lb per gal. In the higher temperature regions the cycles employing regeneration and other means for increasing efficiency are attractive on a fuel-cost basis, especially when compared with other prime movers using liquid fuels.

Figure 8-115 shows, in addition, the specific fuel cost for the various gas-turbine cycles when using coal costing $5 per ton. The desirability of using solid fuels is manifested by the low cost of generating power, as indicated in Fig. 8-115. In the upper temperature ranges the fuel economy is better than that of present-day steam stations using fuel of equivalent price.

Optimum Pressure Ratio. Although the pressure ratio at which maximum efficiency occurs in a given cycle is not precisely a linear function of temperature, it may be approximated as such, as shown in Fig. 8-116. It can be seen that the greatest variation in optimum pressure ratio with temperature occurs in the basic cycle Thus, to build such a cycle for maximum performance at elevated temperatures would necessitate many stages in the turbine and compressor. By adopting regeneration (cycle B), these elements can be simplified, because of the lower pressure ratio required, and higher efficiency can be achieved at a given temperature. Except in some special applications which may justify it, it is unlikely that the basic cycle would be constructed for peak performance at high temperatures.

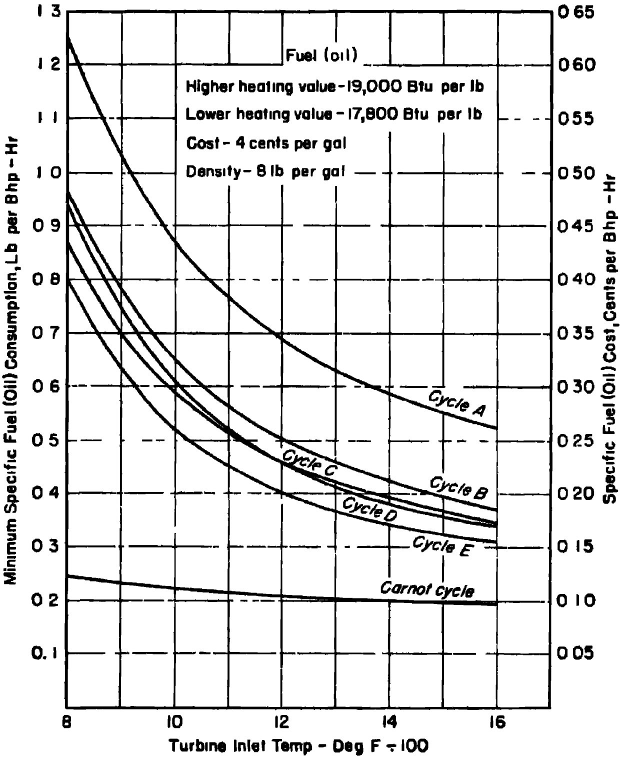

FIG. 8-114. Minimum specific fuel consumption and cost for various cycles using oil fuel

Reference to Fig. 8-116 reveals that the adoption of reheating or intercooling, individually or in combination, necessitates higher pressure ratios for the attainment of optimum conditions. Above a turbine-inlet temperature of 1050°F, however, even with cycle E, these pressure ratios are still less than the basic cycle requires.

Effect of Ambient Temperature. As mentioned previously, the foregoing performance data are based on the air entering the compressor having a temperature of 60°F. Any variation in this temperature will be reflected in a change in performance. In general, the thermal efficiency will decrease about one percentage point in efficiency for each 15° increase in inlet air temperature.

Performance at Partial Load. In Figs. 8-104, 8-106, 8-108, 8-110, and 8-112 the maximum thermal efficiency is depicted as a function of pressure ratio for various turbine-inlet temperatures. Usually the maximum efficiency will occur at or near the full-load point of the unit. Operation at partial loads is accompanied by reduced thermal efficiency, and the degree of reduction depends upon the cycle arrangement and the mode of operation adopted.

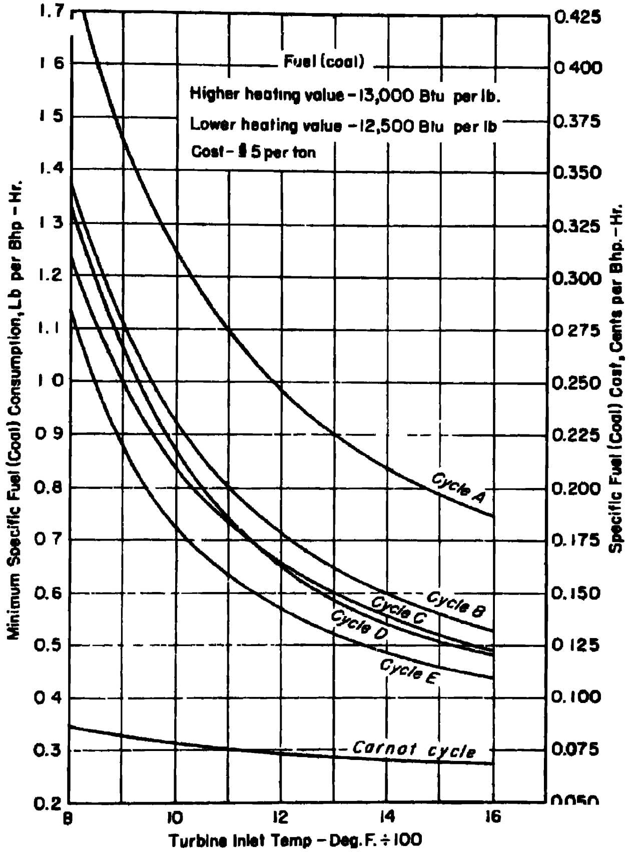

Fig. 8-115. Minimum specific fuel consumption and cost for various cycles using coal fuel.

In general, maximum thermal efficiency at partial load can be achieved by maintaining the turbine-inlet temperature at a high value. Optimum conditions at reduced load ensue when the temperature is kept constant at the design value for all loads. In order to accomplish this in open cycles at reduced output, it is necessary to diminish the flow of the working substance, which requires variable compressor speed. Where the nature of the load is such that constant rotative speed is not necessary, the variable-flow requirement can be fulfilled even in cycles comprising only a single shaft with one turbine and one compressor, thereby making possible the

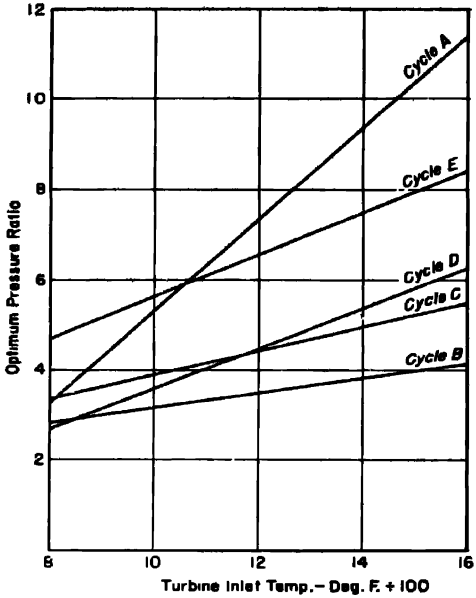

FIG. 8-116. Optimum pressure ratios for various cycles.

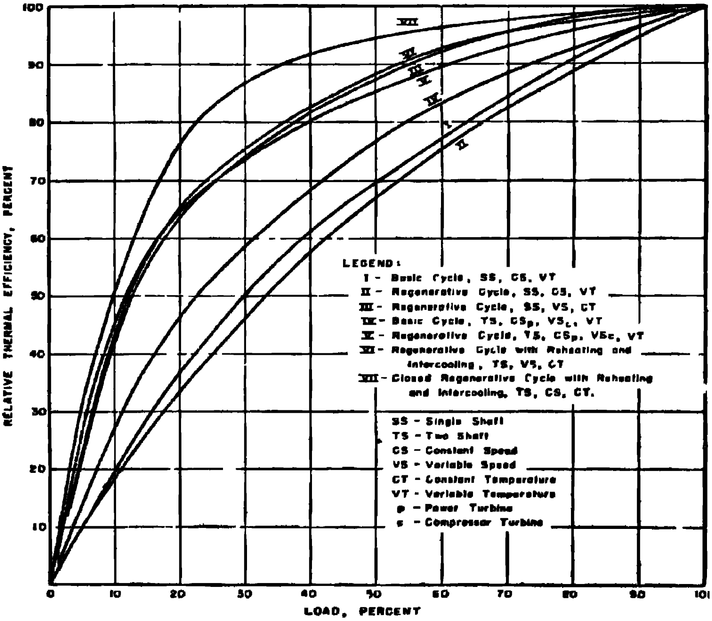

FIG. 8-117. Thermal efficiency at partial load for various cycles.

attainment of good partial-load efficiencies. If the load is of a fixed-speed type, such as an a-c generator operating at constant frequency, in order to achieve variable flow a multiple-turbine arrangement is necessary where one turbine drives the generator and the other the compressor.

The relative thermal efficiencies of various gas-turbine cycles are given in Fig. 8-117 as a function of load. It can be seen that the flattest characteristics are obtained in cycles III, VI,[12] and VII,[14] where the turbine-inlet temperature is maintained essentially constant at the normal design value at all loads. In order to accomplish this, it will be noted from the legend that variable-speed operation is employed in the open cycles. The greatest variation in thermal efficiency is experienced in cycles I and II, where the single-shaft, constant-speed arrangement necessitates the adoption of reduced temperatures at light loads with resulting lower efficiency under these conditions.

The partial-load characteristics of the basic cycle I can be improved by using two shafts, as indicated by cycle IV. In the latter arrangement the variable-flow feature permits higher temperatures to be used in the light-load region. It will be noted that the legend signifies variable-temperature operation for cycle IV. It is so designated since there is a slight decrease in temperature with diminishing output, but the temperature will still be maintained at higher values than in the case of the single-shaft arrangement of cycle I. A similar demonstration of the beneficial effect of multiple shafts can be obtained by comparing the regenerative cycles II and V. The sustained higher temperatures at reduced load, possible with cycle V, yield a flatter efficiency characteristic.

From Fig. 8-117 it can be seen that the closed cycle VII possesses the most desirable light-load performance. This is one of the advantages of closed systems and is produced by a type of control whereby the quantity of the motive fluid circulating through the circuit is varied. Thus, the temperatures, velocities, pressure ratios, and directions of flow remain essentially identical at all loads even though the pressure level of the cycle varies. The component parts of the cycle are, therefore, operating approximately at their normal design conditions under all outputs so that the efficiency is maintained at a high value even at light loads.

CLOSED CYCLES FOR GAS TURBINES

The majority of gas turbines that have been built operate on an open cycle of the type depicted by cycles A to E, inclusive. In contrast to this kind of cycle, however, there is another type referred to as a closed cycle where the motive fluid is confined to a closed system and is not discharged to the atmosphere at any point, as in the open cycle.

Escher-Wyss Closed Cycle. A closed-cycle experimental gas turbine[14] of 2,000-kw generator output which has been proposed and built by the Escher-Wyss Engineering Works, Ltd., of Zurich, Switzerland, is shown in Fig. 8-118. Air is used as the working fluid in the closed circuit of this unit. Starting at the intake, the air traverses the axial-flow compressor and two intercoolers, after which it leaves the compressor and passes through a counterflow heat exchanger where its temperature is raised by the turbine exhaust air. The heated air leaving the high-pressure section of the regenerator enters an indirect-fired combustion chamber where its temperature is increased to the desired turbine-inlet value. After expanding through a high-pressure turbine, which drives the compressor, it then passes through a low-pressure turbine furnishing power to an electric generator. The exhaust air from this turbine has its temperature reduced in the regenerator from which it enters a precooler where its temperature is further diminished indirectly by cooling water. The cooled air then enters the compressor, and the cycle is resumed. The use of the precooler is necessary so as to prevent prohibitive compressor power requirements.

Control of Closed Cycle. In a closed cycle the output may be varied by changing the quantity of fluid circulating through the system. With a decrease in load, the speed-responsive governor actuates valves which permit some of the motive fluid to be withdrawn from the cycle and stored in a low-pressure accumulator. When the load increases, fluid is readmitted to the system from a high-pressure accumulator.

A withdrawal of less than 20 per cent of the working fluid is sufficient to vary the output from full load to no load. A separate compressor set is used to charge the high-pressure accumulator to compensate for fluid withdrawn during governing. Fuel supply to the system is altered so as to maintain essentially constant motive-fluid temperatures at all loads.

Advantages of Closed Cycle. Several points of advantage are claimed for the closed cycle over the open type. The fact that the system is closed means that it is possible to use fluids other than air in the cycle. For instance, if a monatomic gas, with its higher isentropic exponent, were used instead of air, optimum performance could be obtained at a lower pressure ratio. When lighter gases are used, the output for given plant dimensions is increased. With inert gases, the tendency toward oxidation of metallic parts would be reduced.

Since the system is closed, the working fluid may be kept clean as there are no combustion products circulating through the internal circuit. Hence, the possibility of deposits occurring on blading and heat-exchanger surfaces is reduced to a minimum so that high turbine efficiency and heat-exchanger effectiveness may be maintained.

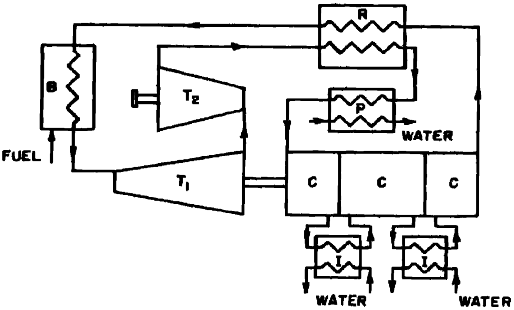

FIG. 8-118. Escher-Wyss closed cycle.

T_1 = compressor turbine
T_2 = power turbine
C = compressor
B = combustion chamber
R = regenerator
P = precooler
I = intercooler

The optimum pressure ratio of a closed-cycle gas turbine will be about the same as that of an essentially equivalent open-cycle unit, but its pressures at corresponding points in the circuit may be much higher. In the Escher-Wyss cycle shown in Fig. 8-118, for instance, the pressure at the compressor discharge at approximately full load is given as 342 psia when the intake pressure is 85 psia. The pressure ratio of 4.04 is of the order of that which would exist in a similar open cycle, but because of the much higher pressures themselves the densities of the motive fluid in the closed system are increased considerably.

Because of the greater density the dimensions of the equipment for a given output are correspondingly reduced from those of an open cycle. This results in small, lightweight, high-speed, lower cost machinery. With the closed cycle it appears feasible to build gas-turbine units having a capacity up to 25,000 kw and with space requirements as low as 3.5 cu ft per kw. The low-pressure levels existing in open cycles result in large specific volumes and concomitantly increased dimensions which limit the maximum capacity of such cycles to approximately 10,000 kw at the present time.

In addition to reducing dimensions, the higher density greatly increases the heat-transmission coefficients in the cycle. Therefore, the combination of these two effects, coupled with the improved cleanliness factor, results in much smaller heat-exchanger equipment.

One of the most important advantages of the closed cycle, where control is by variation of the quantity of motive fluid in the system, is that the efficiency at partial loads is maintained at a high value. For example, tests on the Escher-Wyss unit showed an over-all thermal efficiency of 25.5 per cent at one-quarter load compared to 31.4 per cent at full load. These efficiencies are based on the lower heating value of the fuel, in accordance with standard European practice, and with very cold circulating water, which existed at the time the tests were performed, which would tend to increase efficiency.

The flat efficiency characteristic is obtained because, with control by quantity variation, even though the pressure level in the system is changed, the temperatures, pressure ratios, velocities, and blading angles of attack remain practically the same at all loads. Therefore, the respective cycle elements are operating at or near their design conditions approximately continuously.

With a closed cycle, because of the indirect type of heater employed, it is possible to use either solid, liquid, or gaseous fuel since the products of combustion do not pass through the other elements in the cycle.

The closed cycle would appear to be particularly suitable for marine applications, primarily because of the large quantities of water available for cooling purposes but also because of the reduced size of external ducting since the only outside air requirements are those for burning the fuel and not for supplying the entire cycle motive fluid, as in an open system. Accordingly, the intake and exhaust piping could be much smaller.

Disadvantages of Closed Cycle. Counteracting some of the previously enumerated advantages, the closed cycle also has certain undesirable features not found in gas turbines of the open type. The precooler, a characteristic element of the closed cycle, is not required in an open system. It is a relatively large piece of equipment since it must reduce the temperature of the working fluid entering the compressor to a reasonably low value in order to minimize the negative work of the cycle.

The indirect heater that is required is also of appreciable size. For a pulverized-coal installation, it would be approximately of the same proportions as a steam-generating unit for a steam plant of equivalent output. It is possible to reduce the size, however, by resorting to a pressurized construction. As a compensating feature, the heater does lend itself to outdoor installation which tends to mitigate the objection of excessive size. A further disadvantage of the heater is that it operates indirectly and, therefore, less efficiently than a combustion chamber in an open cycle.

Although some of the principal advantages of the closed cycle are realized because of the high-pressure levels at which it functions, this particular feature increases the difficulty of preventing leakage. More elaborate designs of glands are required than in an open system which operates at lower pressures. In cycles where motive fluids other than air are employed, the importance of minimizing leakage is manifest.

An attractive feature of the open cycle is that practical and efficient designs can be built without any water requirements. Such is not the case for a closed circuit as relatively large quantities of water are needed in the precooler. This limits the range of applications of closed-cycle gas turbines as it would not be feasible to use them in locomotives or aircraft or in localities where water is not readily available. If air instead of water were used as a coolant, the space requirements of the heat exchangers would be appreciable and might be prohibitive for a practical installation.

Westinghouse Modified Closed Cycle. The Westinghouse Electric Corporation in this country has under development a modified closed cycle[14] which eliminates the conventional indirect heater, as shown in Fig. 8-119. In this arrangement a direct-fired combustion chamber of smaller size and higher efficiency, similar to that of an open cycle, is used. Since the system is internally fired, the oxygen required for combustion must be continuously replenished. This is accomplished by an auxiliary turbine compressor which supplies fresh air to the main cycle at the upper pressure level in sufficient quantity to furnish the requisite oxygen. The auxiliary turbine is driven by gas having the same initial conditions as the main turbine, but its pressure ratio and that of the auxiliary compressor are much higher than that which exists in the main circuit.

While the cycle depicted in Fig. 8-119 replaces the indirect heater with a smaller and more efficient type, it still requires the precooler necessitating large quantities of water for its operation. Since it passes the products of combustion through the internal parts of the main system, subjecting them to any contamination that may be present, it is similar in this respect to the open cycle. It also requires an additional turbine and compressor for its proper functioning, and there would be no choice of working fluids, as in the case of the conventional closed cycle, since the use of air is mandatory.

Because of the higher efficiency of the direct-fired combustion chamber, the arrangement shown in Fig. 8-119 should give better optimum performance than a conventional closed system, other things being equal. However, any such advantage may diminish with time if there is deposition of foreign material on the blading and heat-exchanger surfaces.

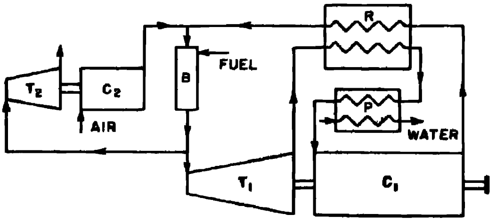

FIG. 8-119. Westinghouse modified closed cycle.

T_1 = main turbine
T_2 = auxiliary turbine
C_1 = main compressor
C_2 = auxiliary compressor

B = combustion chamber
R = regenerator
P = precooler

If the cycle is governed basically by fuel supply, as in open systems, the partial-load efficiency would be less than that for the cycle of Fig. 8-118 where quantity control of the motive fluid is employed.

Sulzer Bros. Modified Closed Cycle. Another modification of the closed cycle, which appears to have certain advantages, is being developed by Sulzer Bros. of Winterhur, Switzerland.[15] This cycle, shown in Fig. 8-120, retains the indirect heater and, consequently, the purity of the motive fluid in the main cycle, but it also utilizes the products of combustion by expanding them in a second turbine which furnishes the useful output. The combustion air is obtained from the primary system and is restored by an auxiliary compressor driven from the main shaft. Unlike the conventional closed system, the motive fluid is restricted to air in the main circuit and combustion products in the power turbine.

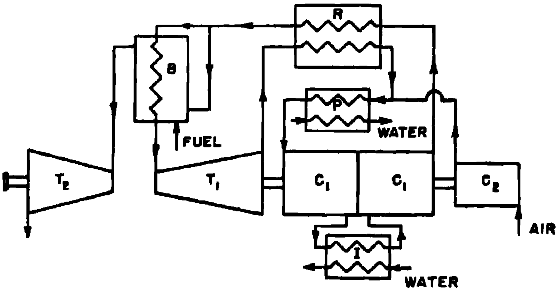

FIG. 8-120. Sulzer Bros. modified closed cycle.

T_1 = compressor turbine
T_2 = power turbine
C_1 = main compressor
C_2 = auxiliary compressor

B = combustion chamber
R = regenerator
P = precooler
I = intercooler

This arrangement combines some of the advantages of both of the cycles shown in Figs. 8-118 and 8-119, although it still requires a precooler with its accompanying water supply. As in the case of the cycle of Fig. 8-119, the optimum efficiency would probably be higher than for a conventional closed system composed of otherwise corresponding elements. Except for the power turbine, however, it would not be subject to decreased performance due to flue-gas contamination.

The comments presented previously regarding the effect of the method of governing on partial-load efficiency of the cycle of Fig. 8-119 also apply, in general, to that of Fig. 8-120. In the latter cycle, however, the cleanliness factor will be higher, but any gain in this direction is counteracted by the lower efficiency of the auxiliary compressor and power turbine because of their operating at variance with design conditions when under partial load. This is a more influencing factor than the auxiliary turbine of Fig. 8-119 because the power turbine involves more energy and, therefore, will affect cycle performance to a greater extent.

OPERATING PROCEDURE

The exact gas-turbine operating procedure in a given installation will depend upon the design and size of the particular equipment involved. For instance, the lightweight, high-speed, and relatively small aircraft jet-propulsion gas turbines can be started from cold, in a push-button manner, in less than 60 sec, primarily because of their simplified and symmetrical design. For more elaborate plants, such as the stationary type, however, where complex piping systems and other influencing factors are involved, the starting and loading interval must be of somewhat longer duration. In general, the following procedure will be applicable for most gas-turbine installations. In particular instances, after a definite starting routine has been established, it may be decided to omit some of the steps suggested below.

Starting.

1. Start auxiliary oil pump If separate relay and lubricating pumps are provided, these may be started individually.
2. Check oil pressures and oil-sight feeds. This also applies to starting device, whether motor, steam turbine, or other type.
3. Arrange all valves in system so that minimum compressor-discharge pressure will exist when maximum flow is passing through turbine that drives compressor. This is particularly necessary where axial-flow compressors are involved so as to prevent the occurrence of unstable conditions.
4. Test gas-turbine overspeed device by tripping by hand, and then reset.
5. If starting device is steam turbine, the following additional procedure should be carried out
   - *a*. Test steam-turbine overspeed device by tripping by hand, and then reset.
   - *b*. Admit cooling water to steam-turbine bearings if oil-ring type.
   - *c*. Open all steam-turbine drain valves.
   - *d*. Open steam-turbine exhaust valve.
6. Engage starting device and bring compressor unit up to about 35 per cent of normal rotative speed. If steam turbine is used, a lower speed than this should first be attained by cracking throttle valve and checking immediately to see if oil rings are revolving. Close drain valves when water is out of steam system.
7. Admit water to oil cooler when temperature of return oil from main bearings reaches 125°F. Regulate flow with discharge valve so as to maintain temperature between 125 to 130°F.
8. Check bearings for sound and temperature. Check glands for sound. Open valves to gas-turbine gland seals. Check sound of rotors for rubbing.
9. Close fuel-oil shutoff valve to burner and start fuel pump.
10. Adjust burner fuel control so that flow will be about 10 per cent of normal.
11. Turn on ignition device.
12. Open shutoff valve to burner. Flame should develop immediately in combustion chamber, resulting in a temperature rise of several hundred degrees Fahrenheit in the turbine-inlet gas temperature.
13. Turn off ignition device.

14. **Increase fuel flow until speed of unit is self-supporting.** The rate of increase in fuel flow will depend somewhat upon the design of the equipment, but for a unit operating on the basic cycle, the temperature may be increased approximately at the rate of 100°F per min up to the self-supporting point. For more complex cycles involving several turbines and more elaborate piping, it may be desirable to establish a reduced heating rate in conformity with the particular installation concerned.

15. Disengage and shut down starting device. If steam-turbine type, close throttle and open drains.

16. If load-absorbing means is a-c generator, increase fuel flow according to above rate of temperature increase until normal speed is attained.

17. Synchronize the generator.

18. Apply load by varying fuel flow in conformity with rate of temperature increase established above. If other type of load-absorbing means is involved, apply previously established appropriate rate of temperature increase until desired conditions obtain.

19. Shut down auxiliary oil pump when main pump is furnishing proper relay pressure.

Compressor Stability. In the operation of gas turbines care must be exercised not to permit conditions to exist which would cause the compressor to operate in an unstable region. This applies particularly where axial-flow compressors are involved, as this type is the most susceptible to instability. This results from the steep pressure-volume characteristic associated with compressors of this kind. Unstable operation is referred to as "surging" or "pumping" because of the pulsations which occur when working beyond the normal operating range. Under such conditions violent surging may occur, resulting in potential damage to the equipment, thereby indicating the obvious necessity of avoiding such incidents.

Pumping is caused by the existence of excessive pressures at the compressor discharge, resulting in a breakdown of stable operating conditions. The pumping limit may be considered the transition point from the stable to the unstable region. It may be established by increasing the discharge pressure of the compressor at various constant rotative speeds until pulsations ensue at each speed. As the pumping limit is approached, usually the pulsations will gradually become audible, but under some conditions no warning pulses will be observed The detection of the approach to the unstable region can be facilitated by connecting a manometer to the compressor discharge and noting the fluctuating columns. The frequency of the oscillations will probably be less than 1 cycle per sec.

The normal design point of axial compressors when operating at rated speed is such that the pressure at the compressor discharge is approximately 20 to 30 per cent less than that corresponding to the pumping limit at that speed. Notwithstanding such a margin, however, in some cycle arrangements certain combinations of conditions may result in unstable operation. Sudden increases in fuel flow, producing rapid rises in temperature, accompanied by corresponding pressure increments, may cause pumping.

As mentioned previously, pumping ensues when the pressure at the discharge of the compressor exceeds the stable value. The determining factor which establishes the magnitude of the discharge pressure is turbine capacity. Thus the turbine nozzles and blading represent a constriction in the compressor-discharge system. The stability margin will be greatest, therefore, in those cycles where the turbine driving the compressor also furnishes the useful output. In such an arrangement, because of the large turbine capacity, the peak pressures in the cycle would not transcend the pumping limit over the usual load range, and stable conditions would prevail. In cases, however, where the function of one turbine is only to drive the compressor and the useful output is delivered by another turbine on a separate shaft, special design precautions must be adopted to avoid pumping.

One method of accomplishing this is to provide a by-pass arrangement on the compressor turbine so that additional capacity may be obtained by shunting the initial stage of the turbine. Such a procedure is shown in Fig. 8-131. If the turbines are arranged in series and the high-pressure turbine drives the compressor, increased turbine output may be obtained by by-passing the low-pressure turbine so that the exhaust of the compressor turbine discharges to atmosphere. In this manner, because of the greater energy drop produced, additional power is obtainable from the high-pressure turbine without its inlet pressure approaching the pumping limit.

Regulation. Governor regulation of a prime mover is defined as the change in speed, usually expressed as a per cent of normal speed, resulting from a load change equal to the full load of the unit. For steam-turbine practice where the driven unit is an electric generator, the speed regulation is of the general order of 3 or 4 per cent of the normal speed. In the case of steam turbines, the governor regulates the valves controlling the flow of the working substance, steam. Because of the large forces required to actuate the valves, a relay system is employed where the governor only operates a pilot valve. The latter, in turn, by means of a hydraulic system transmits the action of the governor to power pistons which furnish the amplified forces for positioning the control valves.

With gas turbines a different system of control can be used, requiring much smaller actuating forces. Instead of regulating relatively large valves which control the flow of the motive fluid, as is done in steam-turbine practice, a comparatively simple governing arrangement can be employed in gas turbines whereby the output is varied by regulating the fuel flow. In this instance, a single valve of small capacity is involved, and the required control mechanism can be of reduced proportions. Thus, because of the lower masses and resulting shorter accelerating periods, the gas-turbine mechanical-governing system adapts itself to the attainment of rapid response characteristics. The over-all control characteristics of a gas-turbine unit also depend, however, on the rate of thermal response encountered during the combustion process resulting in the transferring of energy from the fuel to the motive fluid and the subsequent conversion to mechanical work in the turbine.

Owing to the limited number of gas-turbine-electric-generator types of units that have been constructed, there are not many governor-regulation data available. However, the published tests[16] of a 4,000-kw unit, built by Brown-Boveri and installed at Neuchâtel, Switzerland, include regulation results. During these trials, when the load was changed from full to no load, transient and settled speed increases of 5.8 per cent after 22.5 sec and 2.5 per cent after 1 min, 48 sec, respectively, were observed. Application of the load from no load to full load resulted in transient and settled speed decreases of 5 per cent after 33 sec and 2.65 per cent after 1 min, 45 sec, respectively.

MAINTENANCE

As mentioned previously, the commercial application of the modern combustion type of gas turbine has been rather limited and of short duration, so extensive maintenance data regarding gas turbines in general have not been established as yet. The use of the gas turbine in the Houdry catalytic cracking process has afforded about the only opportunity for a consistent service record to be obtained on units in the prime-mover category. The first Houdry unit was installed in 1936, and in the intervening 12 years a total of 38 units have been built, 32 by Allis-Chalmers and 6 by Brown-Boveri, so a sufficient background of experience now exists from which reliable deductions may be formed. Of this number, one unit has a normal rating of 16,000 cfm, 16 of 23,000 cfm, 20 of 40,000 cfm, and one of 60,000 cfm. If used as conventional power units operating on the basic open cycle at a turbine-inlet temperature of 1200°F, these four sizes would develop respective net coupling outputs of approximately 900 bhp, 1,400 bhp, 2,600 bhp, and 4,400 bhp.

One of the principal users of oil-refinery gas turbines has been the Sun Oil Company, of Philadelphia, Pennsylvania, and a paper[17] describing this company's service experience with gas turbines has been prepared. This paper presents one of the few authoritative published discussions of gas-turbine maintenance based on actual operating records, and continued reference will be made to it in this section. Since the method of operation of the oil-refinery turbines has been given in a previous section, it will not be repeated here.

The seven Houdry gas turbines which the Sun Oil Company has been operating in its oil refineries are given in Table 8-44. All the units are of the 40,000-cfm size, shown in Fig. 8-102, except unit D which is rated 16,000 cfm and is a modified 23,000-cfm unit, the latter being illustrated by Fig. 8-101.

Table 8-44. Houdry Gas-turbine Installations, Sun Oil Company

Plant	Location	Capacity		Rpm		Starting device	Date in service	Manufacturer
		Compressor std cfm	Generator hp	Turbine and compressor	Generator

Types of Failures. The operating experience obtained has revealed that the principal causes of shutdown are (1) bearing failures, (2) lubrication failures, and (3) blading failures. A list of all the types of failures encountered which resulted in outages is given in Table 8-45 in the order of their prevalence.

An itemization of the type, frequency of occurrence, and duration of the failures causing gas-turbine outages is given in Table 8-46. It will be noted that bearing failures represent 63 per cent of the total number and account for 56 per cent of the total outage duration. Lubrication difficulties are next, with percentages of 13 and 15, respectively, followed by blading troubles with 9 and 11. Reference to Table 8-46 will show that, while bearing troubles were predominant, the ratio of frequency of occurrence to duration in the case of bearings is higher than that of the other types of failures, indicating that individual bearing failures caused less proportionate delay than the others.

Table 8-45. Types of Failures Causing Gas-turbine Outages, Sun Oil Company

1. *Bearings*
   - Thrust bearings
   - Spring rings (roller bearings)
   - 1,500-hp motor bearings
2. *Lubrication*
   - Dirt in oil sprays, causing bearing failures
   - Water in oil (condensate) causing bearing failures
   - Main oil pumps, broken shaft spline as result of bearing failures
   - Auxiliary oil pump, failure to start when main pump failed
3. *Blades*
   - Loose blades (latest design with integral root, no loose blades in 22 months on one unit)
   - Erosion, gas-turbine blades.
4. *Air-seal strips* (failure does not necessarily cause shutdown)
   - Material
   - Rubbing, due to change in alignment
   - Expansion joints, harness
5. *Explosions*
   - By-passing air into oil vapors, experimental case
   - Reformer, air by-passed into oil vapors
   - Cases, gas explosion, gas burner opened by mistake
   - Dirty oil burner, no atomization
6. *Miscellaneous*
   - Foreign objects in compressor or turbine
   - Failure to synchronize before cutting motor in when starting unit

In Table 8-44, units A to F, inclusive, were originally installed with an angular-contact ball-bearing type of thrust bearing, but, because of the difficulties that developed, these have been changed to the Kingsbury type. Unit G has always had a Kingsbury thrust bearing. There have been no thrust-bearing failures with the Kingsbury type, and the belief is advanced that the bearing change has essentially eliminated future trouble from this source. Some bearing outages were caused by failure of the spring support rings of the roller bearings supporting the rotating shafts. In later designs where sleeve bearings have been used for this purpose, an exemplary service record has been achieved.

Table 8-46. Number and Duration of Failures Causing Gas-turbine Outages, Sun Oil Company

Plant	Bearings		Lubrication		Blades		Air seals		Explosions		Miscellaneous		Total	
	No	Days	No.	Days	No	Days	No.	Days	No	Days	No	Days	No.	Days
A	18	43							1	5	1	2	20	50
B	4	12			1	4	1	3	1	2			7	21
D	4	31	3	14									7	45
E	3	15	3	11					1	5			7	34
F					3	15					2	14	5	29
G													0	0
Total	20	101	6	28	1	19	1	3	3	12	3	16	46	179
Per cent	63	56	13	15	9	11	2	2	6.5	7	6.5	9	100	100

The outages caused by lubrication difficulties resulted primarily from foreign matter in the oil and oil-pump failures. The installation of blotter presses has apparently corrected this condition as no lubrication failures have occurred since they were used.

Blading failures, while in third place as far as duration is concerned, are probably the most serious type of individual failure with respect to the delay and expense involved. As has been previously described, the original blading designs comprised separate spacer pieces which held the blades in their grooves. Observations indicate that failures have occurred primarily due to fatigue cracks originating from an indentation produced at the line of contact of the spacer pieces and the blade surfaces. In later designs by Allis-Chalmers, where integral-root blades have been employed, no difficulties have been encountered in an operating period of almost 4 years.

Unavailability of the equipment due to failures of air seals at the ends of the rotating shafts has been of minor consequence. Mishaps of this sort would rarely cause any extended delays as such repairs can be postponed until regularly scheduled shutdown periods.

Table 8-46 also indicates that explosions have been responsible for 6.5 per cent of the total outage period. These explosions occurred because of operating errors with other pieces of equipment in the cycle and have no relation to the design of the gas turbine. No serious damage resulted from any of the three explosions listed in Table 8-46.

Several miscellaneous shutdowns due to maintenance errors and not related to turbine design were experienced. Under this category are included outages caused by leaving foreign objects in the compressor and similar mishaps.

Availability. Reference to Table 8-47 will show that the average availability of the gas-turbine units reported was 98.1 per cent. Figures of this order are very good and indicate a high degree of reliability. It should be pointed out, however, that the Houdry gas-turbine equipment is of conservative design, operating at low stresses and temperature, the latter being in the range of 875 to 900°F which is well below the temperatures advocated for present-day gas-turbine power units. It might be contemplated, therefore, that higher temperature designs may exhibit a tendency toward increased maintenance over that stated above until further operating experience at elevated temperatures is obtained.

The availability of 98.1 per cent noted above corresponds approximately with that of central-station steam-turbine equipment. Such similarity is to be expected, however, as modern steam turbines are operating at approximately the same temperature and stress levels, and the purely rotary motion of both types of turbines is conducive to low maintenance.

Anticipated Availability of Modified Designs. It is interesting to reflect on what the anticipated availability might be of Houdry gas turbines whose designs have been modified in accordance with the dictates of operating experience. For instance, the Sun Oil engineers estimate that thrust-bearing outages would have been reduced 60 per cent if the Kingsbury instead of the ball type of thrust bearing had been used in the original designs. Assuming further that sleeve instead of roller bearings were adopted, a revised value of 70 per cent would probably be reasonable. Using this figure, the outage for bearings of 101 days, given in Table 8-46, would become 30.3 days.

Table 8-47. Summary of Gas-turbine Operation to May 31, 1945, Sun Oil Company

Plant	Total days	Outage		Availability	
		Days	Per cent	Days	Per cent
A	2,657	50	1.88	2,607	98.12
B	1,921	21	1.09	1,900	98.91
D	1,458	45	3.09	1,413	96.91
E	1,438	34	2.36	1,404	97.64
F	1,394	29	2.08	1,365	97.92
G	569	0	0	569	100.00
Total	9,437	179	1.90	9,258	98.10

Referring to lubrication difficulties, since no failures of this type have occurred subsequent to the installation of blotter presses, it is assumed that shutdowns of this nature would be reduced 75 per cent if these had been employed originally. On this basis, the 28 days' outage of Table 8-46 would diminish to 7 days.

As mentioned previously, no blading failures have occurred since the installation of the new integral-root blading in the Houdry gas turbines of the Sun Oil Company. If this modified design had been applied initially, it is reasonable to expect that blade life would at least have been doubled, so that an outage of 9.5 days would result instead of the 19 days of Table 8-46.

In establishing an anticipated availability with modified design, it is assumed that delays due to air-seal difficulties would be of the same order as those actually experienced as these are of minor importance. Also, inasmuch as shutdowns due to explosions and miscellaneous causes had no relation to gas-turbine design, these have been omitted in determining expected availability. Accordingly, if a Houdry gas turbine of modified design functioned in conformity with the aforementioned assumptions and on the same operating schedule as the units reported on, it would have an availability of 99.5 per cent, a value hardly excelled by any other type of equipment.

It is desired to reiterate that the exceptionally good availability figures under discussion refer to equipment designed for long life with relatively low stresses and moderate operating temperatures—under 1000°F. The good service records obtained with existing units do demonstrate, however, that the gas turbine is a reliable piece of equipment and not a radical innovation. Other types of gas turbines now being proposed and built where efficiency, weight, or space is of prime importance will be designed for considerably higher temperatures, probably in the range from 1200 to 1600°F. Designs employing the upper temperature region represent an appreciable advancement in the state of the art and, considering the ultimate gains to be achieved with developments of this nature and scope, any necessary concomitant increased maintenance should be condoned until the experimental phase is consummated.

MATERIALS

As has been previously observed, the performance of gas turbines improves with the use of elevated temperatures. Consequently, the necessity for adopting suitable materials to withstand high-temperature service is manifest. Progress in the gas-turbine field will always be contingent upon metallurgical advances, and real incentives exist for the development of alloys capable of operating at extreme temperature limits. In an attempt to accomplish such attainments, serious consideration is being given to the use of ceramics with the anticipation that the employment of temperatures in excess of 2000°F may be a reality in the not too distant future. Experiments with ceramics, both as a coating for metallic parts as well as a base material, indicate encouraging results. Other than for some limited small-scale laboratory investigations, however, all gas turbines so far have been constructed of metals, and the greatest impetus is being devoted to metallurgical research on metallic materials.

The metallurgical background for the production of adequate high-temperature alloys for gas turbines has been obtained from the many years devoted to the development of materials for use in the construction of steam turbines operating at increased temperatures. After an evolutionary period embracing approximately half a century, the steam-turbine art has reached the stage where it is now considered feasible to build a unit to operate at 1000°F. Reference to the performance data previously presented makes it rather obvious that, for gas-turbine service, temperatures below 1000°F could not be tolerated if reasonable efficiency is desired.

Hence, the seemingly incongruous situation exists where, for similar types of equipment, a temperature of 1000°F represents an upper limit in one case and a lower in the other. The apparent inconsistency is partly explainable when it is considered that steam turbines are normally designed for a minimum service life of approximately twenty years. A comparable figure for gas turbines of the prime-power type is about ten years, which would permit the use of higher temperatures. Also, the maximum pressures encountered in open-cycle gas turbines are less than 10 per cent of those of modern steam plants, so for units of the same output and factor of safety, the stationary parts, such as piping and casings, of an efficient gas-turbine cycle may operate at increased temperatures, notwithstanding the larger specific volumes of the motive fluid involved.

Furthermore, because of the required higher temperatures of gas-turbine plants it has been necessary to accept creep rates approximately ten times as much as those used in the design of corresponding parts of steam turbines, and the stress level is lower than that found in steam turbines. In addition, because of the much shorter bearing span of spindles for gas turbines, somewhat higher temperatures can be sanctioned since the clearance and distortion problems under otherwise similar conditions are normally less acute

In general, at the present time the maximum design temperature for prime-mover type of gas turbines having a service life of about ten years is approximately 1300°F. Higher temperatures than this have been employed, however, in special applications. For instance, temperatures as high as 1600°F are used in gas-turbine superchargers for aircraft. Also, for aircraft jet-propulsion units, temperatures of 1500°F are used at the inlet to the gas turbine. In these cases, however, since space and weight are at a premium, the higher temperatures required to produce these features are condoned, and limited-service life is accepted. In aircraft equipment of this type, such life is considered in terms of hundreds of hours instead of years.

High-temperature Alloys. The materials used in the higher temperature steam turbines were not considered adequate for gas-turbine service, so since 1940 a large-scale metallurgical development program has been conducted under sponsorship of various government agencies. Scores of different alloys were investigated, but at present some of the most promising materials[18] appear to be as shown in Table 8-48.

The alloys listed in the table are of two general kinds: forged and cast. The forged type can be further divided into two classes: those which are normally used without heat-treatment and those which usually obtain their optimum properties when heat-treated. Alloys 1 to 6, inclusive, would be of the first class and 7 to 18, inclusive, of the second. Alloys of the first class are usually cold-worked so as to realize the best results from the materials. The cast alloys, such as 19 to 24, inclusive, when used for smaller parts, such as turbine blading, are made by the lost-wax precision-casting process which will be described in more detail later. Alloys 25 and 26 have been used for turbine diaphragms and casings which are produced by essentially standard foundry methods. While alloys 1 to 18 have been included in the forged classification, some of them, also, show good properties when in precision-cast form.

Table 8-48. High-temperature Materials for Gas Turbines

Alloy	Name	Chemical composition, per cent												
		C	Si	Mn	N	Cr	Ni	Mo	Co	W	Cb	Ti	Al	Fe

26	25-20		2.00			25.00	20.00							

The materials which have probably been used in greatest quantities are the 16-25-6, alloy 5 and vitallium, alloy 19. These two materials were used for disks and blades, respectively, in the gas-turbine wheels of the aircraft turbosuperchargers which were manufactured in such large volume during the Second World War. One of these superchargers is shown in Fig. 8-140, and the exposed turbine wheel may be readily observed. In this application, the cast-vitallium blades were welded to the forged 16-25-6 wheel by means of the union-melt process. More than 6,000 tons of the Timken alloy have been produced, so much experience has been gained with it. Before adopting a high-temperature alloy, it is desirable to determine its properties when produced in large heats, as the results obtained from laboratory samples may not be entirely representative.

Elements. The metallurgy of alloys suitable for high-temperature service is a complex phenomenon, and the attainment of a superior alloy is usually the result of painstaking experimentation. It is generally known what elements are desired to produce beneficial high-temperature properties, but even after the kind and magnitude of the ingredients of an alloy have been established, it is usually the subsequent treatment and processing that determine the final properties of the material.

In general, the elements given in Table 8-48 contribute some desirable characteristic to high-temperature alloys. Practically all high-temperature materials will be of the chromium-nickel type, and most of them will contain molybdenum. The forged and cast alloys are usually of the iron- and cobalt-base type, respectively, but some work is being done on vacuum-cast chromium-base alloys which show much promise for still higher temperatures.

Molybdenum is a desirable constituent as it produces strength at high temperatures. Chromium offers resistance to oxidation and corrosion. Nickel, in proper proportions, improves ductility and produces an austenitic structure. It also increases the strengthening effect of carbon and the corrosion resistance of chromium. Carbon and nitrogen have strengthening and stabilizing characteristics, but higher carbon contents tend toward lower ductility, which is undesirable. Nitrogen also improves grain refinement and ductility in steels high in chromium. Silicon in small amounts in combination with other alloying elements, such as chromium, enhances resistance to corrosion and heat. Manganese acts as a deoxidizing agent and, in proper amounts, increases strength. Cobalt in many respects is similar to nickel in the properties which it produces. Tungsten as an alloying element has an effect similar to molybdenum, but several times as much is usually required. Titanium and columbium are stabilizing elements used to prevent intercrystalline carbide precipitation. Aluminum is primarily used as a deoxidizer and for grain refinement. Resistance to oxidation is also improved by the use of aluminum.

Physical Characteristics. In the design of high-temperature gas turbines, the following information is required regarding the materials involved in the construction of the equipment:

1. Ultimate strength
2. Yield strength
3. Stress-rupture
4. Creep
5. Fatigue
6. Elongation
7. Reduction in area
8. Hardness
9. Impact
10. Oxidation
11. Corrosion
12. Damping capacity
13. Relaxation
14. Modulus of elasticity
15. Thermal expansion
16. Thermal conductivity

Most of the above tests are fairly well standardized, so no further elaboration of their nature will be presented here. The stress-rupture test, however, may not be so well known as it has become particularly significant recently because of the advent of the gas turbine. It probably furnishes the most useful information to be used in the design of gas turbines. It can be considered as a modified or long-time type of ultimate-strength test.

The test for ultimate strength is a short-time tensile test at constant temperature where failure occurs in a matter of minutes. If a sustained lighter load had been applied, a longer time would have been required for failure of the specimen. Therefore, if a succession of diminishing static-breaking loads is applied to a group of specimens at a constant temperature, respective failures will take place at correspondingly increasing time intervals. A test of this nature is referred to as the stress-rupture type. The stresses at which rupture occurs are usually plotted as ordinates against the times for rupture as abscissas on log-log coordinates, and a linear relationship is generally found to exist for most alloys. In the majority of cases, tests of this nature are usually conducted for a period of about 1,000 hr, and the linear-relationship feature affords a ready means for extrapolation to longer time intervals. This latter operation should be pursued with caution, however, as erroneous predictions can result, especially if the material is susceptible to oxidation.

A conception of some representative stress-rupture values at 1200 to 1500°F may be obtained from Fig. 8-121 where alloys 16-25-6,[19] S-590,[20] and 422-19[18] have been selected at random for illustrative purposes. Alloys 16-25-6 and S-590 are of the forged type, and 422-19 is precision-cast. It can be seen that the cast alloy shows superior properties at high temperatures. The forged 16-25-6 alloy, as mentioned previously, has been used in very large quantities for supercharger and jet-propulsion gas-turbine disks where temperatures are in the 1200°F range. It has very good stress-rupture properties at such temperatures. For gas-turbine disks operating in the vicinity of 1500°F, some of the more recently developed forged alloys, such as S-590 or S-816, show good characteristics. It will be noted that the relative difference between S-590 and 16-25-6 at 1200°F is less than at 1500°F. For smaller parts, such as blading, which adapt themselves to the size limitations of the precision-casting process, the cast alloys lend themselves to ready adoption and show good strength at high temperatures, as can be seen from Fig. 8-121.

It will also be noted from Fig. 8-121 that the slope is steeper at the higher temperatures, indicating that materials lose strength at a more rapid rate at elevated temperatures. Because of the importance of this time factor involved, the stress-rupture test is possibly the most informative for furnishing high-temperature gas-turbine design data.

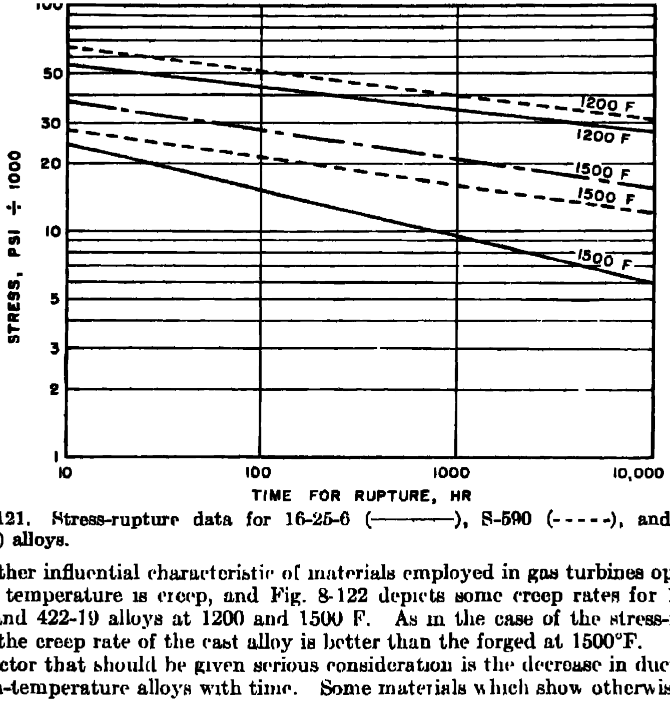

Fig. 8-121. Stress-rupture data for 16-25-6 (————), S-590 (- - - - -), and 422-19 (— — —) alloys.

Another influential characteristic of materials employed in gas turbines operating at high temperature is creep, and Fig. 8-122 depicts some creep rates for 16-25-6, S-590, and 422-19 alloys at 1200 and 1500 F. As in the case of the stress-rupture values, the creep rate of the cast alloy is better than the forged at 1500°F.

A factor that should be given serious consideration is the decrease in ductility of the high-temperature alloys with time. Some materials which show otherwise excellent properties exhibit elongations as low as 5 per cent after testing for several hundred hours at temperatures in the range of 1500°F. In general, the cast alloys show the lowest ductility under sustained stress at high temperatures.

While a material may exhibit good short-time properties, if it has poor oxidation or corrosion resistance, failure may occur after a certain period of operation because of increased stresses caused by reduced cross section resulting from loss of metal. Therefore, these characteristics should be given adequate consideration because of the possibility of the diminishing factor of safety which can occur after a design has been established. Oxidation tests on some high-temperature alloys, by the gain-in-weight method, show an increase in weight of about 1 mg per sq cm at 1500°F in 1,000 hr.

Comparison of Forged and Cast Alloys. No one type of alloy is superior in all respects. Forged materials have advantages in certain characteristics and cast in others. In stress-rupture tests at 1500°F, the cast alloys of the Co-Cr-Ni- and Co-Cr-base type show better strengths than the forged alloys. The higher the temperature, the more predominant the difference becomes. In general, the cast alloys show better creep resistance at 1500°F than forged alloys, but this situation is reversed at 1350°F. Also at 1200°F, the forged alloys have the best fatigue properties, while at 1500°F the cast alloys are better. The ductility of the forged alloys is better than that of the cast. In general, it may be stated that in the vicinity of 1500°F and above, the cast alloys, except for ductility, exhibit properties superior to those of forged materials.

Because of the forging operation, the wrought materials have a fine-grain structure in contrast to the coarse grains of the cast alloys. The larger grains of the cast materials result in beneficial high-temperature stress-rupture and creep properties as their presence reduces the magnitude of the weaker grain boundary. On the other hand, the coarser grains decrease the endurance limit.

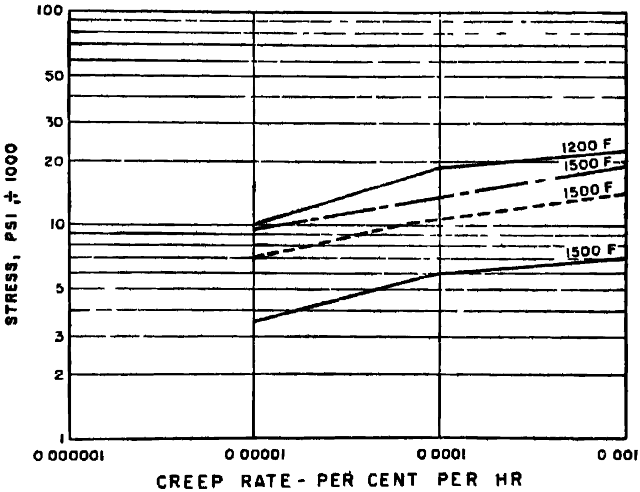

FIG. 8-122 Creep rates for 16-25-6 (— — —), S-590 (- - - - -), and 422-19 (— — —) alloys

The test results obtained with forged alloys appear to be more consistent and amenable to duplication from one heat to another than do those of cast materials. This is probably due to the more difficult control aspects of the precision-casting process. Another important consideration is that for forged alloys the physical properties of the material as determined in the laboratory are essentially representative of those of the machined part as finally installed in the turbine. For cast alloys, however, there is the possibility of divergence between the properties as obtained in the laboratory and those actually existing in a precision-cast part of the same material. In a precision-cast test specimen of uniform circular section, the grain orientation will be different from that of a turbine blade of unsymmetrical cross section. The results obtained on a test specimen with essentially uniformly arranged coarse grains will not necessarily be applicable to a blade where the thin trailing edge will exhibit a fine-grained structure, and the heavier inlet and center portions will have larger grains

Under such circumstances, because of the unrelated grain structures, the physical properties obtained on the test specimen are not directly applicable to the blade, and to use them as a basis for design may result in fallacious factors of safety. The situation is particularly aggravated in the blade-trailing portion where greatest divergence from test conditions occurs The blade would tend to have lower stress-rupture and creep-resistance properties because of its finer grain structure in this region.

Precision-casting Process. The precision-casting or "lost-wax" process, previously used primarily by the dental and jewelry trades, was adopted during the Second World War as a means of mass-producing gas-turbine supercharger blades The vitallium alloy, listed in Table 8-48, has been employed to the greatest extent, but other shapes and alloys are being used. The process actually had its origin in China about 2000 B C. and was perfected by Benvenuto Cellini for use in his medieval statuary. It was then dormant for many centuries until revived by the dental trade. The term "lost wax" is applied since the wax pattern is melted out and, therefore, "lost" during the process The method is a valuable contribution to gas-turbine construction as some of the best high-temperature alloys are produced by it.

The precision-casting process requires that first a master pattern be made of metal or wood, slightly oversize to allow for shrinkage or draft. From the master pattern, an injection die of soft metal is prepared A special wax is injected into the die under pressure and assumes a shape identical to the master pattern After solidifying, the wax pattern is removed, and several of them are mounted in a cluster, connected to each other by wax runners, and these, in turn, are joined to a main gate The runners and gate provide channels for the subsequent flow of metal into the mold.

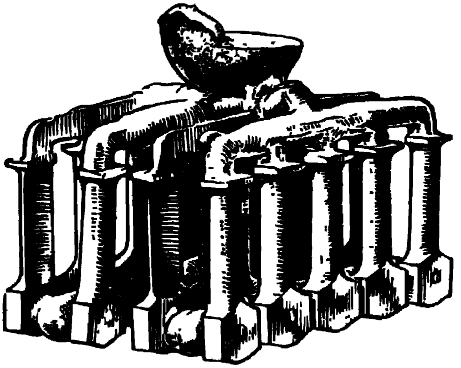

FIG. 8-123. Precision-cast, gas-turbine, supercharger blades

The wax-pattern assembly is coated with a fine silica solution which will become the mold facing and give a smooth velvet finish to the surface of the final metal casting. The coated wax assembly is placed in a container in which an ethyl silicate mixture, or investment, is poured around it. The container or flask is then vibrated until the investment solidifies into a firm, self-venting mold surrounding the wax assembly. The completed molds, in inverted position, are placed in an oven where the melted wax drains out, leaving cavities in the mold which are replicas of the master pattern.

The incandescent mold is clamped with its opening opposite that of a furnace containing the molten metal to be cast. The assembly is inverted, causing the metal to run into the mold, and air pressure is applied to ensure filling all cavities After cooling, the investment is knocked from the casting assembly. Figure 8-123 shows such an assembly of gas-turbine supercharger blades with the gates and risers still in place. An abrasive wheel then cuts off the gates and risers, and the individual cast pieces are sand- or shot-blasted. Any local surface irregularities are corrected by grinding, but no machining is required. The castings are finally inspected radiographically by automatic X-ray equipment.

Practically all kinds of castable metals can be used in the lost-wax process. Tolerances ranging from 0 003 to 0.008 in per in are possible of attainment, depending upon the shape and weight of the objects being cast The process is particularly suitable for intricate shapes that are too complex for conventional casting or machining. In its present state of development, the maximum size of part for which the method is suitable is approximately 20 lb, with no dimension exceeding 15 in.

In the precision-casting process, it is important that accurate control be maintained if it is desired to produce anticipated properties in the product. Grain size is directly affected by metal pouring temperature and mold temperature. The nature of the investment material and the shape of the casting are also influencing factors. Therefore, in order to obtain uniform results, coordination of all these variables is necessary.

Design Considerations. In steam-turbine practice, various properties of the materials employed have been used as a basis for design. In particular, the ultimate, yield, and creep strength values have been found useful in determining the proportions of structures having suitable factors of safety based on these properties. In gas-turbine design, however, where higher temperatures are usually encountered, the most informative property of the materials, from a design standpoint, is the stress-rupture value, as has been mentioned previously. It is more significant than ultimate strength as it involves the element of time to a much greater extent.

Reference to Fig. 8-121 will show that the higher the temperature, the more rapidly the material loses strength. Thus, the designer must take cognizance of the time factor involved when selecting or specifying materials. In steam-turbine design where substantially lower temperatures are involved, the time element is not of so much significance as far as rate of loss of strength is concerned. In gas turbines, however, where elevated temperatures are necessary, the length of operating period must be considered.

Therefore, in order to obtain a comprehensive representation of all the factors involved in the design of a high-temperature gas turbine, it is necessary to consider simultaneously (1) the desired service life of the equipment, (2) the temperature at which it will operate, (3) the allowable deformation of the respective parts, and (4) the appropriate stress.

Knowing the time and temperature factors involved, a design could be based on the total allowable deformation of the respective elements of the equipment occurring in the time interval. The permissible stress would then be the one that resulted in the prescribed deformation in the time allotted and at the specified temperature for a given material. If the deformation is put on a relative basis, it is referred to as strain and is stated in terms of per cent. It can be determined from the initial deformation under load and the secondary creep rate. In the design of a unit intended for long service life, it would be well to limit the maximum total strain to 1 per cent. This is particularly applicable to the high-temperature materials which would be used in gas-turbine construction. It is known that the ductility decreases with time, and in general, tests have not been performed much beyond 1,000 hr on these materials, so for conservative design, the total deformation should be restricted to a low value so as to preclude the possibility of failure due to poor ductility.

Another basis of design is to use stress-rupture values with a suitable factor of safety incorporated. A satisfactory design of a long-life unit, *e.g.*, a service life of 10 years, could employ average stresses of one-half the rupture value at 10,000 hr for the particular temperature involved. This would be a more conservative basis than limiting the deformation to 1 per cent total strain. In aircraft applications, where weight and space are at a premium, limited service life is accepted, and higher stresses are used. On this basis, some aircraft gas turbines have been designed with a factor of safety of 1 based on the stress-rupture value at several hundred hours.

Actually the above two bases of design could be considered equivalent. The *allowable total strain* could be determined as that produced by a rupture stress at a given time corrected for an appropriate factor of safety. Conversely, an *allowable stress*, based on a rupture value incorporating a safety factor, could be selected so as to result in an acceptable total strain. In actual design practice, however, using the latter or rupture basis with a safety factor appears to be the most direct and readily applied procedure. Nevertheless, it should be remembered that both methods will produce the same result if they are mutually appropriately related.

From a design standpoint, other properties of materials are also important. The fatigue or endurance limit should be considered because of the vibratory nature of the forces encountered in turbine practice. It is difficult, however, to establish a design criterion based on fatigue, for at high temperatures there does not appear to be a definite fatigue limit even after 500 million cycles of testing in some cases. It is usually assumed that a design based on rupture or total strain considerations, as previously described, will result in stresses well removed from the endurance limit, so the former bases are believed to reflect adequate conservatism.

The amplitude of vibration of a structure is influenced by the damping capacity or logarithmic decrement of the material. The damping capacity is a measure of the tendency of a material to come to rest, because of internal molecular friction, after it has been set freely vibrating. Because of the pulsating exciting forces prevalent in turbine designs, harmful vibrational stresses can occur, particularly in partial-admission turbines, and a high damping capacity is desirable so as to reduce such stresses to a minimum. Unfortunately, the high-temperature alloys do not exhibit good damping properties, particularly with increasing time and temperature, so compensating features must be incorporated into the design.

The natural frequency of the various parts of construction and the critical speeds of the rotating elements are dependent upon the modulus of elasticity of the material employed. At elevated temperatures the modulus decreases appreciably from its value at room temperature. For instance, the latter figure[20] for S-590 is 29 million psi, while at 1400°F the modulus of elasticity is 16 million psi, a reduction of 45 per cent. Consequently, in order to avoid dangerous resonant conditions, high-temperature gas turbines require designs with relatively higher room-temperature vibrational-frequency characteristics than steam turbines if similar multiples of rotational frequencies are desired under operating conditions.

In designing the bolting on gas turbines, it is important to know the relaxation properties of the material employed. When a nut and bolt combination is tightened initially, a strain results which produces a stress sufficient to maintain a tight joint With the passage of time, the bolt will lengthen or creep, because of plastic flow, and a relaxation or residual stress less than the original will ensue. The magnitude of the residual stress may be calculated by special formulas[21] after the relaxation-creep properties of the alloy have been determined It is necessary that the residual stress be sufficiently high to maintain joints without leakage. Relaxation-creep tests on the forged S-816 alloy show that, with an initial tightening stress of 50,000 psi at room temperature and a resulting deformation of about 0.173 per cent, the residual stress after 1,000 hr at 1350°F would be 11,725 psi for the same strain. After 10,000 hr, other conditions remaining the same, the residual stress would be 8,860 psi. For the same conditions, the corresponding residual stresses for 19-9 DL are 6,925 psi and 4,115 psi, respectively.

Thermal-conductivity data are also required. The use of the high temperatures encountered in gas-turbine practice necessitates in many instances the adoption of various means of cooling some of the parts. The turbine shown in Fig 8-131, for instance, has provision for cooling some of the disks and nozzles. The quantities of cooling air required and the heat flow in the metallic parts can be determined with a knowledge of the thermal conductivity of the materials involved.

The thermal expansions of the various elements of a gas-turbine installation can be of appreciable magnitude because of the large temperature differences involved. From cold to hot conditions, the axial expansion of a turbine may approach ½ in. Throughout such motion the proper axial clearances between the stationary and rotating elements must be maintained. Hence, it is necessary to know the coefficients of thermal expansion of the materials employed so as to make correct allowance for relative displacement. The problem is accentuated with the types of alloys used in gas-turbine construction as their expansion coefficients are appreciably higher than those of ordinary steel. For instance, at 1500°F the S-590[20] alloy has a coefficient of 8.4×10^{-6} in. (in.)(deg F). The piping is also influenced by thermal motion, and in order to prevent excessive strains, it is necessary to incorporate expansion and swing joints in appropriate locations.

The machinability and weldability characteristics of an alloy must be considered as they directly affect the manufacturing of the equipment. Most of the high-temperature materials do not machine as readily as ordinary steels, and some of the cast alloys necessarily have no machining operations performed on them, but grinding is used instead For turning operations cemented-carbide tools are generally used, and high-speed steel tools are employed for milling, broaching, reaming, and drilling

In many cases the design is facilitated if a welded construction is employed. This applies particularly to the fastening of blading to disks, for in such instances, for the same stress, welding will permit a narrower rim width and, consequently, shorter spindle with higher critical speed than if a mechanical blade fastening is used Welding is also used in joining adjacent disks to each other With the high-temperature alloys, in particular, there is a size limitation on the obtaining of sound forgings Therefore, in some designs the disks are machined from individual forgings and subsequently welded together to form the complete spindle In the turbine shown in Fig 8-131 the two impulse disks and the reaction drum were each machined from separate forgings and then joined by welding The resulting structure was then welded to the adjacent shaft at the low-pressure end of the reaction drum

GAS-TURBINE APPLICATIONS

Various present-day applications of the gas turbine, indicating the practicability of this type of equipment, have furthered its emergence from a realm of academic interest to one of reality The many advantages of the gas turbine make it a natural aspirant for numerous applications in land, marine, rail, and aircraft fields, and these will be dealt with individually below

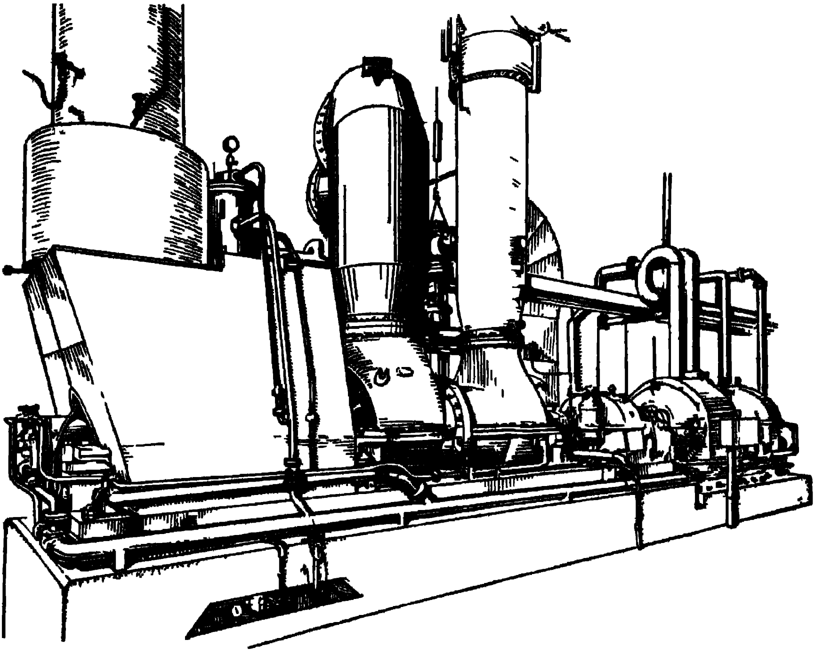

Fig 8-124 Allis-Chalmers Houdry gas-turbine unit of 60,000 cfm capacity.

Land. As mentioned previously, the combustion gas turbine in the United States has had its principal commercial application in the oil-refinery industry where it operates in conjunction with the Houdry process A typical installation view of such an application employing a 60,000-cfm unit is shown in Fig 8-124, wherein, from left to right, may be seen the gas turbine, axial compressor, reduction gear, generator, and a steam turbine for starting purposes In this application, because of the pressure drop encountered in the process, the energy supplied to the generator is less than if the unit were used primarily for purposes of power production.

The first unit of this type has been in service since December, 1936. At present 28 of the Houdry gas turbines are in operation in this country. Of these, 6 were built by Brown-Boveri and 22 by Allis-Chalmers. The latter company has also built 10 additional units for installation in Europe.

A 4,000-kw electric-generating unit,[16] built by Brown-Boveri, has been installed in an underground emergency stand-by power station in the city of Neuchâtel, Switzerland. Since early in 1940 this unit has been operating for certain periods every week. Its simplicity and independence of water facilities ideally adapt the gas turbine to this class of service. Recently published tests indicate a coupling thermal efficiency of 18.04 per cent for this unit when operating on a nonregenerative cycle with a turbine-inlet temperature of 1000°F. Regeneration was not adopted since it could not be economically justified because of the anticipated intermittent operation associated with this particular installation. This is the first unit designed for the primary purpose of producing power. The Neuchâtel unit on exhibition at the Swiss National Exposition at Zurich is shown in Fig. 8-125.

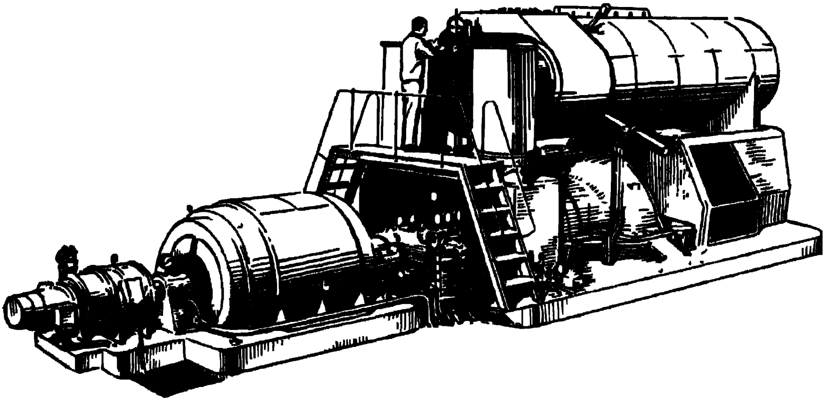

FIG. 8-125. Brown-Boveri gas-turbine–electric-generating unit of 4,000 kw capacity.

Brown-Boveri has also built a 10,000-kw gas-turbine electric-generating unit intended as a stand-by set for the Filaret plant of Bucharest, Rumania. The machine consists of a two-shaft arrangement employing reheating and intercooling, but because of the stand-by nature of the service, no regenerator will be used. The equipment is shown in Fig. 8-126, the low-pressure turbine, compressor, and generator being at the left, the combustion chambers, the high-pressure turbine, and compressor in the center, and the intercoolers on the right. A 4,000-kw unit for Peru is shown in the upper right center of the figure. Tests on the unit showed a thermal efficiency of 23 per cent at full load, based on the lower heating value of the fuel. With a turbine-inlet temperature of 1112°F and inlet air of 68°F, a maximum load of 12,000 kw was maintained.

About 80 gas-turbine–axial-compressor sets have been built by Brown-Boveri to operate in conjunction with the Velox boiler, a pressure-combustion type where the axial compressor furnishes air at a pressure of 30 to 35 psi gauge to the combustion chamber, and the resulting products of combustion actuate the gas turbine; and hundreds are used for supercharging diesel engines.

While no gas-turbine–electric-generating units have been installed in any central stations in this country as yet, much thought is being devoted to such applications, and a model of a 10,000-kw unit proposed by Allis-Chalmers for utility service is shown in Fig. 8-127. A schematic diagram of its regenerative cycle with reheating and intercooling is also depicted. A two-shaft arrangement is employed whereby the high-pressure turbine drives the compressors, and a separate, double-flow, low-pressure turbine is connected to the 10,000-kw generator The cycle is designed for an inlet temperature of 1300°F to both turbines, and regenerator and intercooler

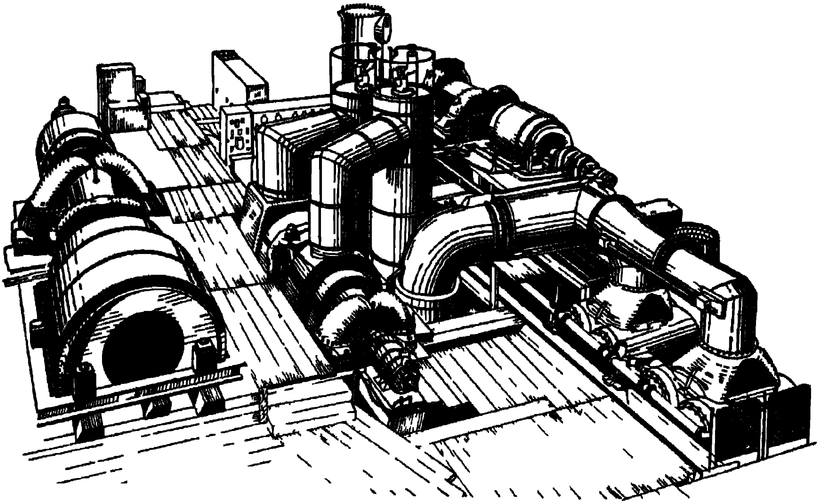

Fig 8-126 Brown-Boveri gas-turbine electric-generating unit of 10,000 kw capacity

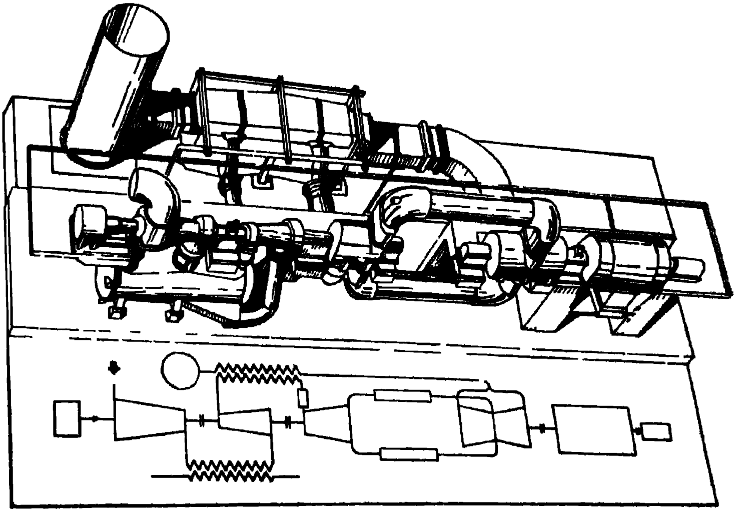

Fig 8-127 Model of 10 000-kw Allis-Chalmers gas-turbine unit including cycle diagram.

effectivenesses of 75 and 85 per cent respectively, under which conditions a coupling thermal efficiency of 30 per cent is obtainable

A promising application for the gas turbine is its use as a blast-furnace blower In such an arrangement no excess power need be developed, but, instead, the equivalent required quantity of air for the blast-furnace operation is tapped off the compressor at some appropriate intermediate pressure In applications of this nature the blast-furnace gas could be used as a fuel, but in order to introduce it into the combustion chamber, its pressure would have to be increased. This could be accomplished by a separate compressor driven from the main shaft. Because of the low heating value of the gas, relatively large quantities would be required, resulting in an appreciable power consumption for the fuel compressor. The majority of this energy is recovered, however in the subsequent expansion through the turbine. It would be desirable to use a regenerator in the cycle so that the discharges from the main and fuel compressors could be preheated by the turbine exhaust gas prior to entry into the combustion chamber and thereby increase the thermal efficiency of the system.

The use of the conventional open-cycle gas turbine as a drive for automobiles has not appeared as yet. Such an application is technically possible, however, but the small sizes involved would not make it so attractive from a design standpoint as some of the larger units which have been built for other purposes. This may be readily understood when it is remembered that the net power available for useful purposes is the difference between two relatively larger powers. In the size range applicable to automobiles, it is difficult to maintain high efficiency in the turbine and compressor elements, so any variations would seriously affect the net output and thermal efficiency. In smaller sizes the free-piston compressor may be found to have desirable features, particularly with regard to efficiency.

Marine. The use of the gas turbine for marine service is one of the natural applications whereby its many advantages can be employed with benefit. The small space and weight characteristics of the gas turbine are particularly desirable for naval and maritime duty. The reversing operation when employing this type of unit aboard ship could be facilitated by the use of electric drive or a variable-pitch propeller, thus eliminating the necessity of providing a separate astern turbine. Astern operation with gear drive is a more acute procedure in the case of the gas turbine since, unlike the steam turbine, it normally exhausts at atmospheric pressure, thereby requiring a separate vacuum system to provide a low-density atmosphere in which to rotate the astern and ahead turbines during forward and reverse operation, respectively, so as to prevent prohibitive windage losses.

Prior to the Second World War, the Bureau of Ships of the United States Navy, recognizing the potentialities of the gas turbine, contracted with Allis-Chalmers to construct a plant designed for a temperature of 1500°F and an output of 3,500 hp This unit,[24] the largest stationary gas turbine for this temperature in the world, is shown in Fig. 8-128 on the test floor of the U.S. Naval Engineering Experiment Station at Annapolis, Maryland. As of this date, it has successfully completed its tests at temperatures up to and including 1500°F, the highest operating temperature ever attained in a prime mover of this size. The testing program will also include an investigation of the effects of wet compression.

The cycle on which the unit operates, depicted schematically in Fig. 8-129, consists of an axial-flow compressor C driven by turbine T_1, while a separate turbine T_2, arranged in parallel, furnishes the useful output. The air from the compressor enters the regenerator R where it is preheated by the combined exhaust gas from both turbines. It next passes to two combustion chambers B_1 and B_2 which furnish the high-temperature motive fluid to the turbines.

Referring to Fig. 8-128, the axial compressor may be seen in the lower left corner connected to its driving turbine. The power turbine is on the upper right in line with the other rotating elements. The regenerator in the upper left has three large pipes (white insulation) entering it which from left to right are the compressor discharge, compressor-turbine exhaust, and power-turbine exhaust. Directly under the regenerator are located the two combustion chambers from which may be seen emerging the turbine-inlet connections. The compressor intake air is supplied through the lower pipe in the figure.

The arrangement of the equipment may be seen in Fig. 8-130 where the nomenclature is identical with that of Fig. 8-129. A conception of the relative size of the various components may be obtained by noting the operator sketched in the figure. Since this unit was intended primarily for experimental laboratory purposes, no attempt was made to achieve minimum space and weight in the design. On the contrary, it was purposely extended laterally so as to facilitate the dismantling of the turbines and compressor as scheduled in the testing program The fulfillment of such a premise necessitated an elaborate piping system, requiring appropriate expansion and swing joints to accommodate the relative motions of the various components.

R = regenerator

Dictated by the high temperatures involved, a unique design of turbine was adopted as indicated in Fig 8-131 where is shown a section through the compressor turbine In order to dispense with a bearing in the high-temperature end of the machine and thereby eliminate a potential source of trouble and also to provide optimum entrance conditions for the motive fluid, the turbine spindle was overhung

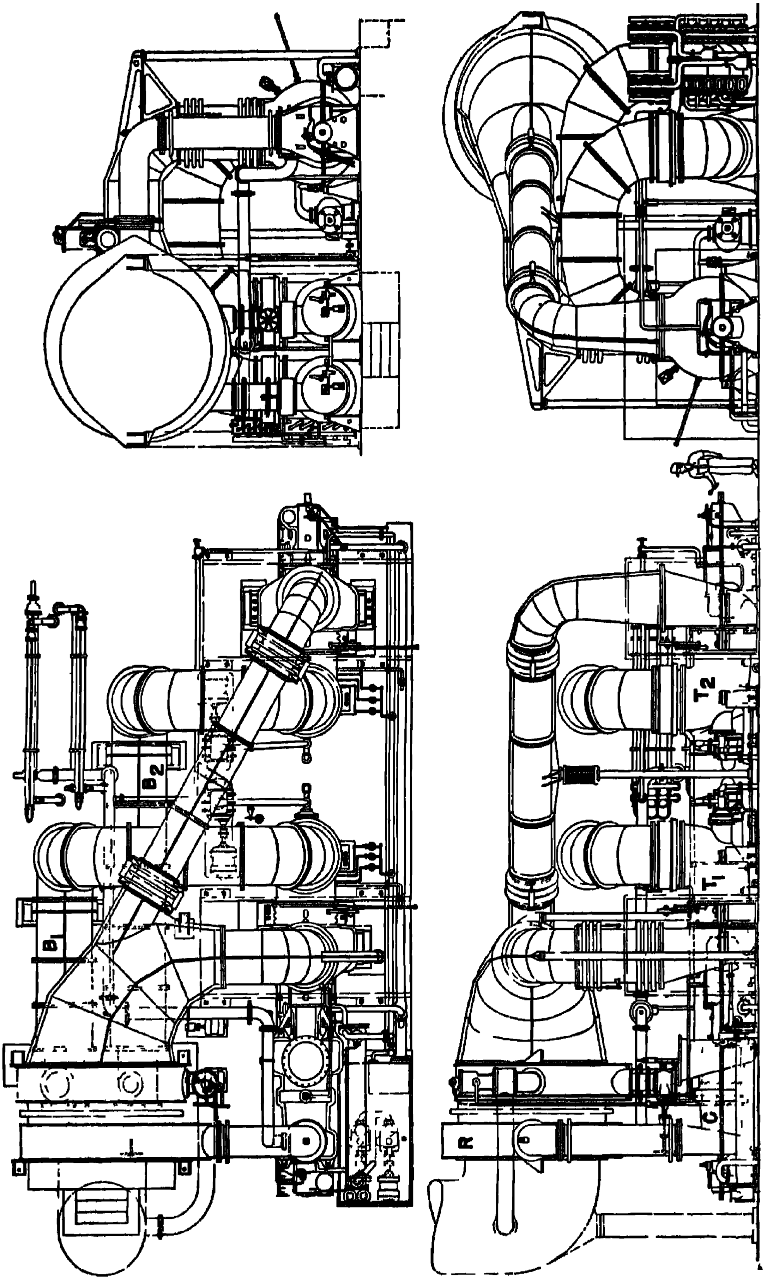

Fig 8-130 Arrangement views of Allis-Chalmers, 3 500-hp, experimental gas-turbine unit.

from a single sleeve bearing at its low-pressure end. The rotating element consists of two Rateau impulse wheels followed by three reaction stages. The individual impulse disks are joined to each other and to the single forging carrying the reaction blading by welding.

Several novel cooling features were employed to mitigate the effects of the exceptionally high temperatures involved. A separate recirculating cooling system directs cooled air on the periphery of the first disk so as to reduce its operating temperature. Air at reduced temperature is introduced radially at several locations in the casing so as to cool the first-stage nozzles and also the second-stage diaphragm, from which it impinges on the downstream side of the first disk. At still another point further down the casing air is admitted to cool the internal-reaction blade ring.

A by-pass is provided on the compressor turbine so that, during periods of starting and rapid acceleration, more capacity may be obtained by the motive fluid circumventing the first impulse stage. The by-pass valve is controlled externally by an air-operated valve. Except for the by-pass valve feature, reduced blade heights, and a modified balance piston, the power turbine is essentially a duplicate of the compressor turbine.

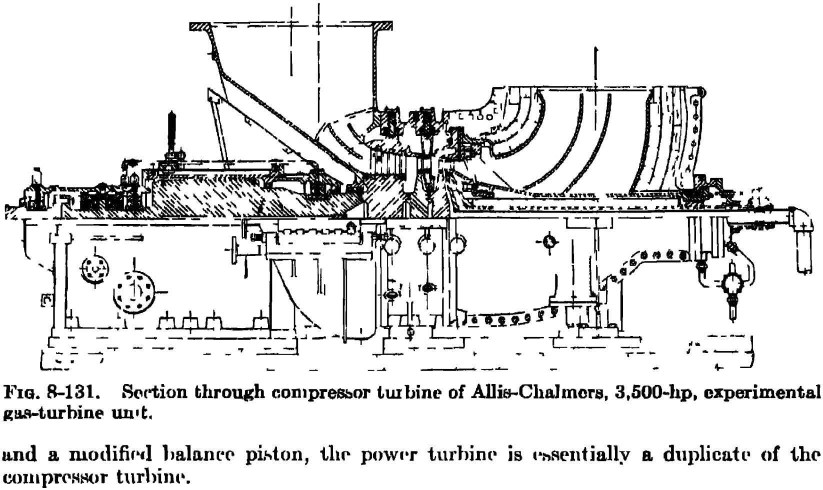

FIG. 8-131. Section through compressor turbine of Allis-Chalmers, 3,500-hp, experimental gas-turbine unit.

The Elliott Company, under the sponsorship of the Bureau of Ships, manufactured a 2,500-hp marine gas-turbine plant[12] which is shown in Fig. 8-132. The unit is designed for a turbine temperature of 1200 F. A novel feature is the use of a Lysholm positive-displacement type of compressor which has the advantage of a flat efficiency characteristic, although its peak efficiency is not so high as that of the axial compressor.

A schematic diagram of the regenerative cycle with reheating and intercooling is given in Fig 8-133 Atmospheric air enters the low-pressure compressor C_1 from which it is discharged to the intercooler I where its temperature is reduced. After next traversing the high-pressure compressor C_2, it passes through the regenerator R where it absorbs heat from the turbine exhaust gas. Fuel is burned with the heated air in combustion chamber B_1, and the resulting high-temperature gas drives the high-pressure turbine T_1 which furnishes power to the low-pressure compressor. The exhaust gas from the high-pressure turbine, still containing adequate oxygen to support combustion, has its temperature increased by the burning of additional fuel in combustion chamber B_2. The ensuing products of combustion, at a temperature approximately the same as that at the inlet to the high-pressure turbine, propel the low-pressure turbine T_2, which has the dual function of driving high-pressure compressor C_2 and also furnishing the useful shaft output. The exhaust gas from the low-pressure turbine, after disposing of heat in the regenerator, is discharged to the atmosphere.

Based on the lower heating value of the fuel, tests on the plant showed coupling thermal efficiencies of approximately 29, 28, 26, and 20 per cent at full, three-fourths, one-half, and one-fourth load, respectively

Rail. In all probability the most desirable application of the gas turbine is in the heavy-traction field When used as a locomotive drive, its many advantageous characteristics place it in an exceptionally favorable position when compared with conventional types. When operating on a regenerative cycle at 1300°F, a rail thermal efficiency of 17 per cent is readily attainable with the gas turbine. Even with liquid fuel, because of the low-grade type it can use, fuel costs for the gas turbine would be lower than for the majority of conventional steam locomotives burning coal and at least equivalent to the best where an efficiency of 9 per cent is rarely exceeded. It would also have lower fuel costs than the diesel locomotive whose better thermal efficiency is offset by the higher grade of fuel it uses. When coal fuel is used in the gas-turbine cycle, the comparison becomes even more favorable.

Since no water is required in its operation, the gas-turbine cycle should be particularly attractive for locomotive installations. Elimination of the now-necessary water-treating provisions and frequent inspections, cleanings, and repairs of boilers used on present steam locomotives should certainly be desirable. Of additional importance would be the improved operating schedules possible on runs that formerly made stops for water.

The large amount of excess air used in the gas-turbine combustion process permits a clear stack completely free from smoke at all loads on the unit. The desirability of such a feature in view of some present city ordinances is manifest.

The purely rotary motion of the gas turbine will result in minimum maintenance and vibration. Absence of any reciprocation, with its concomitant unbalanced forces, is obviously beneficial. Since the elements of the gas turbine are similar to those of steam turbines, maintenance after development should be essentially of a moderate order except for such additional incremental amount as might result from the higher temperatures employed. Operating experience with the Houdry turbines of similar design indicates very low maintenance for this equipment which operates at temperatures in the range of those employed in modern high-temperature central-station practice. Several of the oil-refinery gas turbines have demonstrated an exceptionally high order of reliability by operating continuously for as long as 2 years without shutdown.

Lubrication costs of the gas turbine, there being no sliding surfaces except for journal bearings, should not exceed 1 per cent of the fuel costs. Such costs on present railway equipment are substantially in excess of this figure.

When dynamic braking is considered, the application of the gas turbine to locomotives is exemplary. By operating the traction motors as generators, the motorized main generators may be loaded by driving the gas turbine and its associated compressor. The energy required during compression can be dissipated by discharging the compressed air to the atmosphere. With such an arrangement, the electrical-resistor grids normally required for dynamic braking are eliminated.

In 1941, Brown-Boveri completed a 2,200-hp gas-turbine electric locomotive[23] for the Swiss Federal Railways. A shop view of the gas-turbine power plant is shown in Fig. 8-134. From left to right may be seen the 200-kw auxiliary d-c generator, main d-c generator, reduction gear, regenerator, gas turbine, and vertical combustion chamber. The locomotive has a maximum specific service weight, including fuel, of 92 lb per bhp. Its maximum speed is 70 mph. The tractive effort at starting is 29,000 lb. Acceptance tests of the power plant showed a maximum coupling thermal efficiency at three-fourths load of 18 per cent based on the lower heating value of the fuel.

Based on the experience gained with their first locomotive, Brown-Boveri has recently completed a 4,000-hp gas-turbine power plant for another locomotive.[24] This new unit, shown in Fig. 8-135, is reported to have substantially higher efficiency than the first power plant, and notwithstanding its greater capacity, its physical size is not much larger than its predecessor. The improvement in efficiency and capacity is accomplished by incorporating a device referred to as a "comprex," whereby the over-all pressure ratio of the cycle is increased.

The Locomotive Development Committee[11] is now engaged in a research program which embraces the greatest potentialities regarding the application of the gas turbine as a railway power plant. This committee was formed as an agency of Bituminous Coal Research, Inc., in the latter part of 1944. The committee is composed of the chief executives of six leading coal-hauling railroads and three major coal companies. It was established for the purpose of developing a bituminous-coal-burning locomotive

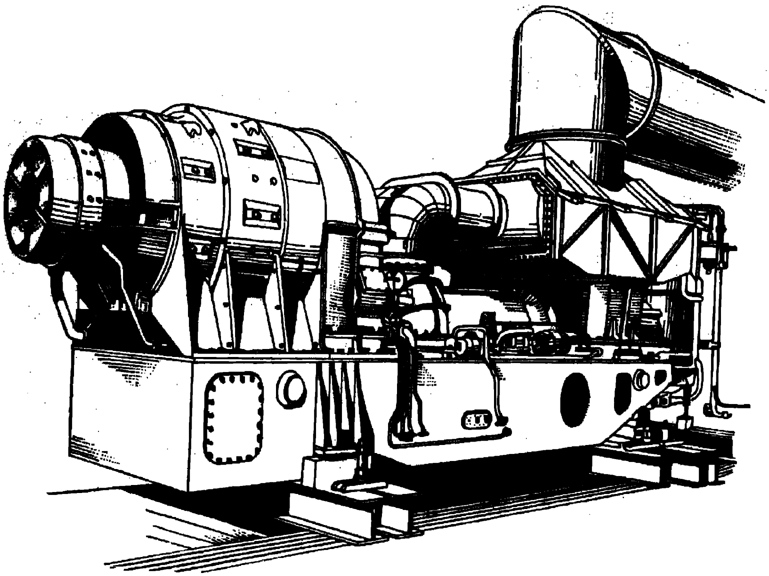

FIG. 8-134. Brown-Boveri 2,200-hp locomotive gas-turbine unit.

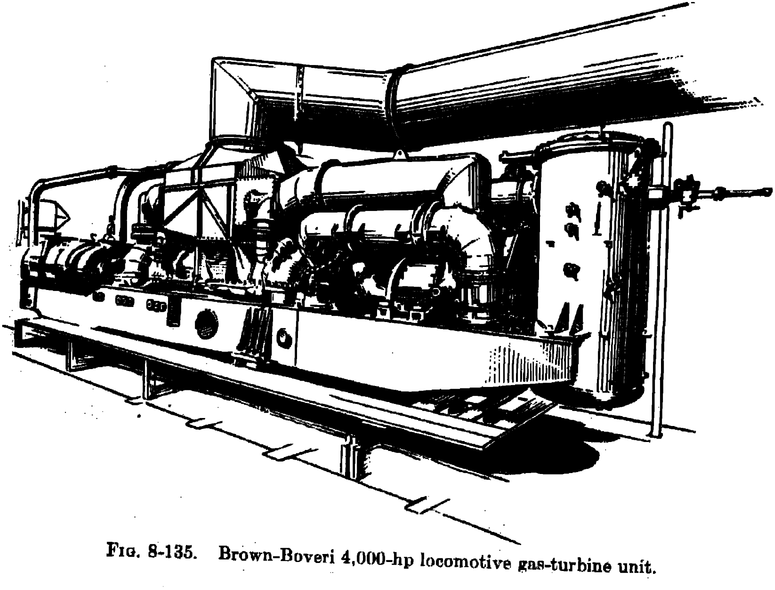

FIG. 8-135. Brown-Boveri 4,000-hp locomotive gas-turbine unit.

which could compare favorably with the diesel locomotive. In the fulfillment of this aim, the gas turbine has been selected as the prime mover which best adapts itself to the requirements involved.

The proposed arrangement of the equipment to be used on the coal-burning gas-turbine locomotive is depicted schematically in Fig. 8-136. The coal is fed from bunker *A*, by means of a motor-operated screw, to crusher *D* where its size will be reduced to −16 mesh. Turbine exhaust gas will be used for drying the coal. By means of fan *E* the coal is conveyed to pressure tanks *F* and *H* after it is crushed. The twin-tank system of coal storage is necessary because of the different pressure levels in the cycle. While one tank is being replenished, it is isolated by means of valves from the high-pressure circuit, and coal is used from the other tank under full pressure.

For instance, when tank *F* was being filled, valves 1 and 2 would be open, and 3 would be closed. The tank would then be under the low pressure existing in the conveying system. The crushed coal mixed with its conveying air enters the tank where an internal cyclone separates the coal from the air, the latter being vented. After tank *F* is filled and tank *H* exhausted, valves 1, 2, and 6 are closed and valves 3, 4, and 5 opened, whereupon the full pressure required for pulverizing exists in tank *F*.

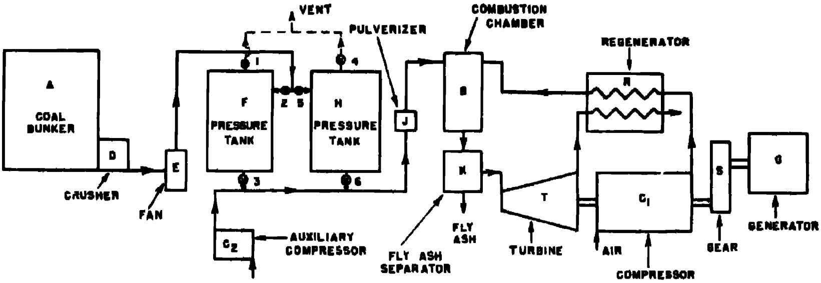

FIG. 8-136. Cycle for coal-burning locomotive gas turbine proposed by Locomotive Development Committee.

The air compressor C_2 will produce a pressure of approximately 140 psig maximum required for pulverization. The intake will be connected with the discharge of the main compressor C_1, and a variable-speed drive of C_2 will permit independent pressure relationships. After the crushed coal from tanks *F* or *H* is picked up by the high-pressure air, it is led to the inlet of the pulverizer *J*. This latter device was developed at the Institute of Gas Technology of the Illinois Institute of Technology in Chicago and was used to produce finely pulverized coal for gasification. It consists of a nozzle through which the compressed air, laden with crushed coal, is expanded to a pressure essentially equivalent to that at the turbine inlet, which will be approximately 60 psig at full load. Expansion through the nozzle imparts a high velocity to the air-coal mixture, which subsequently impinges on a target and is finely pulverized by impact and attrition. With proper design, a product as fine as 80 to 90 per cent of −325 mesh and 5 per cent or less of +100 mesh is obtainable with an air consumption of approximately one pound per pound of coal. Because of its extremely small size and effective pulverization, the adoption of this device appears to be the logical procedure for applications where space is at a premium, as in the case of locomotives.

The pulverized coal and primary air next enter combustion chamber *B* where they mix with the preheated air from the regenerator. The combustion chamber will be basically similar to that shown in Figs. 8-95 and 8-100, comprising an inner shell, where burning will occur with about 40 per cent excess air, surrounded by an annular space through which flows the diluent air. After mixture, the temperature of the gas entering the turbine will be 1300°F. Since the products leaving the combustion chamber contain fly ash, which would seriously erode the turbine blading, it is necessary to introduce an ash separator *K*. This device will consist of a series of is arranged at each end of the locomotive cab, permitting the weight to be more uniformly distributed, with most of it directly over the trucks. For each power unit, the common frame carrying the turbine, compressor, reduction gear, and generators is supported at three points for the purpose of maintaining correct alignment. Two of the support points are located laterally directly over the center axle of each truck, while the third, in vertical line with the No. 1 turbine bearing, is on the center line and near the center of the cab.

The filters for the intake air to the gas-turbine–compressor units are located on both sides of the cab near the top at each end. They are placed as high as feasible so as to reduce the possibility of disturbed foreign objects along the roadbed being inducted. Furthermore, the high intakes are desirable when the locomotive is standing in a station with engines running where passengers may be in the vicinity.

The exhaust gases leaving the heat exchangers are discharged through the roof of the locomotive.

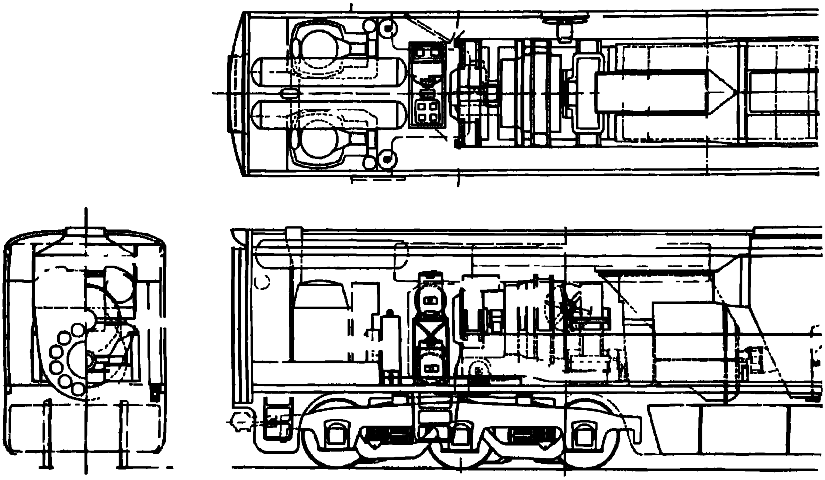

Fig. 8-138. Arrangement of Allis-Chalmers proposed

Two 2,250-lb-per-hr steam generators are provided for train heating. It is possible, with the gas-turbine type of drive, to install a waste-heat boiler in the exhaust passage beyond the heat exchanger and generate steam for heating purposes. However, in the interest of simplicity, it was decided to forego such a refinement on an initial gas-turbine installation, and therefore only the conventional type of boiler is indicated. After a sufficient accumulation of operating experience has proved the merit of the gas turbine itself, it would in all probability be expedient to incorporate in future locomotive designs a waste-heat means of generating heating steam also.

An auxiliary-engine generator set of 150 hp is provided for starting the two gas-turbine power plants by motorizing the main generators. One of the numerous advantages of having two smaller power units instead of a single larger one of the same aggregate output is apparent in this instance, since it permits smaller capacity starting equipment to be employed. By connecting the auxiliary set directly to the traction motors, it may also be used for propelling the locomotive up to speeds of approximately 15 mph, thus enabling the main units to remain shut down when it is desired to move the locomotive about the yards.

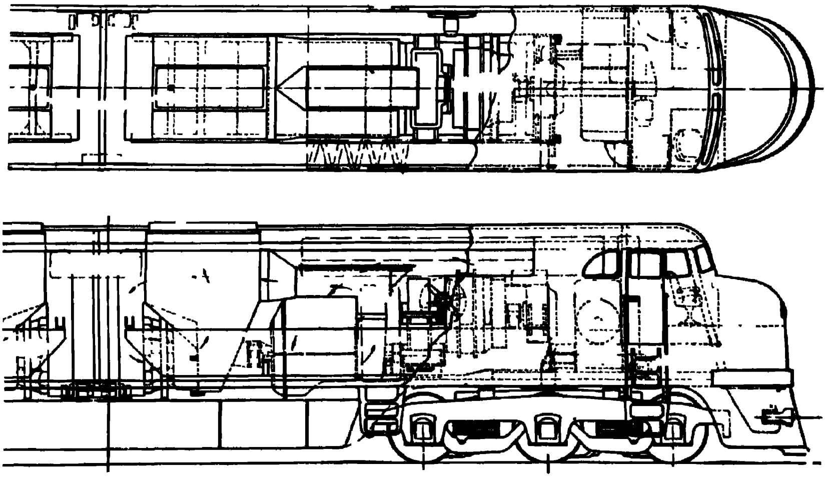
Since the use of a relatively heavy low-grade fuel is contemplated, provision is made for fuel heating. There are various methods of accomplishing this, either with steam or electrical heating, but probably the most logical would be to use the exhaust gas from the turbines. For starting purposes, the light auxiliary-engine fuel, requiring no preheating, could be used temporarily in the combustion chambers of a main power unit until the flow of exhaust gas is established.

In the space under the center of the cab between the two trucks, tank capacity is provided for 4,000 gal turbine fuel oil, 1,500 gal lubricating oil, and 2,600 gal water for train heating. The fuel-oil capacity is sufficient for approximately a 10-hr run. Two 300-gal tanks in the rear of the cab contain fuel for the auxiliary engine and the steam generators.

No water is required for the gas-turbine power plants themselves, as all cooling is done with air, two fan coolers being used for the lubricating oil and blowers for cooling the generators and traction motors.

Train controls and associated electrical equipment are in the forward end of the locomotive.

A section through one of the duplicate gas-turbine power units proposed for the locomotive is shown in Fig. 8-139. A five-stage reaction-type gas turbine *A* drives a 22-stage axial compressor *B*. Filtered air from the atmosphere traverses the compressor where its pressure is increased. It next passes through the cross-flow heat exchanger *C*, where its temperature is raised by the turbine exhaust gas. The heated air then flows in parallel through a group of 12 separate combustion chambers *D* ahead of the turbine. Part of the air is used for combustion purposes in an inner shell, while that remaining flows through the annular space between the inner and outer shells and cools the products of combustion to a satisfactory turbine-inlet temperature. A series of smaller combustion chambers is used instead of a single large one, as it has been found that in certain instances more satisfactory combustion at higher heat release can be obtained in this manner. The gas, a mixture of air and combustion products, then expands through the turbine from which it is exhausted to the atmosphere through the heat exchanger where it preheats the air from the compressor. The power developed by the turbine is greater than that required by the compressor, and the excess power is supplied through the reduction gear *E* to the main generator *F* and the auxiliary generator *G*.



4,800-hp gas-turbine locomotive with electric transmission.

In order to start the unit from a standstill, the generator is switched from shunt to series field and motorized by an auxiliary-engine generator set, bringing the unit up to about 30 per cent of maximum operating speed, at which point the turbine, at full gas temperature, is capable of driving the unit by itself. The full-load speed of the turbine and compressor is 5,000 rpm, and that of the generators is 900 rpm.

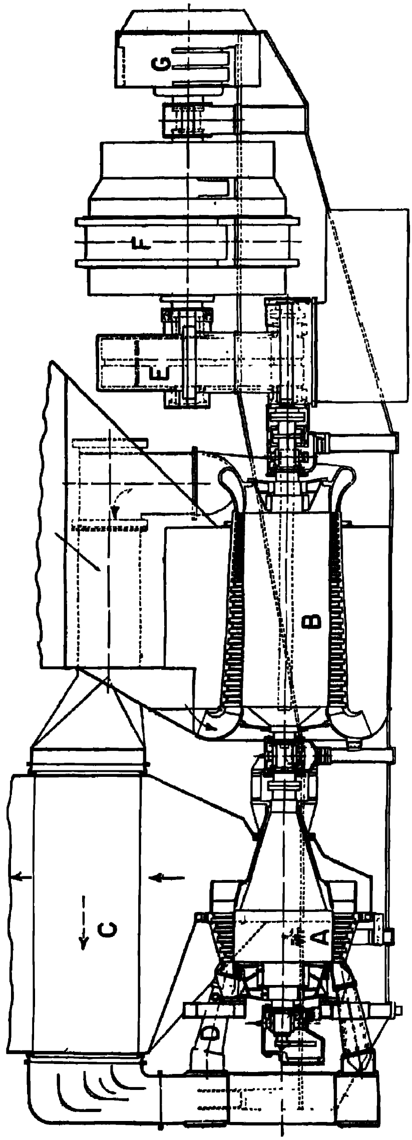


Fig. 8-139. Section through Allis-Chalmers proposed 2,400-hp locomotive gas-turbine power plant.

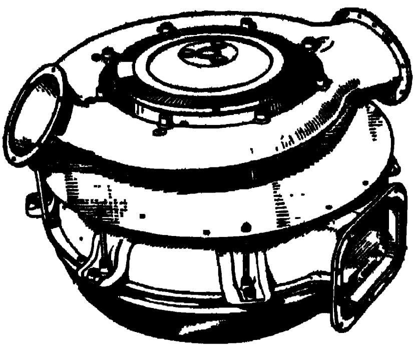

FIG. 8-140. Gas-turbine supercharger.

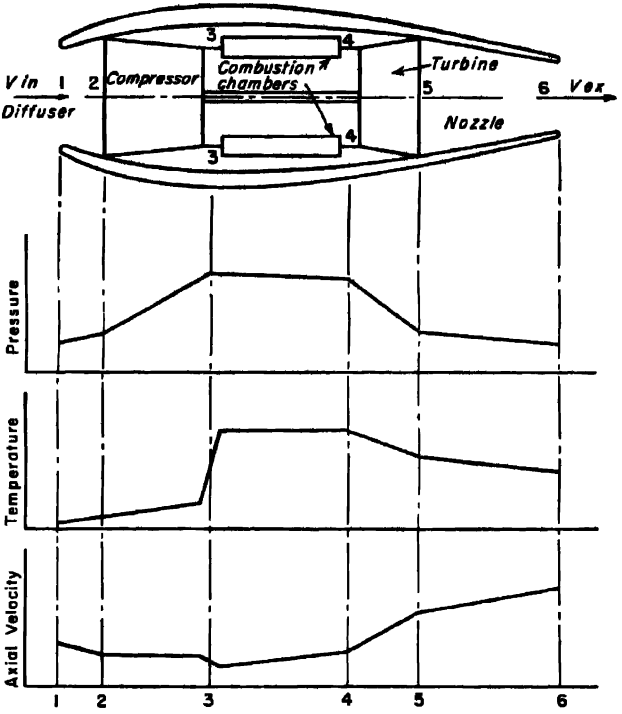

FIG. 8-141. Schematic arrangement of jet-propulsion unit showing variation of pressure, temperature, and axial velocity.

The turbine and compressor, supported on a common frame with the gear and generators, are arranged as a three-bearing unit.

The cross-flow, tubular-type heat exchanger has a surface of 1.4 sq ft per useful horsepower output of the gas-turbine power plant. The effectiveness of the heat exchanger is 50 per cent.

Aircraft. Vast numbers of high-speed, lightweight gas turbines were manufactured during the war and used in aircraft turbosuperchargers. These units operating at 24,000 rpm with a turbine-inlet gas temperature of 1600°F were designed and built by General Electric. Under license arrangement they were also manufactured by Allis-Chalmers and the Ford Motor Company. The combined production of the three companies totaled many millions of horsepower. Figure 8-140 shows one of these turbosuperchargers with the gas turbine on the left and the centrifugal compressor on the right. The exposed turbine wheel may be clearly seen. These units were used on such aircraft as the B-17 (Flying Fortress), the B-24 (Liberator), the B-29 (Superfortress), and the P-38 (Lightning).

Current press releases have publicized the adaptation of the gas turbine to the jet propulsion of airplanes. Figure 8-141 depicts schematically the elements comprising a jet-propulsion unit, as well as the variation in pressure, temperature, and axial velocity occurring throughout the device Referring to the figure, the compressor is driven by the gas turbine, the latter receiving high-temperature motive fluid from combustion chambers interposed between the compressor discharge and the turbine inlet. The residual kinetic energy of the gas leaving the turbine enhanced by a subsequent expansion provides the propulsive jet for propelling the aircraft. The relatively high fuel consumption of the pure-jet type of unit in its present form depreciated its attractiveness for other than military aircraft, although the British have built several transports with turbo-jet engines. Modifications of the current type having improved thermal efficiency and also propeller-jet and reciprocating-engine-gas-turbine combinations, will probably enjoy more diversified future applications.

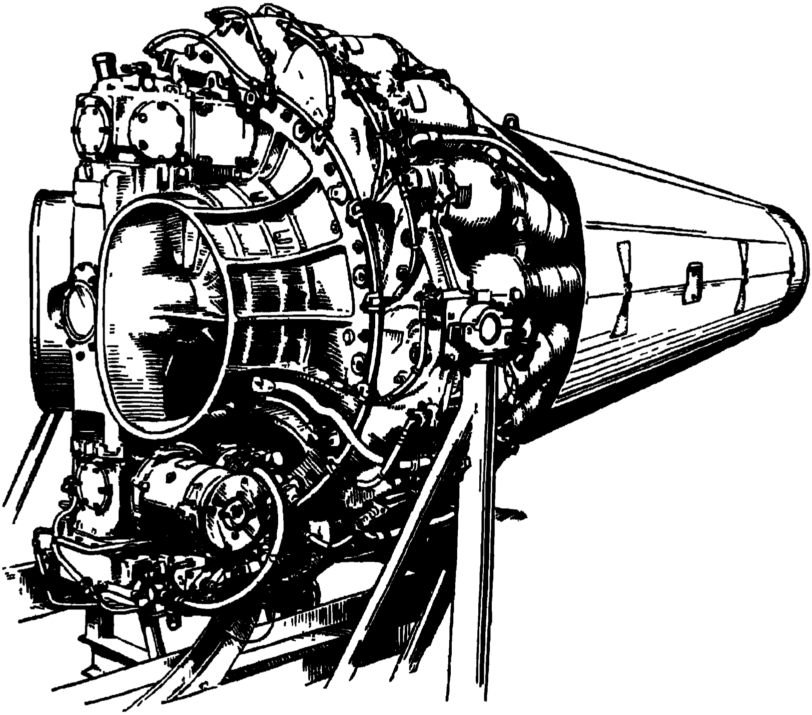

FIG. 8-142. Allis-Chalmers de Havilland 3,000-lb thrust jet-propulsion unit.

All three of the large turbine builders in this country have been engaged in the design and manufacture of aircraft jet-propulsion units Allis-Chalmers, while having several designs of its own which have not yet reached the manufacturing stage, built jet-propulsion units during the war according to the designs of the de Havilland Engine Co., Ltd., of England. Figure 8-142 shows an external view of one of these engines. This design employs a single-stage centrifugal compressor, with single-sided entry of air driven by a single-stage turbine. The unit develops a static sea-level thrust of 3,000 lb when rotating at 10,500 rpm with a turbine-inlet temperature of 1500°F. The complete weight with all auxiliaries is 1,500 lb, resulting in a specific weight of 0.5 lb per lb static thrust. The fuel consumption is approximately 1.2 lb per hr per lb static thrust. The maximum over-all diameter is 50 in.

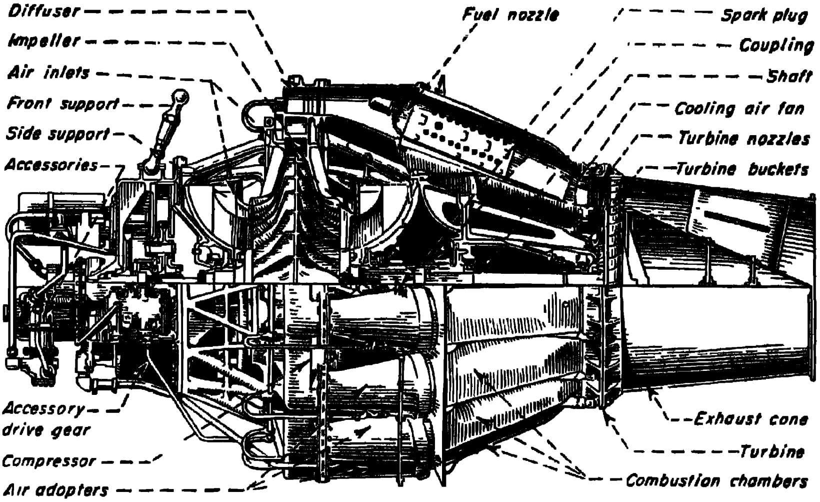

Fig. 8-143. General Electric 4,000-lb thrust jet-propulsion unit.

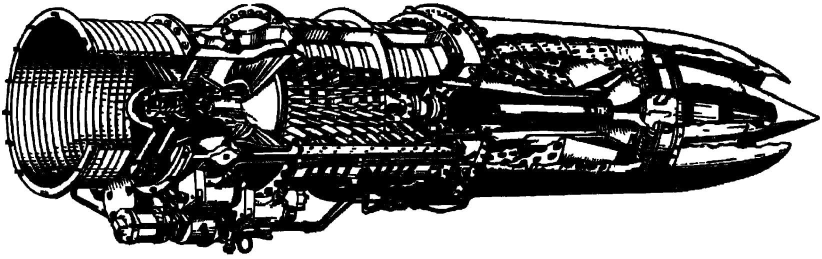

Fig. 8-144. Westinghouse 1,600-lb thrust jet-propulsion unit.

The General Electric Company originally built jet-propulsion engines according to British designs but later developed a unit of higher rating known as the I-40. This unit, shown in Fig. 8-143, while retaining some of the features of the prototype designs, has a sea-level static-thrust rating of 4,000 lb at a rotative speed of 11,500 rpm and a turbine-inlet gas temperature of approximately 1500°F. The specific fuel consumption under these conditions is about 1.2 lb per hr per lb static thrust. The average specific weight of the unit is about 0.45 lb per lb static thrust. The engine has a single-stage centrifugal compressor, with air entry on both sides of the impeller, driven by a single-stage gas turbine. The maximum over-all diameter is 48 in. The double-entry feature has the advantage of reducing the over-all diameter of the unit, although it complicates inlet-flow conditions on the rear side of the impeller.

General Electric also has a pure jet-engine design, designated as TG-180, employing an axial-flow compressor. Another unit, the TG-100, is a propeller-jet combination again with a compressor element of the axial-flow type. The axial-flow compressor has the advantage of higher efficiency and smaller diameter, the latter resulting in reduced drag of the airplane.

The Westinghouse Electric Corporation has designed and built its X19XB-2B jet-propulsion engine employing a 10-stage axial compressor driven by a single-stage turbine. The unit, shown in Fig. 8-144, produces a static sea-level thrust of 1,600 lb when rotating at 17,000 rpm with a maximum turbine-inlet temperature of 1500°F. The specific weight is 0.45 lb per lb static thrust. The diameter is 19 in. The fuel consumption is 1.15 lb per hr per lb static thrust.

COMPRESSORS AND PUMPS

BY A. W. LOOMIS, B.S.

Mechanical Engineer, Ingersoll-Rand Company

COMPRESSORS

Uses of Compressed Air

Compressed air has a wide variety of applications Following are some of its uses:

1 To operate reciprocating tools, such as riveting hammers, chipping hammers, scalers, paving breakers, diggers, tampers, etc.

2. To operate rotating tools, such as grinders, wrenches, screw drivers, air motors, drills, reamers, air-operated pumps, etc.

3. To spray paint, oils, insecticides, etc.

4. To operate air pistons for presses, opening doors, lifting, clamping, etc.

5. Air jets for cleaning, moving packages, etc.

6. To inflate tires and casings of all types, to charge shock absorbers, etc.

7. To start diesel engines

8. To operate control instruments, valves, etc.

9 To aerate and agitate liquids.

The above list is far from complete, but it indicates that compressed air may be utilized to produce almost any mechanical motion. Air-operated tools and devices of many types are available in standard sizes

Types of Air Compressors

Compressed air is air from the atmosphere compressed or squeezed into a small space The extent of the squeezing determines the pressure attained Machines for compressing air are of several types:

1 Reciprocating compressors have a piston moving back and forth in a cylinder. This is the most widely used type of compressor.

2 Turbo- or centrifugal compressors have a bladed impeller which rotates within a casing Such units are normally used for low and moderate pressures up to, say, 40 psi.

3. Rotary compressors are of several types: (*a*) two-impeller, with intermeshing gear-type elements, (*b*) sliding vanes, with a vaned rotor eccentrically mounted in a casing, (*c*) liquid-piston, with a multibladed rotor revolving in a casing partly filled with liquid which acts as a piston.

4. Axial-flow compressors have a bladed rotor or rotors and bladed stationary vanes similar to a reaction steam turbine.

Of the above types the reciprocating compressor has the most general application for the operation of laborsaving tools. The other types, while overlapping the field of the reciprocating compressor to a certain extent, are mainly used where air is required at moderate pressures.

In most plants the general air supply is maintained at 100 psi pressure. Machines for higher or lower pressures are also available. Standard units are supplied for pressures as high as 3,000 psi, and special units for higher pressures have been built.

While we have been speaking in terms of air compressors, the same type of machine is also used for compressing gases of various types. Where a machine is needed for such purposes, a reliable manufacturer should be consulted as special materials and design features may be required depending on the nature of the gas.

Mention should also be made of vacuum pumps. These machines, except air ejectors, are essentially the same as an air compressor except that they operate in a pressure range below atmospheric pressure instead of above.

Selection of a Compressor

A number of factors are involved in the selection of a suitable air compressor or compressors for a plant.

Pressure. First of all, the pressure needed must be determined. Most air-operated tools are designed to operate at pressures from 90 to 100 psi. If this is the case, a 100-lb compressor would normally be selected, and the air-distribution lines laid out to assure a pressure of 90 psi or greater at the tools. Where long distribution lines are required, it may be desirable to install a machine discharging at 110 or 125 psi.

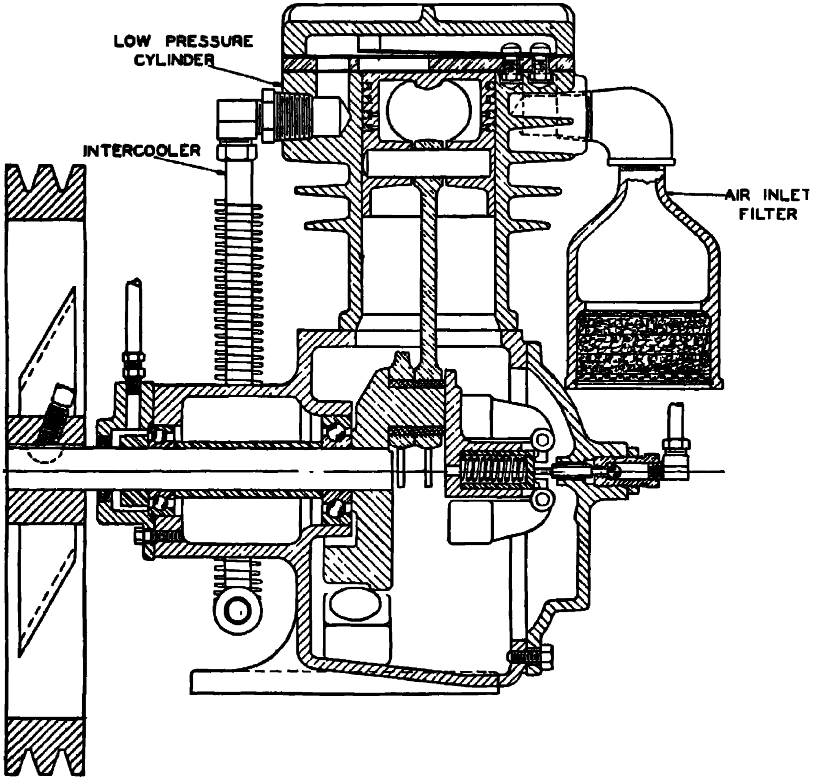

FIG. 8-145. Section through one cylinder of a two-stage air-cooled compressor

Where one or two operations require air at a higher pressure, it is usually more economical and more convenient to install a separate small compressor to furnish air for these operations.

Where small amounts of air are required at pressures lower than that carried in the main distribution lines, they may be obtained by installing a reducing valve in the branch line leading to the operation requiring the low-pressure air. If large amounts of low-pressure air are required, it is more economical to install a separate compressor for the purpose.

Where the air pressure is less than 30 psi and the volume required is comparatively large, a turboblower or rotary-type compressor should be considered.

Capacity. Another important factor in compressor selection is the capacity or volume of air required. This is a factor which is sometimes extremely difficult to evaluate. Obviously the unit selected should be large enough to supply all the air devices which will be operating at any one time. If all the air operations are continuous, the capacity required is simply the sum of the air consumption of each individual tool. In most plants, however, air tools such as chipping hammers, grinders, hoists, etc., are operated intermittently. The compressor capacity in this case is that required to operate as many air-consuming devices as would ever be in use at one time. This may be anywhere from 10 to 100 per cent of the total required by all the tools, depending almost entirely on the nature of the work in the plant. The experience of another plant doing similar work is very helpful. Air-compressor and air-tool manufacturers can often aid in determining the air capacity required. Tables 8-49 and 8-50 will be useful in determining horsepower requirements once capacity has been determined.

Capacity Control. In most installations the demand for air is irregular, and therefore some means of controlling the output of the compressor is necessary. The choice of control depends upon the character of the air load.

Practically all compressor capacity or unloading devices (Fig. 8-151), as they are usually termed, are actuated by the pressure on the discharge side of the compressor. A falling pressure indicates that air is being used faster than it is produced, and more air is required. A rising pressure indicates that more air is being produced than is being used, and therefore less air is required.

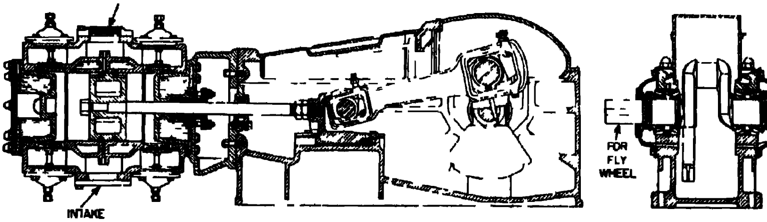

Fig. 8-146 A typical single-stage water-cooled compressor.

An obvious method of controlling a compressor's capacity is to vary the speed. This method is applicable to steam-driven reciprocating and to rotary compressors and, within certain limits, to centrifugal compressors and blowers. It is also applicable to some units driven by internal-combustion engines. In these cases the pressure regulator actuates the steam-admission or fuel-admission valve on the compressor driver and thus controls the speed.

By far the greatest number of compressors, however, are motor-driven, and since a motor is essentially a constant-speed machine, other methods of controlling the capacity are necessary. On reciprocating compressors up to about 100 hp, two types of control are usually available. These are automatic start-and-stop control and constant-speed control.

Automatic start-and-stop control, as its name implies, stops or starts the compressor by means of a pressure-actuated switch as the air demand varies. It should be used when the demand for air will be intermittent.

Constant-speed control should be used when air demand is fairly constant. With this type of control, the compressor runs continuously until shut down but compresses air only when it is needed. Two methods of unloading the compressor with this type of control are in common use: (1) closed-suction unloaders and (2) open-inlet-valve unloaders. The closed-suction unloader consists of a pressure-actuated valve in the compressor intake which prevents compression by shutting off the air intake. Open-inlet-valve unloaders operate to hold the compressor inlet valves open and thereby prevent compression.

It is often desirable to have a compressor equipped with both automatic start-and-stop and constant speed control. When this is done, a switch allows immediate manual selection of either type.

Motor-driven reciprocating compressors above about 100 hp in size are usually equipped with a step control. This is in reality a variation of constant-speed control in which unloading is accomplished in a series of steps, varying from full load down to no load. Three-step control (full load, one-half load, and no load) is usually accomplished with free-air unloaders. Five-step control (full load, three-fourths load, one-half load, one-fourth load, and no load) is accomplished by means of clearance pockets. These pockets or small air reservoirs are opened when unloading is desired. The air is compressed into them on the compression stroke of the compressor piston and refills the cylinder on the return stroke, thus preventing the compression of additional air. On some makes of machines open-inlet-valve and clearance-control unloading are used in combination.

Air-cooled and Water-cooled Reciprocating Compressors. When air is compressed, considerable heat is generated. This heat must be dissipated at least in units where the pressures exceed 25 or 30 psi. On air-cooled machines (Fig. 8-145) this is accomplished by means of fins on the cylinders and a fan which blows air across the fins and also the intercooler surfaces if the machine is of the multistage type. On water-cooled machines (Fig. 8-146), water is circulated in jackets (Fig. 8-150) surrounding the cylinders to pick up and carry away the excess heat. On multistage water-cooled machines, water is also circulated in the intercooler tubes.

In general, air-cooled machines are available for pressures up to 125 psi and horsepowers up to about 100. Some air-cooled units of small size, 5 or 10 hp, are available for considerably higher pressures. Water-cooled units are available from 5 hp on up. Large units are invariably water-cooled.

In the range where both air-cooled and water-cooled machines are available, either or both types may be satisfactory, depending on conditions Air-cooled units are convenient where there is danger of freezing, in isolated locations, and where the expense of attendance or automatic water shutoff valves is not warranted. Water-cooled machines should be used where air temperatures are high or where the heat from the compressor is objectionable.

Single-stage and Multistage Reciprocating Compressors. Single-stage compressors are those in which compression from intake to discharge pressure takes place in a single step; in a reciprocating compressor, it takes place in a single stroke of the piston.

Multistage compressors (Figs. 8-147, 8-148, and 8-149) are those in which compression takes place in two or more distinct steps or stages; in a reciprocating compressor, the succeeding steps usually take place in separate cylinders.

Multistage reciprocating compressors and many multistage machines of other types have intercoolers between stages. These are heat exchangers usually designed to reduce the temperature of the compressed air to near the temperature at which it entered the first stage. This reduction in temperature results in a distinct power saving.

Single-stage air-cooled compressors for intermittent service are available for pressures up to 150 psi in sizes up to about 3 hp.

Two-stage air-cooled compressors (Fig. 8-145) are available for heavy-duty service for 125 psi pressure in sizes up to 100 hp. Two- and three-stage air-cooled units for pressures as high as 3,500 psi are available in sizes below 10 hp.

Single-stage water-cooled compressors (Fig. 8-146) are available for 100 psi pressure in sizes up to 100 hp and for slightly higher pressures at lower horsepowers. Large units (Figs. 8-147, 8-148, and 8-149) are almost invariably of the multistage water-cooled type for pressures above 60 to 80 psi.

Compressor Efficiency. When selecting a compressor, the first requisite is, of course, to choose one that fits the job in hand as regards capacity, pressure, type of control, etc. After that the question of operating efficiency is likely to be considered. So many different efficiency terms are used in connection with air compressors that they become confusing unless one is thoroughly familiar with them. A few of these terms are defined in Table 8-52. When comparisons are made between machines, it

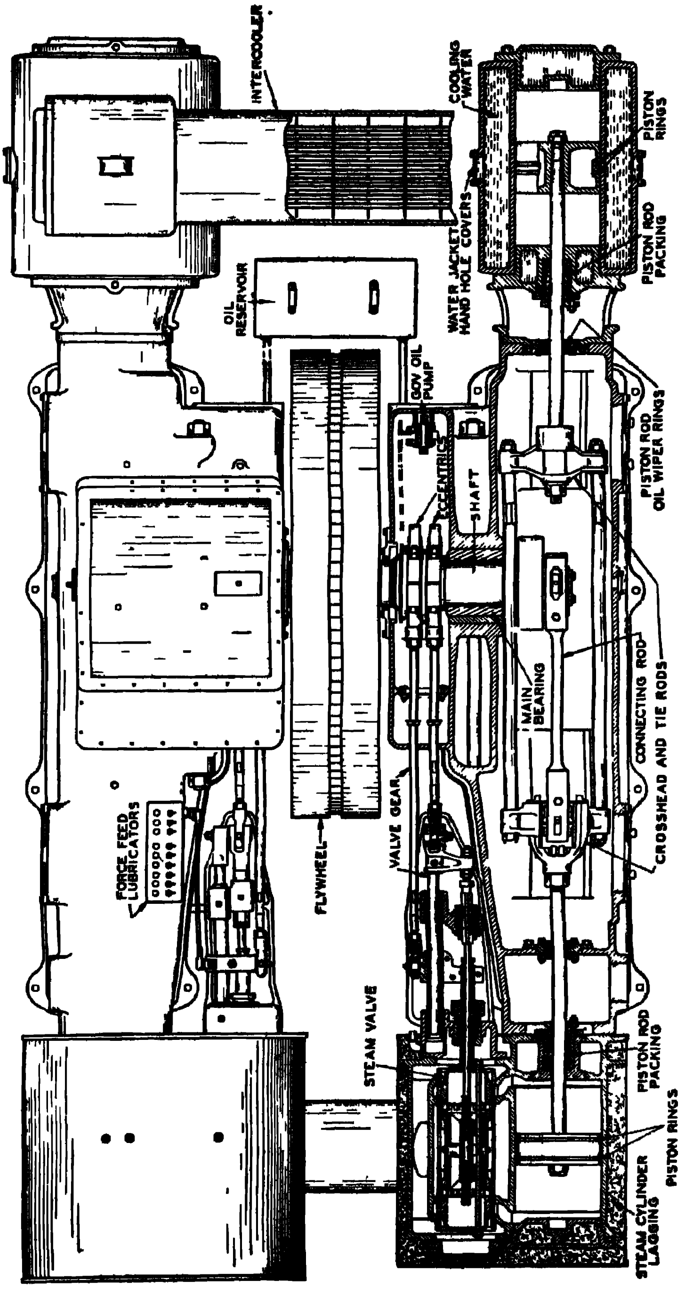

Fig. 8-147. A two-stage steam-driven compressor.

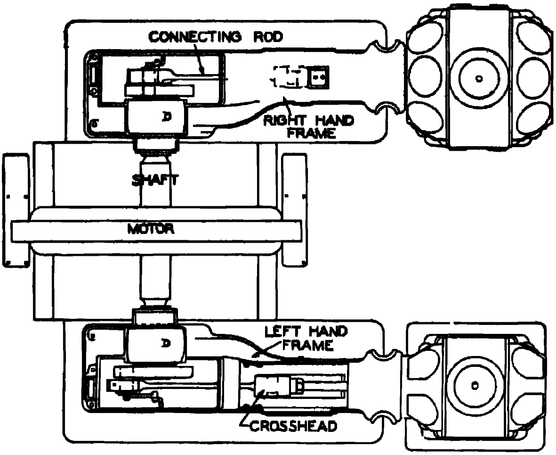

FIG 8-148. View of a duplex compressor looking down from the top

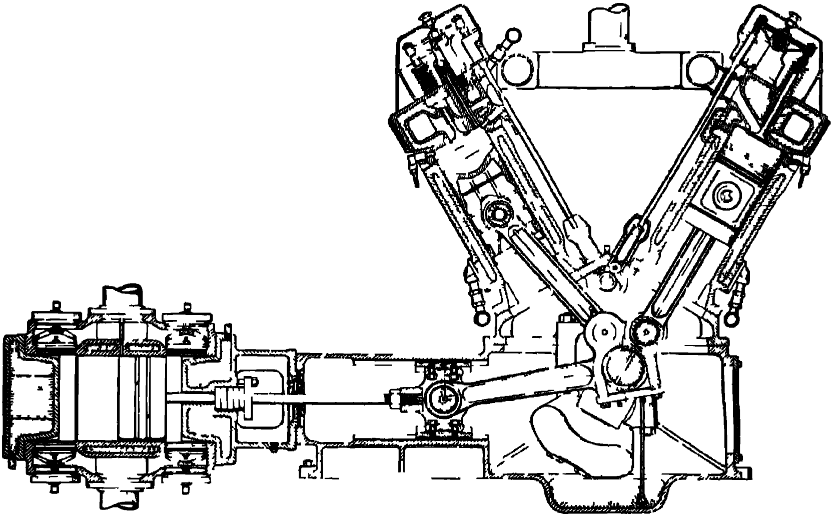

FIG 8-149 A direct-connected diesel-engine-driven compressor

is simpler and less confusing if a basic air delivery and power consumption are used Such measurements for various types of compressors might be

Actual air delivery of, say, 100 cu ft } per {
kwhr (electric-motor drive)
gal of gasoline (gasoline-engine drive)
gal of fuel oil (diesel-engine drive)
lb of steam (steam-engine drive)

If machines with different types of drive are being compared, it is necessary to reduce them all to a common factor by assigning cost values to the different power mediums

Factors other than power cost are involved in operating a compressor. Chief among these are labor, lubricating oil, repairs, depreciation, and interest on the investment. However, power costs are such a large proportion of the total (75 to 85 per cent) that comparisons are sometimes made on this basis alone.

Table 8-50 should be useful in determining approximate horsepower requirements. Table 8-49 gives theoretical horsepower for use in the formulas in Table 8-52.

Water in Compressed Air

All atmospheric air contains moisture. The ability of air to hold this moisture increases with temperature and decreases with compression. Air temperature rises during compression, but in most cases it has dropped to room temperature by the time it reaches the point of use. The net result is that the air has lost its ability to hold the moisture that it originally contained, and the excess condenses in various parts of the distribution system. Since this moisture is detrimental to the operation of air tools and other air-operated equipment, it is essential to remove it.

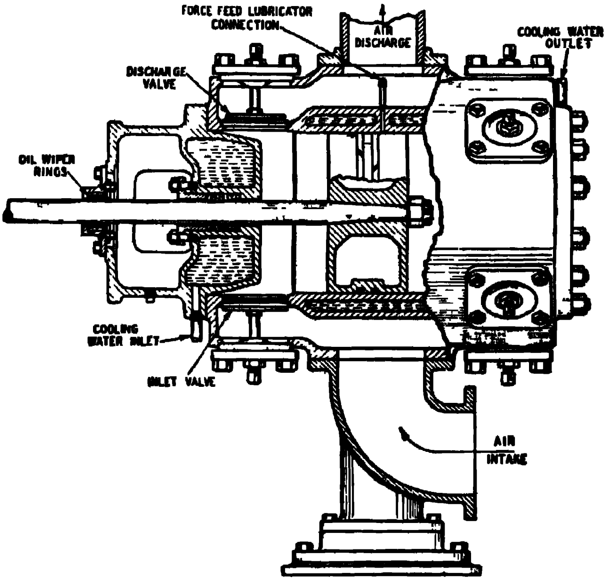

Fig. 8-150. A typical cylinder for a water-cooled compressor.

Intercoolers on multistage machines remove some of the moisture if they are equipped with automatic drains or manual drains which are regularly attended.

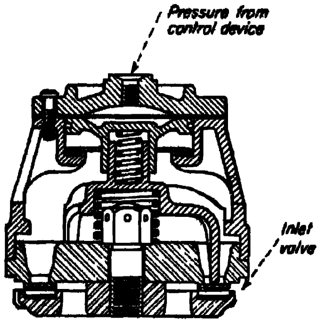
Aftercoolers are a solution to the problem in many instances. These are simple heat exchangers through which water is circulated to cool the air and thus force it to condense excess moisture. In most instances a single aftercooler of suitable size is installed between the air compressor and the receiver.

A number of different types of moisture separators are available These are usually installed at strategic places in the distribution lines near the point of use. Unless regular attendance can be assured, such separators should be equipped with automatic valves for ejecting the moisture they collect.

It is good practice to have branch distribution lines going directly to tools come from the top of the main air-supply line. This prevents moisture which may collect in the main from running into the supply lines.

Air Receiver

An air receiver is a necessity with reciprocating compressors and desirable in many instances with other types. It smooths out the pulsations in flow from a reciprocating machine, provides reserve storage capacity, and helps to cool the air and



Open-inlet-valve unloader

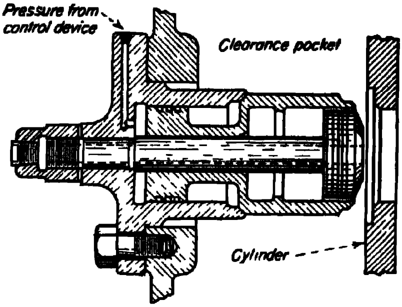
Closed-suction unloader



Clearance valve which opens cylinder into clearance pocket

FIG. 8-151. Compressor unloading devices: (*Upper left*) Open-inlet-valve unloader. (*Lower left*) Closed-suction unloader. (*Upper right*) Actual indicator diagram showing operation of clearance control at five load points of a two-stage compressor. (*Lower right*) Clearance valve which opens cylinder into clearance pocket.

thus condense part of its moisture. The air receiver should be at least large enough to hold all the air delivered by the compressor in 1 min. This may be calculated as follows:

Receiver size, cu ft

$$= \frac{\text{piston displacement or capacity, per min} \times \text{atmospheric pressure, psi}}{\text{discharge pressure, psi,} + \text{atmospheric pressure}}$$

It does no harm to have a receiver larger than this, and in some cases a large one is necessary. This is true where occasional momentary air requirements are greater than the capacity of the compressor. In such instances, the air receiver should have enough capacity to provide all the air required for the momentary operation using air above compressor capacity (also see comments regarding receivers under Safety in the Compressor Plant).

Safety in the Compressor Plant

Compressed air is inherently a safe medium. However, because of its apparent harmlessness, certain fundamental safety precautions are sometimes overlooked.

Air released through a nozzle travels at high velocity. Air at 100 psi expands to nearly eight times its compressed volume on release to atmosphere. It follows, therefore, that workmen should be careful with air jets and should not play pranks with compressed air. Severe cases of internal rupture and even death have resulted when air jets were applied to one of the natural body openings.

Table 8-49. Theoretical Adiabatic Horsepower to Compress 100 Cu Ft per Minute of Air

[Based on sea-level intake (14.7 psi abs) and $n = 1.3947$]

Discharge pressure, psig gauge	Theoretical adiabatic horsepower		Discharge pressure, psig gauge	Theoretical adiabatic horsepower	
	One-stage	Two-stage		One-stage	Two-stage
55	12.6		110	18.9	16.1
60	13.3		120	19.8	16.8
65	13.9		130	20.7	17.3
70	14.6	12.8	140	21.5	17.9
75	15.2	13.3	150	22.3	18.5
80	15.7	13.7	160		19.0
85	16.3	14.1	170		19.5
90	16.9	14.5	180		20.0
95	17.4	14.9	190		20.4
100	17.9	15.3	200		20.9

Theoretical adiabatic horsepower (based on $n = 1.3947$)

Single-stage

$$\text{Hp} = 0.01512VP_1[(P_2/P_1)^{0.283} - 1]$$

Two-stage:

$$\text{Hp} = 0.03084VP_1[(P_2/P_1)^{0.1415} - 1]$$

where V = actual air delivery, cfm, in terms of free air (air at pressure and temperature conditions existing at compressor intake, *i.e.*, at P_1)

P_1 = intake pressure, psia

P_2 = discharge pressure, psia

NOTE 1 Absolute pressure equals gauge pressure plus atmospheric pressure.

NOTE 2 n is ratio of specific heats at constant pressure and at constant volume. It enters into all thermodynamic computations. For air containing 0.57 per cent moisture by weight, the value of $n = 1.3947$, an average for a temperate climate.

Theoretical isothermal horsepower

Single- or multistage

$$\text{Hp} = 0.00436VP_1 \log_e \frac{P_2}{P_1}$$

Air receivers and piping should be heavy enough to withstand the pressure they are to handle. Air receivers should meet code requirements of the state or locality where they will be used (in most cases the ASME code for unfired pressure vessels).

All reciprocating compressors and other positive-displacement compressors will build up higher and higher pressures if air is not used and the compressor is allowed to continue to operate fully loaded. Obviously, under such conditions, if no relief is provided, something must sooner or later give way, and air, because it expands on release, acts with almost explosive force. All compressor auxiliaries such as intercoolers, aftercoolers, and air receivers are equipped with safety valves. These must be kept in service and should be tested at regular intervals. Also, and this is important, a safety valve *must* be placed in the compressor discharge line between the compressor and any stop valve that is placed in this line ahead of the air receiver.

Oil is required to lubricate compressor cylinders. A certain amount of this oil is carried along in the air stream and is condensed out along with moisture in the inter-

cooler, compressor clearance pockets, aftercooler, air receiver, etc. Since oil is inflammable, it is highly important that it be removed. Furthermore, the air receiver, aftercooler, etc., cease to function in the manner for which they were designed if they become filled with water and oil. Drains are provided on all such units. They should be opened at regular intervals or, in the case of automatic drains, should be regularly inspected.

Table 8-50. Approximate Brake Horsepower to Compress 100 Cfm of Air

Altitude, ft	One-stage			Two-stage			
	Discharge pressure, psig			Discharge pressure, psig

3,000	15.7	18.6	20.9	14.0	16.1	18.0	20.0
5,000	15.2	17.9	20.3	13.5	15.5	17.3	19.2
10,000	14.1	16.5	18.6	12.3	14.1	15.6	17.2
14,000	13.1	15.2	17.2	11.3	12.9	14.3	15.7

Note: Actual brake horsepower will vary considerably with size and type of compressor.

Air compressors normally operate at moderate temperatures (Table 8-51), but occasionally failure of some part or of cooling-water supplies will allow temperature to rise high enough to ignite oil or carbon deposits.

Excess oil should be eliminated by draining as mentioned in the preceding paragraph. Carbon deposits on valves should not be allowed to accumulate. Excessive lubrication of the air cylinder should be avoided. Valves or other parts should never be cleaned with gasoline or other highly volatile and inflammable liquids.

Fig. 8-152. Typical arrangement of equipment in a reciprocating compressor installation.

Indications of high temperature should be investigated immediately. Unusually hot valve covers are one indication. These point to broken or leaky valves. An abnormal intercooler pressure is another indication. A high intercooler pressure shows trouble in the high-pressure cylinder, and a low intercooler pressure indicates trouble in the low-pressure cylinder. On 100-lb two-stage sea-level compressors, the correct intercooler pressure is usually 27 to 29 lb gauge

On water-cooled compressors an ample supply of cooling water should be circulated at all times. Open funnels are usually provided in cooling-water discharge lines both to prevent siphoning and to permit visual inspection of the water flow.

If conditions warrant, automatic alarm systems or automatic shutdown devices can be installed to operate when the cooling-water supply fails and when temperature in the air discharge line becomes excessive.

A typical arrangement of equipment in a reciprocating-compressor installation to meet safety and convenience requirements is shown by Fig. 8-152.

Table 8-51. Theoretical Adiabatic Discharge Temperature

[Based on 60°F intake temperature, sea-level intake (14.7 psia), $n = 1.3947$, and intercooling to intake temperature on two-stage machines]

Single-stage

$$T = T_1(P/P_1)^{0.283}$$

Two-stage

$$T = T_1\sqrt{(P/P_1)^{0.283}}$$

where P and P_1 = same as in Table 8-49

T = absolute discharge temperature

T_1 = absolute intake temperature

NOTE. Absolute temperature = deg F plus 460°

Table 8-52. Compressor Efficiencies

$$\text{Volumetric efficiency} = \frac{\text{actual air delivery}}{\text{theoretical air delivery or piston displacement}}$$

$$\text{Compression efficiency, isothermal*} = \frac{\text{theoretical isothermal horsepower}}{\text{indicated horsepower}}$$

$$\text{Compression efficiency, adiabatic*} = \frac{\text{theoretical adiabatic horsepower}}{\text{indicated horsepower}}$$

$$\text{Mechanical efficiency} = \frac{\text{indicated horsepower}}{\text{actual horsepower input (brake horsepower)}}$$

$$\text{Over-all efficiency*} \begin{cases} = \text{compression efficiency} \times \text{mechanical efficiency} \\ = \dfrac{\text{theoretical horsepower}}{\text{actual horsepower input (brake horsepower)}} \end{cases}$$

* When using the terms "compression efficiency" and "over-all efficiency," it is necessary to specify whether the calculation is based on the adiabatic or the isothermal horsepower.

Turboblowers and Compressors

Turboblowers or centrifugal compressors are widely used to handle air or gas at pressures from $\frac{1}{2}$ up to 40 psi. Machines are available for higher pressures up to about 100 psi, but these find their main application in sizes above 15,000 cfm. For pressures below $\frac{1}{2}$ psi, one of the several types of fans is ordinarily selected.

Turboblowers are used for a wide variety of services including cooling; drying; supplying combustion air to furnaces and ovens; for blowing blast furnaces, cupolas, and converters; for transporting solid materials; for flotation processes, for agitation and aeration, for ventilation; as exhausters; etc.

The principle of a turboblower is the same as that of a centrifugal pump, the main difference being that the air or gas handled in a blower is highly compressible, while the liquids handled in a pump are practically incompressible.

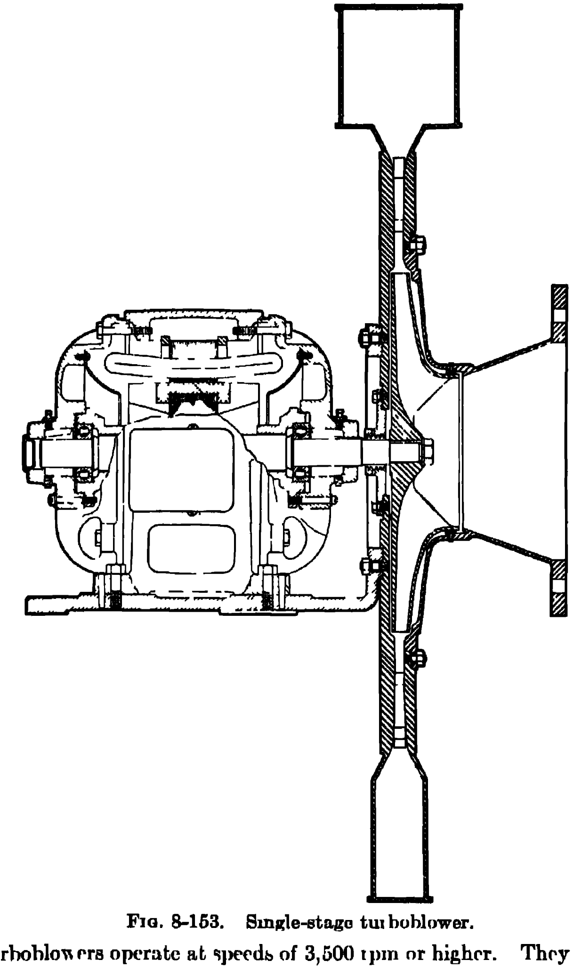

FIG. 8-153. Single-stage turboblower.

Most turboblowers operate at speeds of 3,500 rpm or higher. They are, therefore, almost exclusively driven by electric motors or steam turbines. Single-stage blowers are available to produce a pressure rise of up to 5 or 6 psi (see Fig. 8-153). From two- to seven-stage units produce pressures from 3 to 40 psi (see Fig. 8-154). For higher pressures, even more stages are required.

A turboblower is essentially a constant-pressure machine, and power consumption is almost directly proportional to the volume delivered. Blowers can also be built with impellers designed to produce decreased pressure as the volume increases.

Turboblowers can be equipped with controls to deliver gas at constant-discharge pressure, constant-suction pressure, or constant volume or constant weight

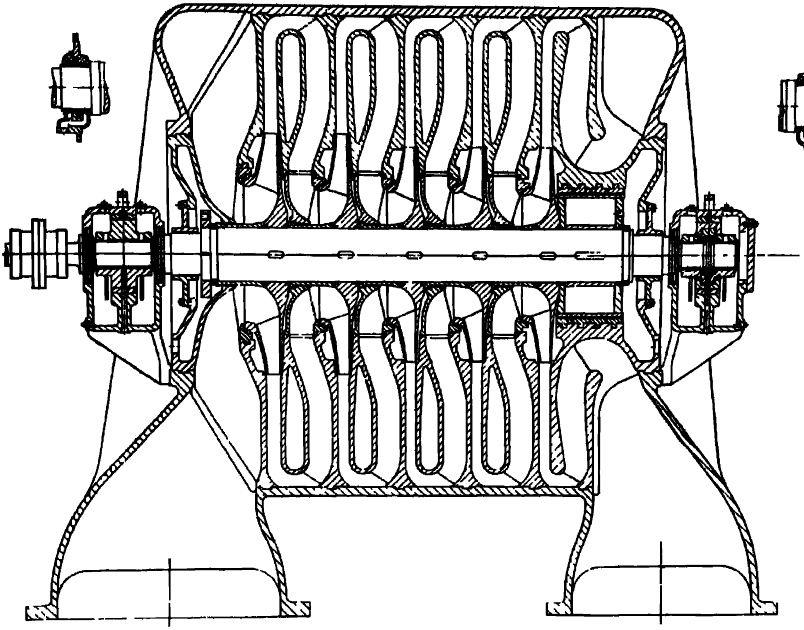

Fig 8-154. A five-stage turboblower.

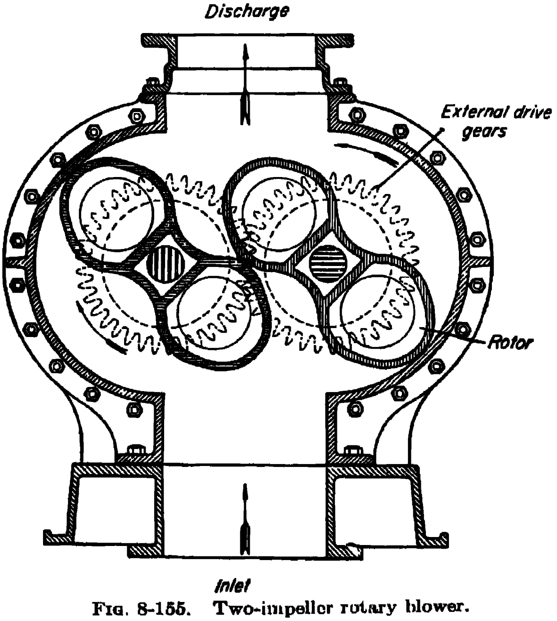

Fig. 8-155. Two-impeller rotary blower.

The usual practice on small- and moderate-capacity units is to insert a blast gate in the inlet or discharge line. This can be set manually to control the volume or pressure.

Where required, the blast gates can be automatically controlled through suitable pressure- or volume-measuring devices. The constant-weight control is an automatic control for the blast gate which controls the volume by correcting for both temperature and pressure changes in the gas handled.

On large turbine-driven units, control is usually effected by varying the speed. On large constant-speed units, control is often effected by the use of inlet guide vanes which can be set at various angles. These vanes on single-stage units show a considerable power saving over the use of blast gate to effect control. On multistage units, additional power savings can be effected by the use of a "power wheel" with the adjustable guide vanes. The power wheel is a reaction-type radial-turbine impeller which converts some of the velocity energy of gas passing at high velocity through the guide vanes into power that assists in driving the blower.

Turboblowers at about one-third to one-half of their rated capacity become unstable in their operation. This point, known as the "pumping or surge point," is accompanied by fluctuations of the inlet and discharge pressures and a whining noise. No damage is done when this point is reached. However, blowers should be selected to operate above the pumping point. Blowers are seldom required to operate at volumes below the pumping point. Where this is necessary, measures should be taken to prevent pumping. The inlet guide vanes previously described make the pumping point come at a lower volume. On small units or on machines where guide vanes will not lower the pumping point sufficiently, it is necessary to have a waste valve in the discharge line.

Rotary Blowers and Compressors

Rotary compressors, blowers, and vacuum pumps are machines of the positive-displacement type Such units are essentially constant-volume machines with variable discharge pressure. Volume can be varied only by changing the speed or by by-passing or wasting some of the capacity of the machine. The discharge pressure will vary with the resistance on the discharge side of the system.

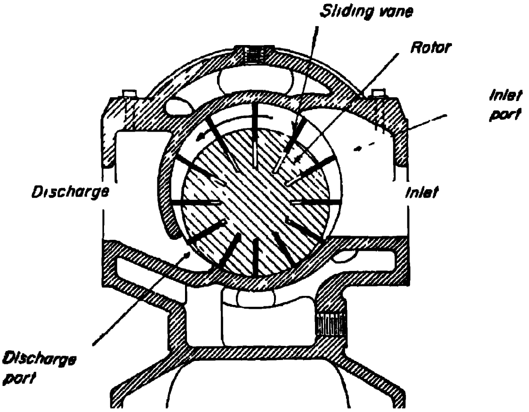

FIG. 8-156. Sliding-vane-type rotary blower.

Rotary compressors are generally classified as two-impeller, sliding-vane, and rotary-piston type

The two-impeller type is illustrated in Fig. 8-155. Such units are available for pressures up to about 15 psi and capacities up to 50,000 cfm. Sometimes multiple units are operated in series to produce higher pressures.

The sliding-vane type is illustrated in Fig. 8-156. These units are offered for pressures up to 125 psi and capacities up to 2,000 cfm. Generally, machines for pressures above 50 psi are built as two-stage units.

The liquid-piston type is illustrated in Fig. 8-157. They are offered as single-stage units for pressures up to about 75 psi and capacities up to about 4,000 cfm. Two-stage units are available for higher pressures. These units have found wide application as vacuum pumps on wet-vacuum service.

The two-impeller and sliding-vane compressors are not satisfactory for handling gas containing dust or other abrasive material. Many such materials also tend to be retained by the liquid in the liquid-piston type. The liquid in the latter type of pump can be selected to prevent contamination of the gas being handled.

Installation and Operation of Compressors

The construction details of various types and makes of compressors differ so widely that only general suggestions can be given here.

The instructions furnished by the compressor manufacturer should be followed. If you do not have these, the manufacturer will furnish them. When requesting such information, the type, size, rating, and serial number of the machine should be obtained from the name plate affixed to it.

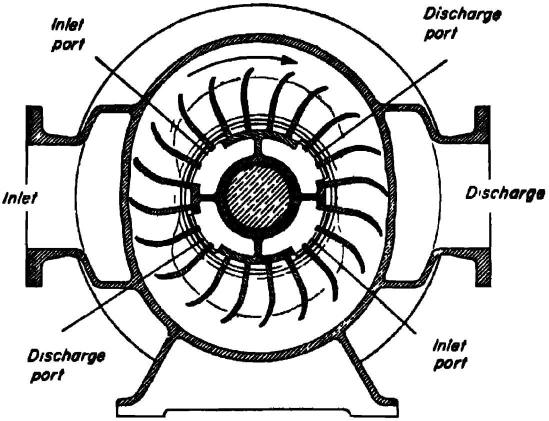

Fig. 8-157 Liquid-piston-type rotary blower.

Machines that are shipped completely assembled can usually be installed by competent mechanics or erectors from your own plant or by experienced local engineers or machinery distributors. It is usually wise on large machines to employ the services of the manufacturer's erector.

The compressor should be located in a clean, light room with ample space around it for cleaning, inspection, etc. On large units, room must be allowed for removing pistons, intercooler tube nests, piston rods, etc.

Some small machines do not require a foundation—just a good solid floor on which they can be set or to which they can be bolted. Most machines, however, will require a concrete foundation.

Compressor intakes should be equipped with intake filters. The compressor-intake piping should be as short and direct as possible. The intake itself should be located away from steam and other exhaust pipes well above the ground and in as cool a place as is available. The intake pipe should be at least as large as the intake opening on the compressor and larger if long. A good rule of thumb is to increase its diameter 2 in. for each 15 ft of length.

Safety valves should be installed on the intercooler, aftercooler, and receiver, and definitely on the discharge line between the compressor and any shutoff valve in the line.

The compressor should be lubricated in accordance with the manufacturer's directions. Small, single-acting machines may use only one type of oil—that placed in the crankcase. Larger machines usually have separate lubrication systems for the cylinders and for the bearings, etc. Air cylinders should not be overlubricated. A good check on oil quantity is to remove a valve and examine it and the cylinder. Parts should have a slight film of oil, but no excess oil should collect in the cylinder or on valve parts.

Valves should be kept clean and free from carbon. Gasoline should never be used in cleaning.

Bearings, crossheads, valves, and other working parts should be regularly checked for wear. When wear becomes excessive, parts should be adjusted or renewed.

The manufacturer's instructions should be carefully studied. His recommendations are based on experience with hundreds or thousands of machines.

PUMPS

Necessity for the movement of liquids by pumping occurs often throughout a manufacturing plant. Raw materials may be delivered to the plant as liquids. Many materials are liquids during all or part of the manufacturing processes. Water and sanitary services may require pumps as does steam-generating equipment, cooling and washing equipment, etc.

Centrifugal Pumps

The centrifugal pump is the type most widely used for transferring liquids of all types—raw materials, materials in manufacture, and finished products; as well as for general services of water supply, boiler feed, condenser circulation, condensate return, etc. They are available through a vast range of sizes; in capacities from 2 or 3 gpm up to 100,000 gpm; and for discharge heads (pressures) from a few feet up to 3,000 psi. The size and type best suited to a particular application can be determined only by an engineering study of the problem.

The principal advantages of a centrifugal pump are simplicity, low first cost, uniform (nonpulsating) flow, small floor space, low maintenance expense, quiet operation, and adaptability to motor or turbine drive.

A centrifugal pump, in its simplest form, consists of an impeller rotating within a casing. The impeller consists of a number of blades, either open or shrouded, mounted on a shaft which projects outside the casing. Impellers may have their axis of rotation either horizontal or vertical to suit the work to be done. Closed-type or shrouded impellers are used for most types of work as they are generally most efficient. Open or semiopen impellers are used for viscous liquids or liquids containing solid materials and on many small pumps for general service. Impellers may be of the single-suction type or double-suction type: single, if the liquid enters from one side; double, if it enters from both sides.

Casings are of three general types but in any case consist of a chamber in which the impeller rotates, provided with inlet and exit for the liquid being pumped. The simplest form of casing is the circular casing, consisting of an annular chamber around the impeller, no attempt being made to overcome the losses that will arise from eddies and shock when the liquid leaving the impeller at relatively high velocities enters this chamber. Such casings are seldom used. Volute casings take the form of a volute, increasing in cross-sectional area as the outlet is approached. The volute converts the velocity energy imparted to the liquid by the impeller into pressure energy, with comparatively low losses.

A third type of casing is used in diffusor-type or turbine pumps. In this type guide vanes or diffusors are interposed between the impeller and the casing chamber. Losses are kept to a minimum in a well-designed pump of this type. This construction is often used in multistage high-head pumps.

Centrifugal-pump Characteristics. Figure 8-108 shows a typical characteristic curve of a centrifugal pump. It is important to note that pump will operate along this curve and at no other points. For instance, on the curve shown, at 200 gpm the pump will generate 87-ft head. If the head is increased to 100 ft, 120 gpm will

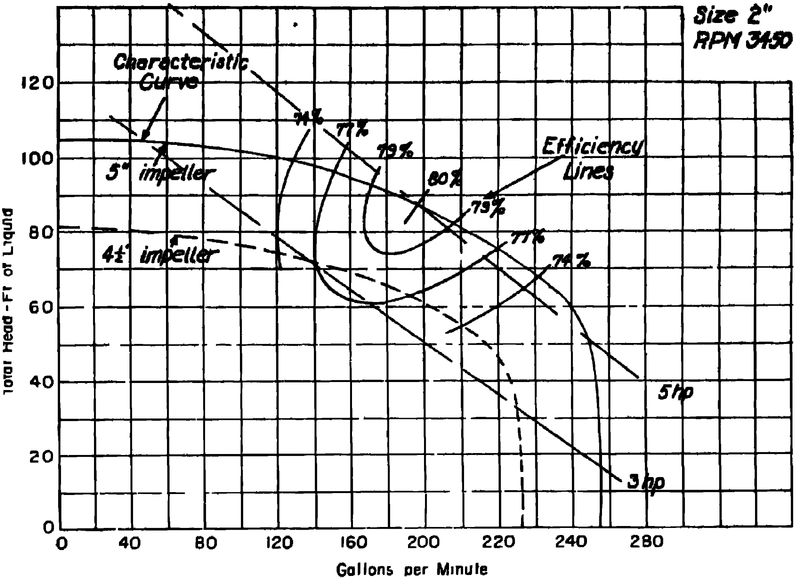

Fig. 8-158 Centrifugal-pump characteristic curve for different impeller sizes

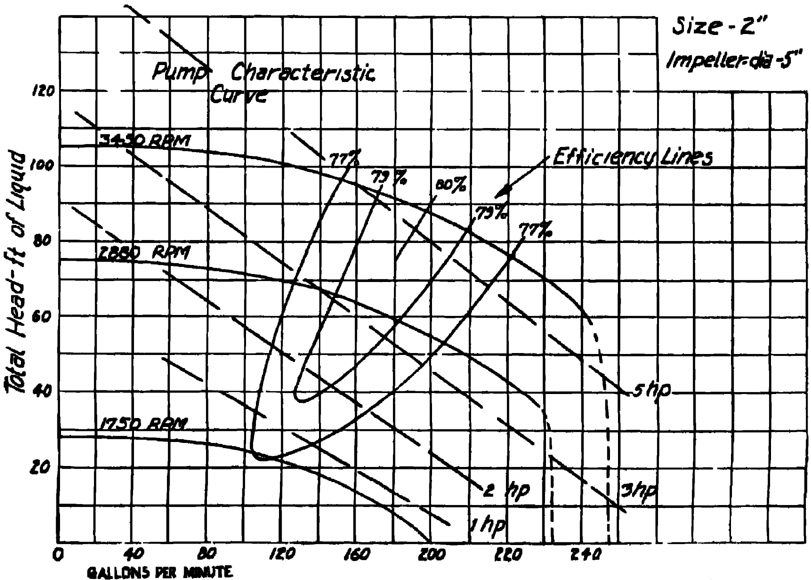

Fig. 8-159. Centrifugal-pump characteristic curve for different speeds.

be delivered. It is not possible to reduce the capacity to 120 gpm at 83-ft head unless the discharge is throttled so that 100-ft head is actually generated within the pump. On pumps with variable-speed drivers such as steam turbines, it is possible to change the characteristic curve as shown by Fig. 8-159.

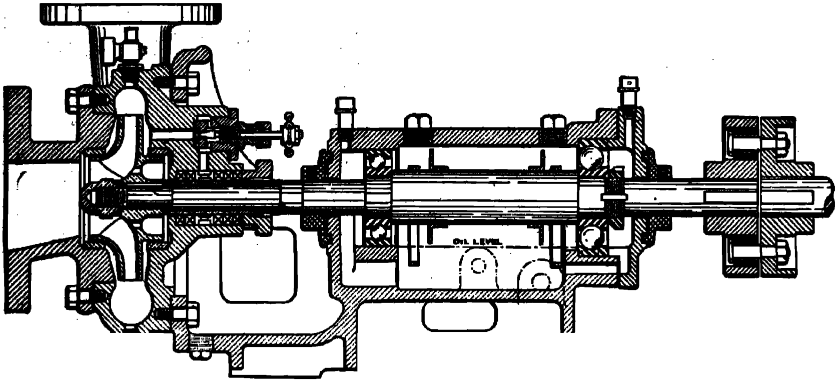

Fig. 8-160. Typical cradle-mounted pump.

Single-stage Centrifugal Pumps. Single-stage centrifugal pumps are available in capacities up to and over 50,000 gpm for heads (pressures) up to 200 ft or sometimes as high as 350 ft. They are available in a variety of designs for particular services.

Cradle-mounted Pumps. Cradle-mounted pump is a term usually applied to single-stage units of simple design with impeller mounted on an overhung shaft for capacities up to about 3,000 gpm and heads up to about 200 ft (see Fig. 8-160). Such units are designed for ease in dismantling and accessibility. They practically always have single-suction impellers.

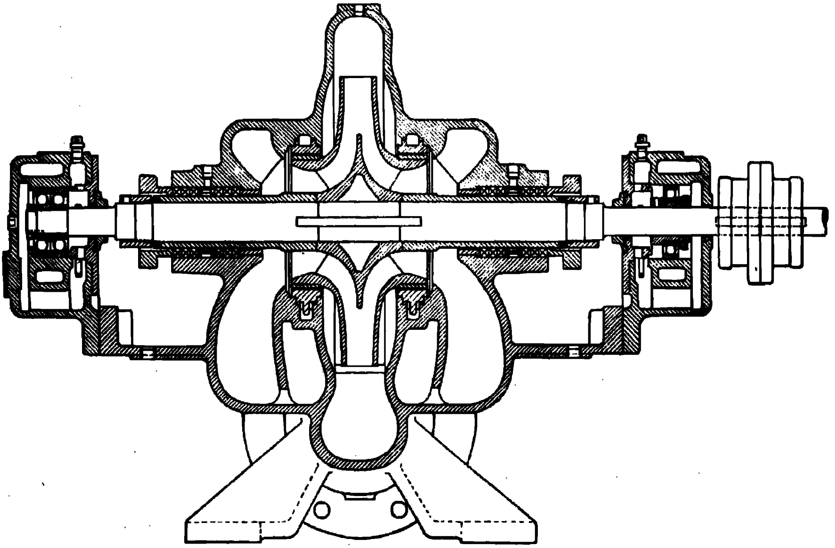

Fig. 8-161. Single-stage double-suction pump.

Double-suction Single-stage Pumps. Double-suction single-stage pumps (see Fig. 8-161) are used for general water-supply and circulating service and for many transfer services. They are available for capacities from about 25 gpm up to and over 50,000 gpm and heads up to 200 ft or so. Such units are available in iron or bronze or iron with bronze fittings. Other materials increase the cost, and where such materials are required, a standard-type chemical pump or other special service pump is usually more economical.

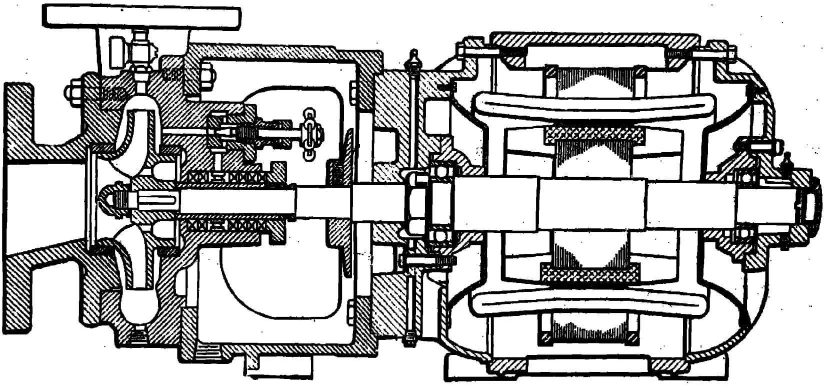

FIG. 8-162. A typical close-coupled pump with built-in motor driver.

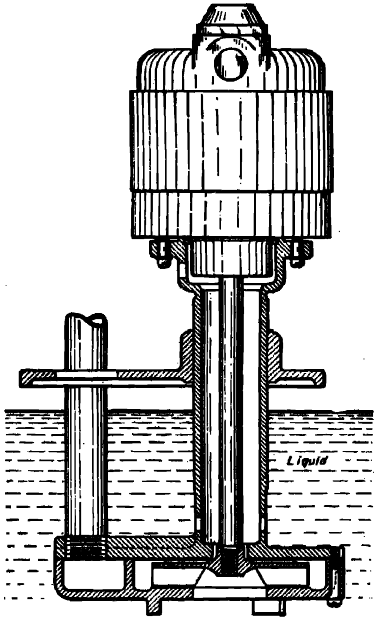

FIG. 8-163. Immersion-type coolant pump.

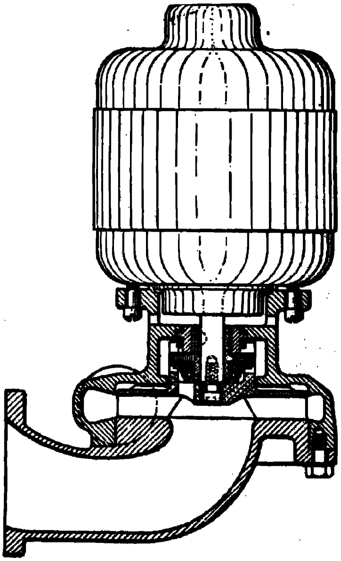

FIG. 8-164. Side-wall-type coolant and circulating pump.

Close-coupled Pumps (see Fig. 8-162). Pumps with built-in electric motor or sometimes steam-turbine driver (*i.e.*, with pump impeller and driver on the same shaft) are known as close-coupled pumps. Such units are extremely compact and are suitable for a variety of services where standard iron and bronze materials are satisfactory. They are available in capacities up to about 2,000 gpm for heads up to about 240 ft. Two-stage units in the smaller sizes are available for heads to around 500 ft, and some manufacturers furnish such pumps with a considerable number of stages.

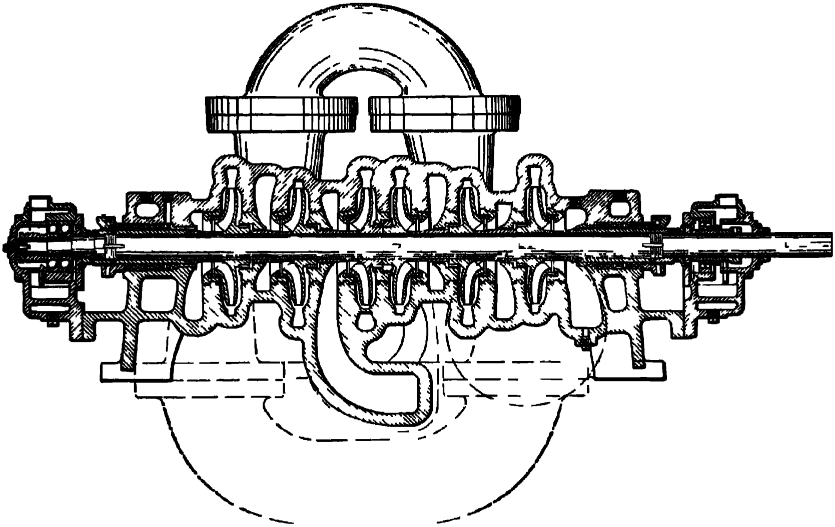

FIG 8-165. Six-stage volute-type pump.

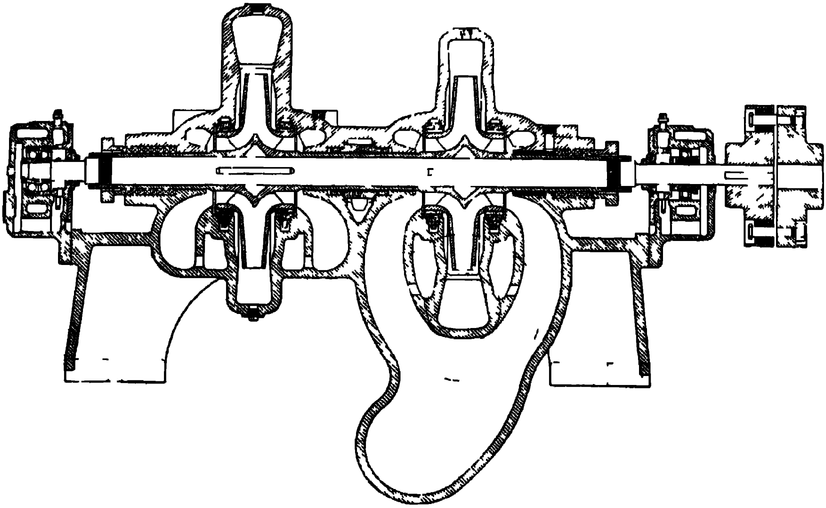

FIG 8-166. Two-stage pump with double-suction impellers.

Special-application Pumps A number of pump designs are available for special applications such as handling chemicals, paper stock, hot liquids, volatile hydrocarbons, etc. Such pumps are basically of the types described but with features designed to meet special needs of the service for which they are to be used. Pump manufac-

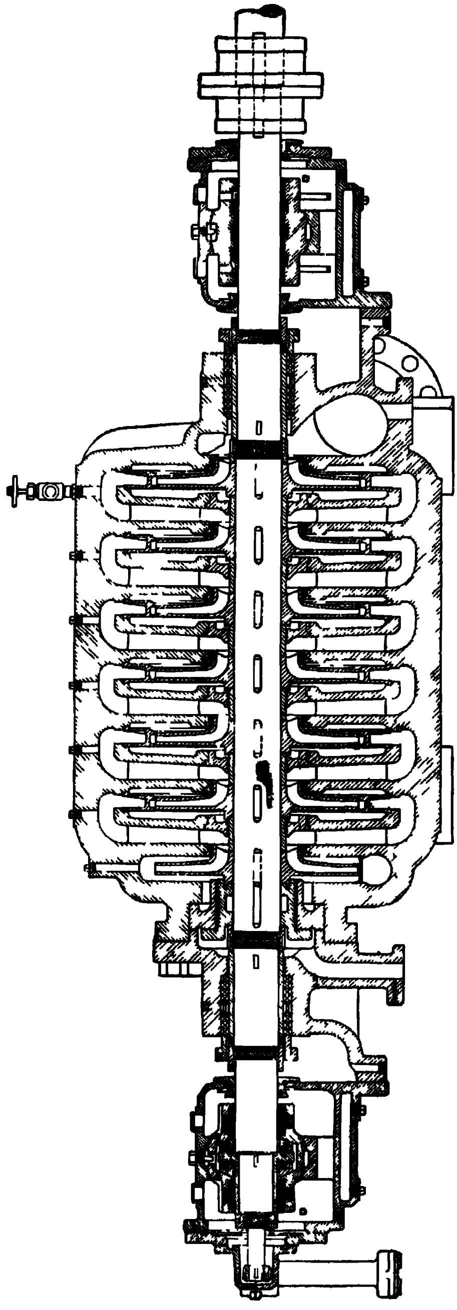

FIG 8-167 Seven-stage diffuser-type pump

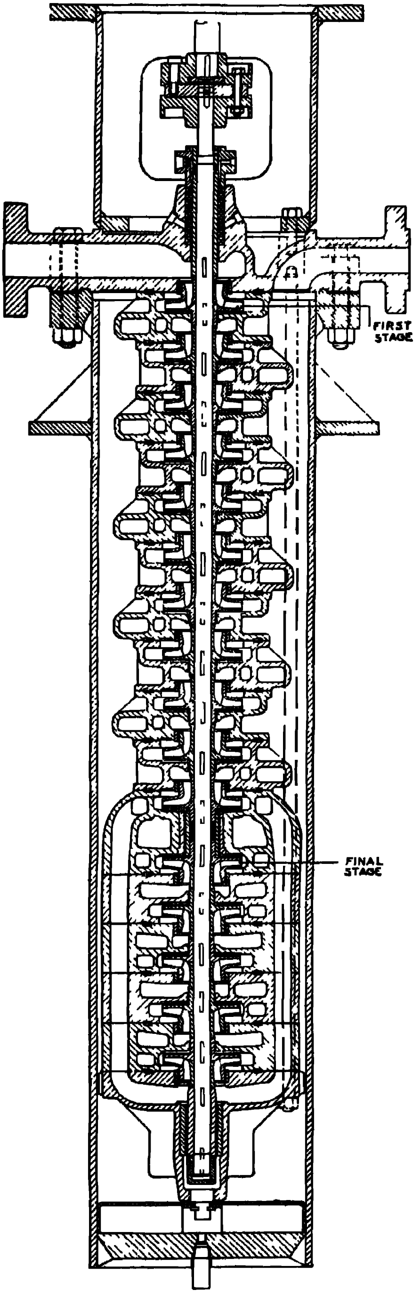

FIG. 8-168 A 16-stage vertical pump

turers can furnish complete information on units for such applications.

Sump Pumps. Sump pumps are small single-stage pumps used to drain shallow pits or sumps. They usually have single-suction open-type impellers. The pump itself is immersed in the liquid and driven by a shaft from a motor or belt pulley above the pit. A tube or column encases the shaft and forms a connecting support between the pump and the driver and for whatever shaft bearings may be required

Coolant Pumps. Coolant pumps are used for circulating coolant on machine tools. These are often of the immersion type in which the pump is immersed in the liquid (see Fig. 8-163) Others of the side-wall type (see Fig 8-164) are mounted on the side of a tank

Multistage Centrifugal Pumps. Multistage pumps are, in general, used for services requiring higher heads (pressures) than can be generated by single-stage pumps. Such services include h-p water-supply pumps, fire pumps, boiler-feed pumps, charge pumps for refinery processes, etc. Such pumps are available for pressures as high as 3,000 psi at capacities up to 3,000 gpm and above

Multistage pumps may be of the volute type or of the diffusor type Volute-type pumps (see Fig 8-165 usually have single-suction impellers arranged with half the impeller inlets facing one direction and half in the opposite direction to balance thrust Some two-stage (see Fig. 8-166) units have double-suction impellers, but this construction, except for special-purpose units, makes the casings of impractical size for more stages.

Diffusor-type pumps (see Fig 8-167) usually have single-suction impellers arranged with all impeller inlets facing in the same direction and impeller thrust neutralized by a differential pressure device known as a "balancing drum"

Pumps for very high pressures often have an inner volute-type casing or assembly of diffusor units placed within a forged-steel shell or barrel.

Multistage pumps for small or moderate capacity are available in a vertical design which for many services simplifies the piping and installation (see Fig. 8-168).

Propeller Pumps

The term "propeller pump" is applied to units with axial-flow or mixed-flow (*i e*, part axial and part centrifugal) impellers Such units are available in capacities from 100 gpm upward for heads up to about 100 ft per stage. Propeller pumps are usually vertical, although some single-stage horizontal units are built.

A common form of propeller pump has the pump element mounted at the bottom of a column which serves as the discharge pipe (see Fig 8-169) Such units are immersed in the liquid to be pumped and are commonly used for large-volume drainage and large-volume circulating service such as surface condensers, etc.

Another form of the pump has a shell surrounding the pumping element which is connected to the intake pipe (see Fig 8-170) In this form the pump is used on condensate service in power plants and for process work such as encountered in oil refineries

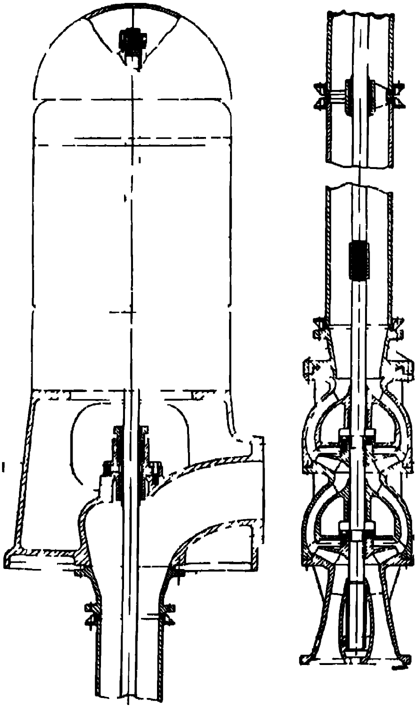

Fig 8-169 A propeller or mixed-flow pump

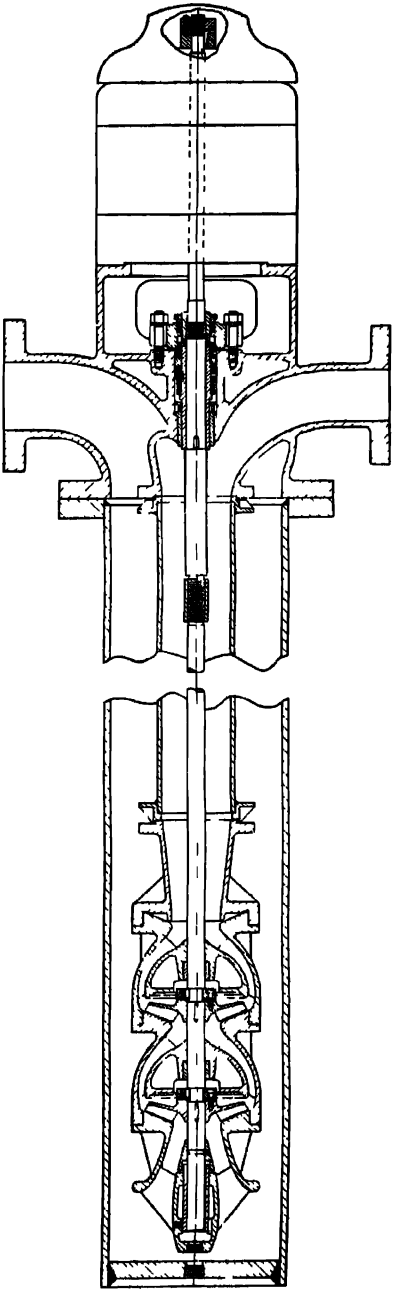

Fig 8-170 A two-stage mixed-flow pump with suction shell

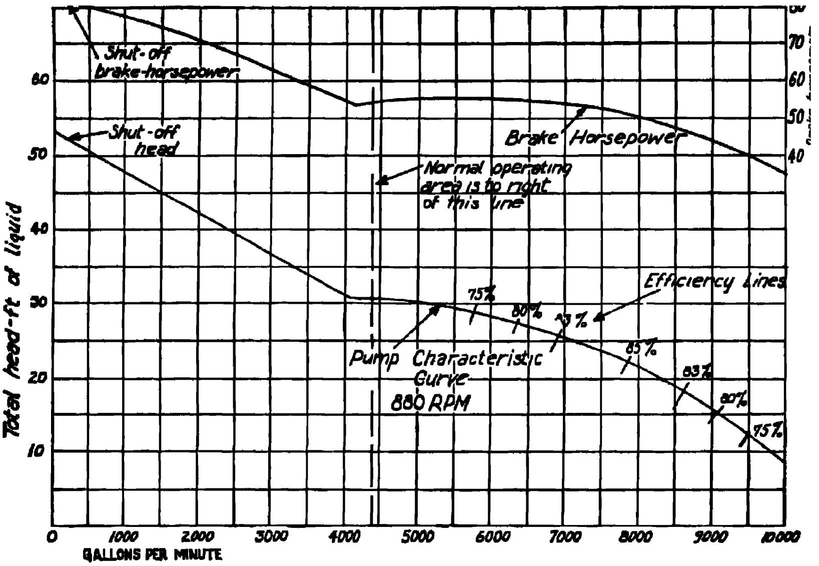

Fig. 8-171. Propeller-pump characteristic curve.

A characteristic curve of a typical axial-flow pump is given in Fig. 8-171. Pumps with mixed-flow impellers have a lower shutoff (i.e., closed discharge) head and lower horsepower at this point, but not so low as for a centrifugal pump.

Selecting a Pump

In selecting a pump, it is necessary to know the liquid to be handled, the total discharge head, the capacity, the suction lift or head, and in most cases, the temperature, viscosity, and vapor pressure of the liquid to be handled.

To illustrate these points, a typical example is given: An industrial plant wishes to install a pump to lift 200 gpm of water at 72°F from a sump to a tank on the roof. The water is to be delivered into the tank at 10 lb pressure. The tank is 58 ft above the sump, and the pump is 4 ft above the water level in the sump. The discharge pipe from the pump to the tank is 400 ft long and contains four standard elbows, one check valve, and one gate valve. A $2\frac{1}{2}$-in. discharge line is already installed which the plant superintendent would like to use if possible. The suction pipe is 4 in. in diameter, 25 ft long, and contains two elbows and a foot valve. For comparison, two solutions are given in Table 8-53: Solution A, using the available $2\frac{1}{2}$-in. discharge pipe, and Solution B, using 4-in. discharge pipe. Friction losses in this problem are based on using old, rough pipe. Solution A shows 295 ft total head which will require a pump driven by a 25-hp motor. Solution B shows 108 ft total head which will require a pump driven by a $7\frac{1}{2}$-hp motor. These two problems forcibly point out the savings that a discharge pipe of proper size makes possible.

Reciprocating Pumps

There are two general classes of piston or reciprocating pumps: steam pumps and power pumps. In general, the action of the liquid-transferring parts of these pumps is the same, a cylindrical piston, plunger, or bucket being caused to pass back and forth in a cylinder. The device is equipped with valves for inlet and discharge of the liquid being pumped, and the operation of these valves is related in a definite manner to the motions of the piston.

Reciprocating pumps are usually provided with an air chamber, as shown in Fig. 8-172. This serves to smooth out irregularities in the discharge of the pump and

Table 8-53

	Solution A 2½-in discharge pipe, 4-in suction pipe			Solution B 4-in discharge pipe, 4-in suction pipe

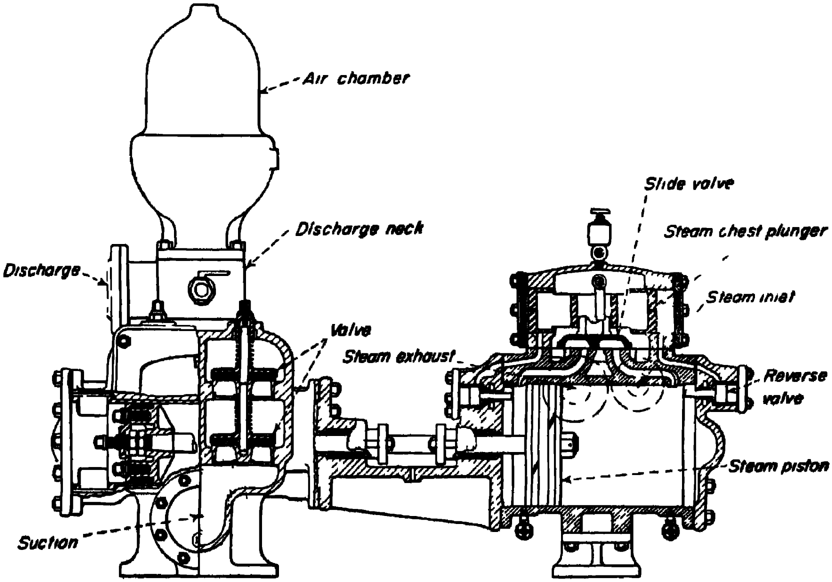

Fig. 8-172. Simplex direct-acting steam pump.

gives a uniform flow It is always used with single steam pumps and power pumps With low-pressure, direct-acting, duplex steam pumps, it is not needed With duplex pumps its volume should be four times the displacement of one piston per stroke, with all other types, eight times

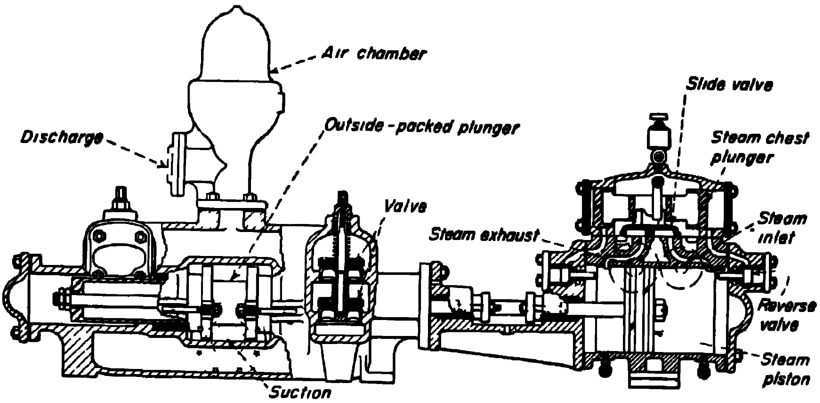

Fig 8 173 A simplex outside packed plunger pump

Types of Reciprocating Pumps The ordinary types of reciprocating pumps are the four pumps described below

1 *Simplex Double Acting* These may be direct-acting (*i e*, direct-connected to a steam cylinder) or power driven (through crank and flywheel from the crosshead of a steam engine) Figure 8-172 is a pump of this type designed for use at heads up to 200 ft

A simplex, outside-packed plunger pump of the type used with hydraulic presses and for similar service is shown in Fig 8-173

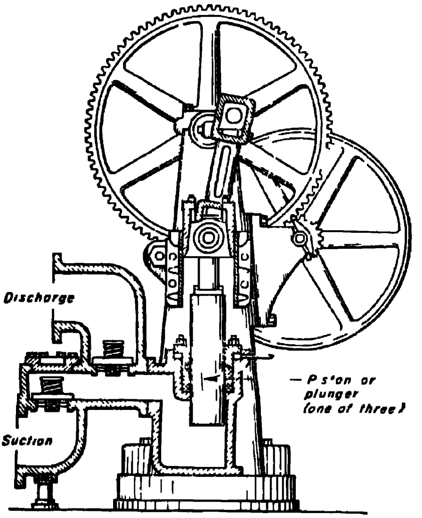

Fig 8-174 Triplex single acting reciprocating pump

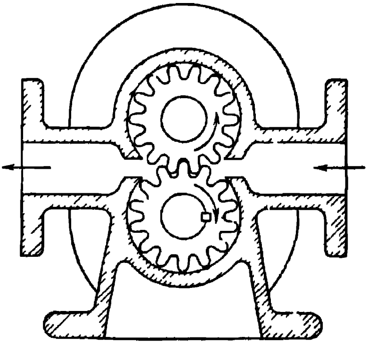

Fig 8-175 Gear-type rotary pump

2 *Duplex, Double Acting* These pumps differ primarily from those of the simplex type in having two water cylinders whose operation is coordinated These pumps may be either direct-acting, steam-driven, or power-driven with crank and flywheel

3. *Triplex, Single Acting.* These pumps have three single-acting plungers and cylinders and are used to give a uniform flow. They are usually of vertical design. The drive may be from a motor, belt, or steam cylinder and is through gears or crank and flywheel. This is the common type of power pump, an example of which, arranged for belt drive, is shown in Fig. 8-174, from which the action is readily traced.

4. *Triplex, Double Acting.* This is a double-acting arrangement of the pump discussed under 3. The design is generally used for horizontal triplex pumps. Other features are similar to 3.

Choice of a Reciprocating Pump. The advantages of a direct-driven pump lie in good efficiency over a wide range of operating conditions and flexibility of capacity, head, and speed. The disadvantages are usually high first cost, large floor space required, noisy operation, and more attention required.

The advantages given for a direct-driven steam pump do not apply to power-driven pumps. A triplex single- or double-acting pump does not have flexibility as to speed or capacity. It does have uniform delivery. Its use is indicated in pumping wells, in handling steady flow of liquids, and in serving machines operated by hydraulic pressure.

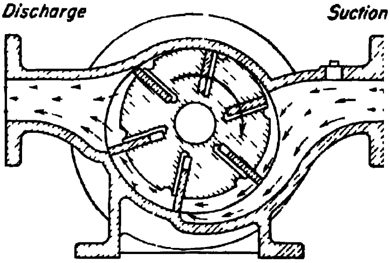

FIG. 8-176. Vane-type rotary pump.

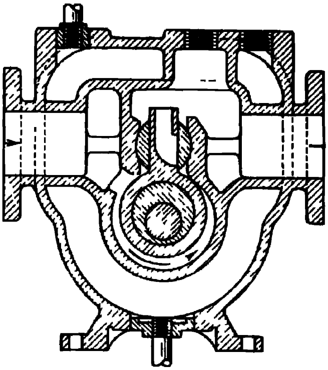

FIG. 8-177. Cam-and-piston-type rotary pump. This unit shown with jackets for heating of viscous liquids.

Simplex double-acting pumps are most suitable for water service and boiler feed.

Duplex double-acting pumps are universally adaptable. When made of the proper materials, particularly as to cylinder linings and valve material, and when of correct design, these pumps are frequently used for tars, oils, and other viscous liquids.

Triplex single-acting pumps are suitable for producing uniform flow when conditions are constant. Triplex double-acting pumps are used under the same conditions as triplex single-acting pumps but are generally of horizontal design.

Reciprocating pumps, particularly of the direct-acting, steam-driven design, are available in a great variety of designs and sizes to fill every need for which such a pump is suitable.

Another form of reciprocating pump is known as the "diaphragm pump." In these units a flexible diaphragm separates the suction chamber from the discharge chamber. The diaphragm moves up and down through the action of a yoke or rod, and a discharge valve forces the liquid from the suction chamber into the discharge pipe. Diaphragm pumps are used for emptying tanks and sumps and for dewatering excavations, etc

Rotary Pumps

Rotary pumps differ from centrifugal and reciprocating pumps in that they will deliver a positive quantity of liquid under conditions of varying head or pressure. These pumps will handle any liquid that contains no grit or abrasive material.

This type of pump consists of a stationary casing in which are located one or more rotating members. When one rotating member is used, it is mounted eccentrically on the shaft. The impeller in this type of pump is usually circular in section and is provided with a reciprocating blade or blades or a horizontal abutment. Figures 8-175, 8-176, 8-177, and 8-177*A*, show several types of rotary pumps.

Rotary pumps are available in two general classes: interior bearing and external bearing. The interior-bearing type is used for handling liquids of a lubricating nature, while the exterior-bearing type is used with nonlubricating liquids. The interior-bearing pump is lubricated by a part of the liquid being pumped, while the exterior-bearing type is oil-lubricated by an attendant.

Among the liquids handled by rotary pumps are water, mineral oils, vegetable oils, animal oils, greases, glucose, molasses, paints, varnish, shellac, lacquers, alcohols, catsup, brine, mayonnaise, sizing, soap, tanning liquors, vinegar, and ink. It should be kept in mind that most rotary pumps are not suitable for handling liquids carrying grit or abrasive material.

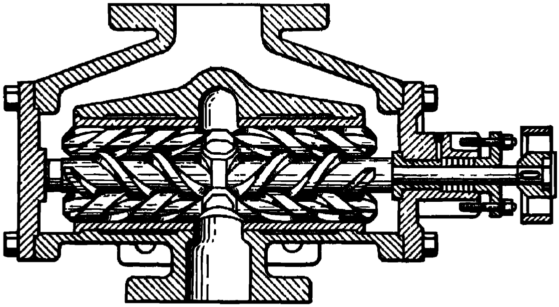

FIG. 8-177A. Screw-type rotary pump.

Air-pressure Pumps

Handling Liquids with Fluid Pressure. In addition to the liquid-handling devices, such as pumps, that depend on the mechanical action of pistons, plungers, or impellers to move the material, there is another group of devices for this purpose that employs gas or air pressure to move the liquid. This group includes air lifts, acid eggs, jet pumps, and pulsometers, among others.

Air Lift. The air lift is a device for raising liquid by means of compressed air. In the past it was widely used for pumping wells but has been less widely used since the development of efficient centrifugal pumps. It operates by introducing compressed air into the liquid near the bottom of the well. The air and liquid mixture, being lighter than liquid alone, rises in the well casing. The advantage of this system of pumping lies in the fact that there are no moving parts in the well. The pumping equipment is an air compressor which can be located on the surface.

Displacement Pumps. Displacement pumps operate by forcing the liquid that is to be moved from one point to another by means of air or gas pressure on the surface of the liquid. The acid egg is a device of this type frequently encountered by chemical engineers. It consists of an egg-shaped container which can be filled with a charge of the liquid that is to be pumped. This container is fitted with an inlet and outlet pipe for the liquid and a pipe for the admission of compressed air or gas. Pressure of air or gas on the surface of the liquid forces it out the discharge pipe. Such pumps can be manually operated or can be arranged for semiautomatic or automatic operation.

Jet Pumps. Jet pumps constitute another class of liquid-handling devices that makes use of fluid pressure as an operating medium. Ejectors and injectors are the two types of most common interest. The ejector, also called siphon, exhauster, or eductor, is designed for use in operations where the head pumped against is low and is less than the head of the fluid used for pumping. The injector is a special type of jet pump used for boiler feed and similar services.

The efficiency of an ejector or jet pump is low, around 1 or 2 per cent. The head developed by the ejector is also low, except in special types. The device has the disadvantage of diluting the fluid pumped by mixing it with the pumping fluid. In steam injectors for boiler feed and similar services, where the heat of the steam is recovered, the efficiency is close to 100 per cent.

The simple ejector or siphon is used, in spite of its low efficiency, for transferring liquids from one tank to another, for lifting chemicals, or solid-containing liquids of an abrasive nature, for priming other types of pumps, etc.

Packing and Shaft Seals

Proper packing and shaft seals are items of major importance, particularly for centrifugal pumps handling chemicals or high-temperature liquids. The success of the pumping installation often depends upon the proper selection of packing. Many types and designs are available, some of which are described below.

Stuffing-box arrangements vary with the liquid, the temperature, and the pressure. They can generally be classified as being packed solid or having a sealing cage located approximately in the middle of the box. In the latter case the sealing liquid may come directly from the pump, in which case it is said to be internally sealed; or if from an outside source, the box is said to have an external seal. The following arrangements will cover most pumping conditions:

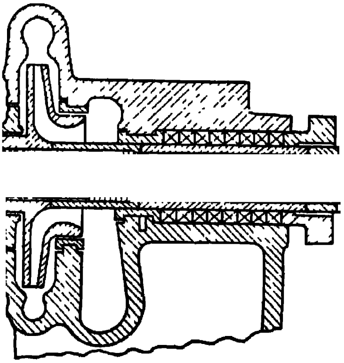

Fig. 8-178. Stuffing box packed solid without seal ring

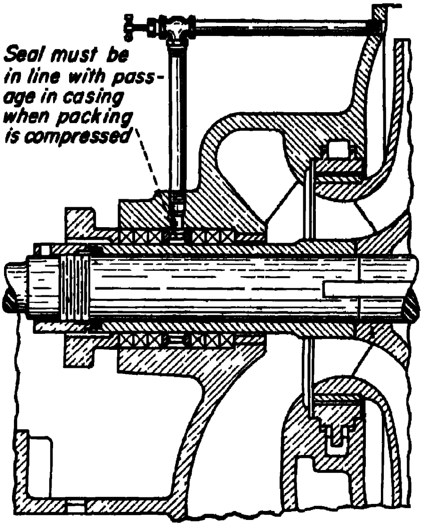


Seal must be in line with passage in casing when packing is compressed

Fig. 8-179. Stuffing box with internal seal.

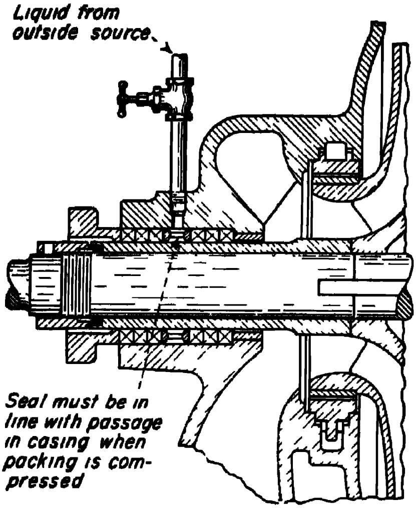
1. **Positive Pressure on the Suction.** When there is a positive pressure on the suction, the seal cage may be omitted, and the stuffing boxes can be packed solid and adjusted so that a slight leakage cools and lubricates the packing (see Fig. 8-178)

2. **Suction Lift.** When a unit is working under a suction lift, it is important to prevent air from leaking into the pump through the stuffing box, for this will cause a reduction in capacity or loss of prime. To prevent air leakage and to lubricate the packing, sealing liquid is injected at a seal cage usually located at approximately the center of the box. When the sealing medium is the liquid pumped, the arrangement is known as an "internal seal" (see Fig. 8-179). When the sealing medium comes from an outside source, it is known as "external sealing" (see Fig 8-180).

3. **Flooded Suction.** An external or internal seal should be provided in order to cool and lubricate the packing (see Figs. 8-179 and 8-180).

4. **Gritty or Corrosive Liquids.** When the liquid handled is gritty or corrosive, the stuffing boxes should be externally sealed with a cool, clean liquid at approximately 10 psi above the suction pressure. The sealing liquid should be supplied at

constant pressure to prevent flexing action in the packing (see Fig 8-180) When gasoline, kerosene, gas, oil, or similar hydrocarbons are being handled with nominal suction pressure, a stick grease-type lubricator can be used to inject grease into the seal cage, instead of using globe valve shown in Fig 8-180



Liquid from outside source
Seal must be in line with passage in casing when packing is compressed

FIG 8-180 Stuffing box with external-seal system

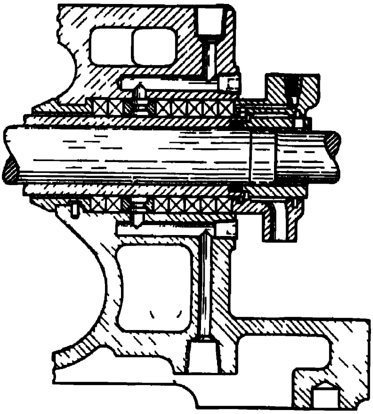


FIG 8-181 Circulating-type stuffing box

5. High Temperature and High Pressure. *(a) Circulating Box* When the temperature of the liquid to be handled is high enough to warrant internal cooling of the packing and the pressure falls within the limits for safe packing, a stuffing-box arrangement as shown in Fig 8-181 can be used in order to provide cooling of the packing Cool, clean liquid enters the sealing cage at one connection, circulates through the seal cage, and leaves at another connection

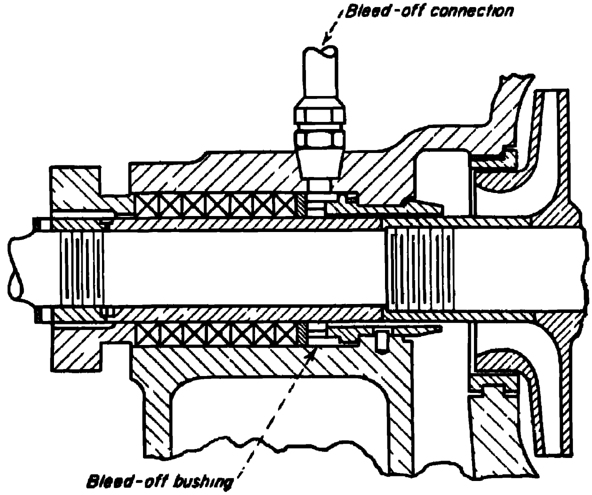

FIG 8-182 Stuffing box with bleed-off bushing

(*b*) *Bleed-off Box.* It sometimes happens that the suction pressure must be reduced to an amount that can be safely packed in order to ensure satisfactory operation of the stuffing box. This can be accomplished by locating a bleed-off bushing in the bottom of the stuffing box as shown in Fig 8-182. The bleed-off bushing can usually be used in conjunction with any of the stuffing-box arrangements previously described. The tapped bleed-off connection must be piped to a low-pressure point in the system. The pressure should never be reduced to such an extent that it will be below the vapor pressure of the liquid at the pumping temperature.

Smothering Glands. When handling liquids where the lubricating leakage through the packing might result in inflammable gas, noxious fumes, or steam, a smothering-type packing gland may be furnished (see Fig. 8-183). The water used for smothering may be taken from a cooling-water line through a flexible hose or dead soft copper tube.

Mechanical Seals. In order to overcome packing difficulties, several types of mechanical sealing devices have been designed and have proved very satisfactory under severe operating conditions (see Fig. 8-184).

Mechanical seals consist of a rotating and a stationary element having sealing faces that are brought into sliding contact under a pressure sufficient to prevent escape of the fluid being pumped.

Mechanical seals are generally used where the fluid handled has at least slight lubricating qualities and is free from abrasive and other foreign material that would tend to destroy the sealing faces.

Satisfactory operation of a mechanical seal depends on maintaining perfect contact of the sealing faces at all times.

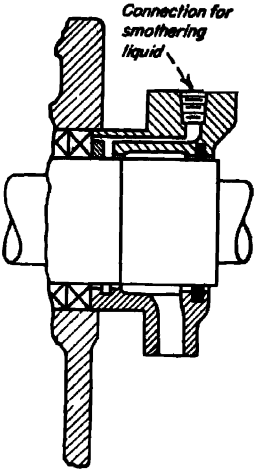

FIG. 8-183. Smothering-type stuffing-box gland

Double Mechanical Seals. There are a few conditions of service where it is desirable to provide a double seal to prevent the liquid being handled by the pump from coming in contact with the sealing parts.

Pumps handling corrosive and high-temperature liquids may require a double seal. In such cases, noncorrosive or low-temperature liquids are injected between the two seals at a pressure slightly higher than that obtained in the pump chamber next to the inner seal.

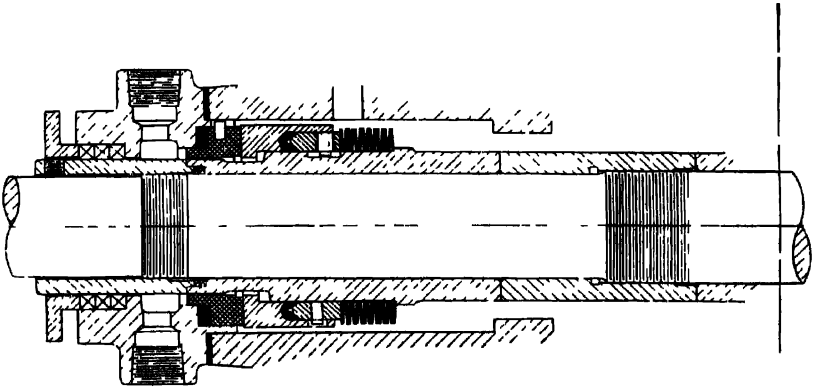

FIG. 8-184. Ingersoll-Rand shaft seal for Cameron pumps.

For double seals, it is necessary to have additional equipment such as sealing-liquid pump, tank, pressure regulator, and piping to the stuffing boxes.

Terms Used in Pumping

Liquids are said to be practically incompressible. This is near enough to the truth at low pressures, but at high pressures there is a slight change in density, which in some cases it is necessary to consider.

The pressure existing at any point in a liquid at rest is caused by the pressure exerted on its surface plus the weight of liquid above the point in question. If the liquid is in an open vessel, the pressure on the surface is atmospheric pressure. Pressure thus exerted on a liquid is equal in all directions and acts perpendicularly to any surfaces in contact with the liquid. All liquid pressures can be thought of as equivalent to a column of liquid of a height sufficient by its weight to produce the pressure in question. In pumping practice, pressures or heads are thus often expressed in feet of liquid.

Capacity. Capacity is the volume of liquid handled by a pump. It is usually expressed as volume per unit of time as gallons per minute (gpm) or barrels per hour (bph).

Velocity. Since a liquid is practically incompressible, there is a definite relation between the quantity flowing past a given point in a given time and the velocity of flow. This relation is expressed thus:

$$Q = Av$$
$$v \text{ (for circular conduits)} = 0.4085 \text{ gpm}/d^2 = 0.2859 \text{ bph}/d^2$$

Viscosity. In flowing liquids the existence of internal friction or the internal resistance to relative motion of the fluid particles must be considered. This resistance is called "viscosity." It varies greatly from one liquid to another and decreases with rising temperature. Viscous liquids tend to increase the horsepower required by a pump, to reduce the pump efficiency, head, and capacity, and to increase the friction in pipe lines.

Friction Head. Friction head (h_f) is the pressure (in terms of feet of liquid) required to overcome the resistance to flow in pipe and fittings.

Velocity Head. Velocity head (h_v) is the vertical distance a body would have to fall to acquire the velocity v. It corresponds to the static or pressure head which would cause that velocity.

$$h_v = v^2/2g = 0.0155v^2 \text{ (approx.)}$$
$$h_v \text{ (for circular conduits)} = 0.00259 \text{ gpm}^2/d^4 = 0.00127 \text{ bph}^2/d^4$$

Velocity head may be converted to equivalent pressure head by suitable means such as a Venturi tube. In any flowing liquid the sum of pressure head and velocity head remains constant.

Total Static Head. Total static head (h_{ts}) on a pump is the vertical distance (in feet) between the free level of the source of supply and the point of free discharge or the level (or equivalent level) of the free surface of the discharge liquid.

Total Suction Lift. Total suction lift (l_s) is the reading of a mercury column at the suction flange of a pump (corrected to the pump center line† and converted to feet of liquid) minus the velocity head (in feet) at the point of column attachment.*

$$l_s = l_{ss} + h_f \text{ suct}$$

Total Suction Head. Total suction head (h_s) is the reading of a gauge at the suction flange of a pump (corrected to the pump center line† and converted to feet of liquid) plus the velocity head (in feet) at the point of gauge attachment.*

$$h_s = h_{ss} - h_f \text{ suct}$$

Total Discharge Head. Total discharge head (h_d) is the reading of a pressure gauge at the discharge flange of a pump (corrected to the pump center line† and converted to feet of liquid) plus the velocity head (in feet) at the point of gauge attachment.*

---

* The text version of these formulas applies to an existing pump installation. The symbol version, following the text version may be used when estimating before a pump is installed.

† On vertical pumps the correction should be made to the eye of the suction impeller.

$$h_d = h_{sd} + h_f \text{ discharge} + \text{velocity} = \text{head loss at discharge of system}$$

Total Head. Total head (H) on a pump is the total discharge head minus the total suction head or plus the total suction lift.*

$$H = h_d - h_s \qquad \text{or} \qquad H = h_d + l_s$$

Net Positive Suction Head (NPSH). Net positive suction head is the head available at the entrance or eye of a pump impeller to move and accelerate the water entering the eye. It is the gauge pressure at the suction flange of the pump (corrected to the pump center line† and converted to feet of liquid) minus the gauge vapor pressure in feet of liquid corresponding to the temperature at the point of measurement plus the velocity head (in feet at the point of measurement).*

$$\text{NPSH} = \text{Atm} + h_s - \text{vp} = \text{Atm} + h_{ss} - h_f \text{ suct} - \text{vp} \qquad \text{or} \qquad \text{NPSH} = \text{Atm} - l_s - \text{vp} = \text{Atm} - l_{ss} - h_f \text{ suct} - \text{vp}$$

When the NPSH required by a pump is known and it is desired to find the static suction lift which the pump will handle, the following form of the formula is convenient:

$$\text{Max static suct lift} = \text{Atm} - \text{NPSH} - h_f \text{ suct} - \text{vp}$$

Suction Limitations on a Pump

The maximum theoretical suction lift would be a distance equivalent in feet of liquid to the atmospheric pressure less the head equivalent to the vapor pressure of the liquid, less the head equivalent to the pressure of any gas in solution, less the friction head, and less the head equivalent to the entrance loss. Practically, however, the suction lift that can be handled without cavitation and vibration in the pump is somewhat less than the theoretical. The actual suction lift obtainable depends not only on the above factors but also on the characteristics of the liquid, the total head, and the pump speed, capacity, and impeller design. Abnormally high suction lifts usually cause serious reductions in the capacity and efficiency of the pump and often lead to serious troubles from vibration and cavitation. Every pump manufacturer knows the suction limitations of each of his pumps. Therefore, when requesting quotations on a pump for a particular job, the suction conditions should be given so that the manufacturer can recommend a proper pump for those conditions.

Work Performed in Pumping

To move a liquid against gravity with a pump, work must be expended. A pump may actually raise the liquid, force it into a pressure vessel, or merely give it enough head to overcome pipe friction. No matter what the service required of a pump, all forms of energy imparted to the liquid in performing this service must be accounted for in establishing the work performed. In order that all these forms of energy may be algebraically added, it is customary to express them all in terms of head expressed in feet of liquid.

In order to determine the work required of a pump, it is necessary to know the total dynamic head and the weight of liquid to be pumped in a given time. Usually weight is not given but rather volume in gallons per minute or barrels per hour, along with the density or specific gravity. The weight can be calculated from this information, but this is not necessary since the horsepower formulas are usually given in terms of gallons per minute or brake horsepower. Theoretical horsepower of a pump is usually called the hydraulic horsepower.

$$\text{Hyd hp} = \frac{\text{gpm}(\text{H})(\text{s})8.33}{33{,}000} = \frac{\text{gpm}(\text{H})(\text{s})}{3{,}960} = \frac{\text{bph}(\text{H})(\text{s})}{5{,}660}$$

---

* The text version of these formulas applies to an existing pump installation. The symbol version, following the text version, may be used when estimating before a pump is installed.

† On vertical pumps the correction should be made to the eye of the suction impeller.

$$\text{Hyd hp} = \frac{(\text{gpm})(H_p)}{1{,}714} = \frac{(\text{bph})(H_p)}{2{,}450}$$

$$\text{Brake hp} = \frac{\text{gpm}(H)(s)}{(3{,}960)(\text{pump eff})}$$

The actual or brake horsepower of a pump is greater than the theoretical or hydraulic horsepower by the amount of the losses incurred in the pump through friction leakage etc. The efficiency of a pump is, therefore, measured as

$$\text{Pump eff} = \text{hydraulic hp/brake hp}$$

Other useful formulas are

For motor-driven pumps:

$$\text{Kw per 1,000 gal per hr of liquid} = \frac{0.00315(s)(H)}{(\text{pump eff})(\text{motor eff})}$$

For direct-acting steam pumps:

$$\text{Duty in terms of ft-lb per 1,000 lb steam} = \frac{\text{theor hp}(1{,}980)1{,}000{,}000}{\text{total steam per hr, lb}}$$

Sometimes theoretical horsepower for figuring duty is calculated using static head instead of total dynamic head. In this case duty is in terms of foot-pounds of useful work done per 1,000 lb steam. As given above the formula is in terms of foot-pounds of actual work done per 1,000 lb of steam.

Symbols Used in This Subsection

A = flow area of conduit, sq ft
Atm = atmospheric pressure, ft of liquid absolute
bph = flow in barrels (42 gal) per hr
d = inside diameter of circular conduit, in.
g = acceleration due to gravity, ft/sec^2 at sea level and 45° latitude; this is 32.174 fps, and this value has been used in conversions
gpm = flow, gpm
H = total head, ft of liquid
H_p = total head, psi
h_d = discharge head, ft of liquid
h_f = friction head, ft of liquid
h_s = suction head, ft of liquid
h_{sd} = static discharge head, ft
h_{ss} = static suction head, ft
h_{ts} = total static head, ft
h_v = velocity head, ft
l_s = suction lift, ft of liquid
l_{ss} = static suction lift, ft
Q = quantity of flow, cfs
s = specific gravity (water at 60°F = 1)
v = velocity of flow, fps
vp = vapor pressure of liquid, ft of liquid absolute

WATER-HAMMER PROTECTION FOR PUMP DISCHARGE LINES

BY JOSEPH SEGEL

Mechanical Engineer (Retired)

DEFINITIONS AND ELEMENTARY THEORY

Water hammer is the rise in pressure that occurs when the water flow in a pipe line or closed conduit is reduced or stopped, regardless of how this flow is checked. Hammer can occur in any line carrying liquids. Usually, the problem is important only in water lines.

The classical water-hammer problem is that of protecting penstocks that supply water to water turbines. If the flow in the penstock is suddenly reduced by action of the gates controlling the water flow to the turbines, the penstock pressure at the gate immediately rises, then drops below the initial pressure, and continues to surge in regular periods until friction damps the surges out.

Pump-discharge-line pressures will surge in the same way if all the operating pumps are stopped at once, except that the initial surge which occurs at the pumping end of the line is downward. The rise in pressure following the downward surge may be sufficient to rupture the pipe or pull the line apart unless protection is provided.

FORMULAS

The formulas most useful in water-hammer problems are (ASME, ASCE symbols)

$$a = 4{,}720/\sqrt{1 + (Kd/Ee)}$$
$$h_{\max} = aV_0/g$$

Period of pipe line = $2L/a$ = one interval, seconds

where a = the velocity of the pressure wave in the pipe line, fps. (This is the velocity of sound in the water of the pipe line.)

K = the bulk modulus of the liquid in the pipe line, psi (approx. 300,000 for water)

E = Young's modulus for the pipe-line material psi (30 million for steel)

d = the diameter of the pipe

e = the wall thickness of the pipe; d and e are always in the same units, *i.e.*, both feet or both inches.

$h_{\max}$ = the maximum pressure rise (or drop) that can occur if the water flow is stopped instantly and there are no complicating features such as nonuniform pipe, branch lines, etc. The unit of $h_{\max}$ of the formula is in feet of the liquid flowing.

V_0 = the velocity in the pipe line just previous to the disturbance causing water hammer, fps

g = gravity, ft/sec²

L = the length of the pipe line, ft

Other terms used in the argument are

h = the hammer pressure actually developed, ft

H_0 = the operating or steady-state pressure in the pipe line just previous to the disturbance causing water hammer, ft

T = the actual time in which the flow is stopped, sec

The value of a normally is somewhere between 3,000 and 3,500 fps. An accurate value usually is not needed for estimating surges in pump discharge lines.

The maximum water-hammer pressure which can occur in a simple pipe system is h_{max}, but this is not the maximum pressure in the pipe line because h_{max} adds to H_0 the existing pressure in the line just previous to the disturbance. The maximum pressure existing is, then, h_{max} plus H_0, and if H_0 is near the design pressure, it may be noted that rupturing pressures may occur. The water-hammer pressure h_{max} is alternately both positive and negative. When negative, the minimal pressure is $H_0 - h_{max}$. Obviously, the pipe-line pressure cannot reduce below zero absolute. If the downward surge carries to zero, vacuum will form, and the collapse of this vacuum may cause a major water-hammer blow. It may be noted that h_{max} is independent of the length of the line and depends only on the water and the wave velocities. The value of h_{max} is usually between 40 and 45 psi per fps of water velocity destroyed.

The period of the pipe line $2L/a$ is, by inspection, merely twice the length of the line divided by the wave velocity. It is the time it takes the pressure wave front to travel from the point of origin to the end of the line or other reflection point back to the origin. The wave of rarefaction, or subnormal pressure wave, also takes $2L/a$ sec to make the round trip. The time by stop watch between two crests of the pressure wave is then $4L/a$ sec. The value of $2L/a$ is important because the actual hammer h is reduced below h_{max} if the time it takes the flow to stop is greater than $2L/a$. This is true because the subnormal phase of the wave reaches the point of origin before the pressure wave has ceased to build up and adds algebraically to the pressure wave. The value of h is for ordinary lines about equal to

$$h_{max}/T/2L/a = h_{max}2L/aT,$$

with the understanding that in this formula T cannot be less than $2L/a$. This formula holds reasonably well except for lines of high velocities and low pressures, in which cases h is much increased. In general, T should be five to ten times the value of $2L/a$ to eliminate destructive water hammer.

On power failure, the pressure drop at the pumps is never h_{max} except for very long lines of high H_0. Short lines, except those of high water velocities, have very little pressure drop since T is large compared to the $2L/a$. Such lines usually need no hammer protection. For intermediate lines the pressure drop on power failure is about one-half aV_0/g. The subsequent pressure rise may be slightly more than that unless a vacuum has formed, in which case nearly the full hammer develops.

PROTECTION AGAINST WATER HAMMER

If the water velocities are low, say, below 2 fps, and the lines are comparatively short (less than 1,500 ft), usually no protection is needed. Water-hammer pressures in other pump discharge lines following power failures can be kept within safe limits either by lengthening the flow-stopping time T to several intervals of $2L/a$ or by spilling water to relieve the pressure, or by both. The measures that may be taken to obtain these effects are listed below.

Stopping the flow in several pipe-line intervals:

Flywheels on pumps
Air chambers
Air aspiration
Air injection
Air valves (These also spill water)

Relieving the pressure by discharging water:

Slow-closing checks at the pumps
Relief valves, several types

There may be other systems of protection, or the line may be built strong enough to take the hammer without damage.

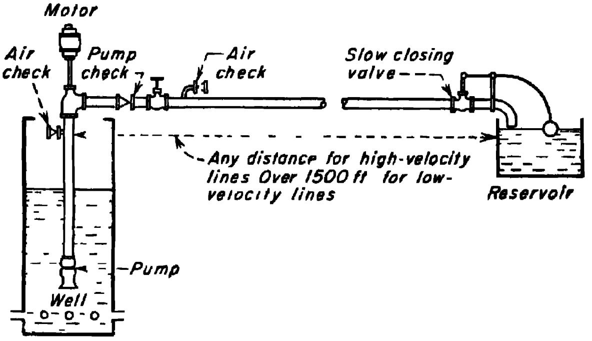
The protection equipment to be used depends mainly on the pressure at the pump end of the line H_0, the contour of the line, the terminal conditions, the maximum

water velocity, the length of the line, and the design pressure of the pipe as compared to the operating pressure.

It is perhaps obvious that, if there are adequate flywheels on the pumps, the discharge lines will not be subjected to appreciable water hammer, regardless of the factors mentioned above. Flywheels can be, but usually are not, used mainly because of costs and energy loss.

Properly proportioned and operated air chambers protect any line. They are, however, seldom used because of high costs and the difficulties of maintaining the air pressure in the chambers.

Air Aspiration. Air aspiration can be used on lines which are fairly level and which discharge into reservoirs having little elevation over the pump heads. A line of this type is illustrated in Fig. 8-185. When there is power failure and no protection, the pressure drops below atmosphere and may go to nearly absolute-zero pressure if the distance from the water level to the pump head exceeds the barometric height. Now, if ordinary brass or bronze check valves are installed in the pipe wall in such a way that air will be drawn into the pipe when the pressure drops below atmosphere, the forward motion of the water (on power failure) is then not retarded, and there will be several intervals before the flow stops. The return velocity—by pipe-line breathing, aided perhaps by the head from the reservoir or other elevation is now much reduced. This, coupled with the air cushion trapped in the pipe, prevents any destructive water hammer.



Motor
Air check
Pump check
Air check
Slow closing valve
Any distance for high-velocity lines Over 1500 ft for low-velocity lines
Reservoir
Pump
Well

Fig. 8-185. Aspirated-air protection. Air checks at pump house only.

This type of protection can be used on any system in which the elevation at the reservoir is not more than 40 ft above the pump head. At greater elevations—unless the water velocity is unduly high or the pipe is very long—the downsurge does not carry well below atmosphere, and protection is impaired. These checks should also be placed at other high points in the line or its connections where a vacuum might develop. If a portion of the line is above the hydraulic gradient (pipe-line pressure below atmosphere), the checks should, of course, be located at the points where the water pressure is normally positive.

The size of the air checks to be used is not critical. Ordinarily, the equivalent of a 2-in. check is sufficient for a 30-in. line. Excess check-valve capacity is no detriment. The checks should be installed in multiple since, if one fails to open, there will be at least partial protection. The check connections should be short to eliminate delay in air inflow upon power failure. It is necessary to protect the checks against frost in exposed locations.

Air-check protection is fully applicable to long flat lines. It is not so applicable to lines having a terminal rise unless the design pressure appreciably exceeds the operating pressure because the surges usually exceed the operating pressure.

The second air check shown in Fig. 8-185, although of some use in reducing hammer in the main line, is installed primarily to prevent destructive water hammer in the pump riser. If the riser exceeds the barometric height, a vacuum will form when the pump is shut down if there is no air inlet. If the pump is immediately started, there is nothing to retard the water flow until the check valve is reached, and a full water-hammer blow results. Air in the riser prevents this.

Air Injection. If the pump discharge lines are of medium length and one-half aV_0/g subtracted from H_0 is not well below atmosphere, they can be protected by the use of an air tank as shown in Fig. 8-186. The tank air pressure is maintained at 10 psi (approx.) below the pipe-line pressure by means of an air compressor controlled by a pressure switch. On power failure the pipe-line pressure drops, air enters, and the water continues flowing for a sufficient length of time to reduce the hammer surge.

The size of the air tank should be such that, on the downsurge following power failure, the air continues to displace water for a period of approximately three times $2L/a$ sec. The tank size needed then varies directly with the expected maximum flow (cfs) and the length of the line and, inversely, as the pressure. A line 3,000 ft long, flowing water at 30 cfs and at a pressure of 50 psig would be adequately protected by an air tank of 50-cu ft volume. The connection between the tank and the pipe line may be 2 in. diameter per 30 in. diameter of water pipe.

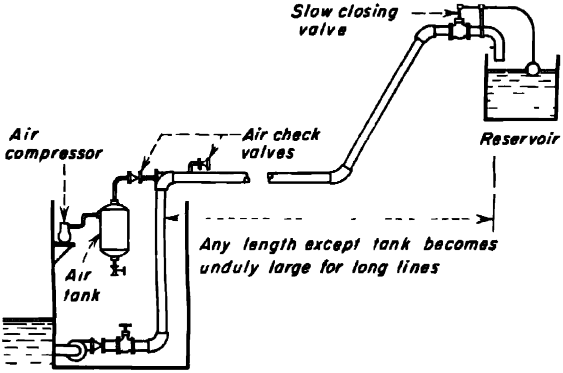


FIG. 8-186. Injection-air protection.

The installation needs operating attention only to service the compressors and its control and to drain leakage water from the tank.

Both this system and that using aspirated air are unsuitable if it is imperative to keep air out of the water line. Both systems are also unsuitable if the operating pressure is very little below the design pressure because some surges above operating pressure will occur in all lines except those which are flat.

Aspirated or injected air, if it can be tolerated, is also effective in reducing cavitation which is fundamentally repeated water hammer on a small scale.

Air Valves. If the line will aspirate air on power failure, and it is important to keep air out of the line and also to prevent any hammer pressure above the operating pressure, the air valve may be used. This valve opens on a drop in pressure below atmosphere but closes slowly under dashpot control when pressure returns. The valve, therefore, discharges air first and then water on the return surge, thereby reducing the surge pressure to safe limits. It is advisable to install an air check in parallel with the air valve as auxiliary protection should the air valve be inoperative because of freeze-up or for any other reason. The air valve should not be installed unless there is a substantial static pressure, say, 30 ft of water or more in the line, since otherwise the valve will not close automatically.

The location for the air valve is the same as that for air-check protection, *viz.*, the high spots in the line near the pump or pumps and elsewhere.

The size and number of air valves may be selected on the basis that one 6-in. valve at each high spot will protect a 30-in. water line.

Slow-closing Checks. If pump operating pressures, pipe-line elevations, water velocities, length of lines, and other conditions are such that air aspiration or injection is not suitable, some way of relieving the return water-hammer surge by spilling water becomes necessary. Slow-closing checks in the pump discharge lines may be used for the purpose. These checks are provided with controls to prevent the checks from closing immediately on a reversal of water flow. These valves are usually hydraulically operated, and the closing rate can be predetermined.

Slow-closing-check protection can be used on lines of the type shown by Fig. 8-187. Upon power failure, the line acts as two separate lines. The column of water separates at B, and the section A to B surges separately from that part of the line from B to C. The section A-B is protected by spilling water backwards through the checks and the pumps. For full protection, the closing time of the checks should be not less than five times the period ($2L/a$) of the pipe line A to B. This time is not excessive if the line A-B is short, say, from 1,500 to 3,000 ft. Shorter lines ordinarily need no protection. Longer lines require such slow closing that the backflow of water may damage the pumps.

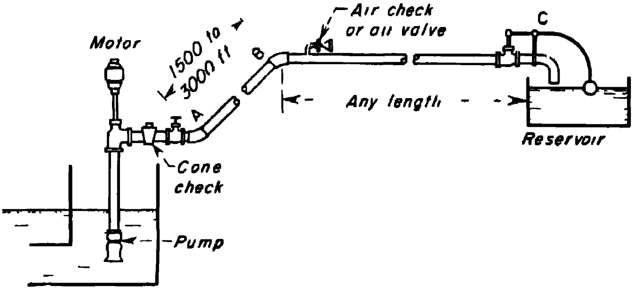

FIG. 8-187 Slow-closing pump-check and aspirated-air protection

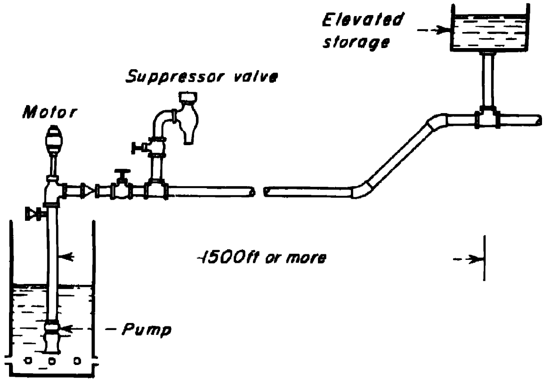

FIG. 8-188 Surge suppressors protect entire line

The lines like A-B of Fig. 8-187 and any other line in which the pressure does not drop below atmosphere on power failure can be protected by surge suppressors. These valves are installed on the pump discharge pipes and on the line side of the check valves. The suppressor valves open if all the pumps stop, and the water then discharges to waste. The effect of the valve action is the same as that of the slow-closing checks, but the pumps are now by-passed and, therefore, are not distressed. A typical installation is shown by Fig. 8-188. These valves open on interruption of electric current to solenoids. A pressure switch set to open the solenoid circuit when the water pressure drops is a usual auxiliary. Consequently, the valves open if the pumps stop for any reason. The opening and closing times of the valve are adjustable. The opening cycle of the valve may be set at 2 to 4 sec. The closing time should be at least five times the pipe-line period ($2L/a$) for ordinary short lines and ten times for long lines or short lines having high water velocities. The valve is hydraulically operated and closes automatically, regardless of the presence or absence of current in the solenoid circuit. Electricity supplies the trigger action only.

The water-discharge capacity of the valve or valves may be somewhat less than the maximum estimated flow in the line to be protected. It is advisable to install two or more valves rather than one large valve. If there is a change in size in the pumping main, such as usually exists in a well field, one suppressor should be installed at or near the point where the full-sized main begins.

These valves, if properly selected, installed, and operated, will prevent any pressure rise in excess of the design pressure.

Spring-loaded relief valves are not used for water-hammer protection. They open too late, and they may set up a cyclic disturbance exceeding even the original water-hammer surge.

Hydraulically operated relief valves without the solenoid feature are adapted to control surges that do not have steep wave fronts. These valves open on a pressure rise and close slowly when the pressure drops. They are mostly useful to protect lines having booster pumps where the accumulated shut-in pressure of the pumps in series exceeds the design pressure of the lines. These valves may be installed in out-of-the-way locations where some hammer protection is desirable, but electric current is not available.

INDUSTRIAL WATER-COOLING SYSTEMS*

BY L. T. MART

President, The Marley Company, Inc., Kansas City, Kansas

FUNCTION

In nearly all industrial processes large quantities of heat must be dissipated. This is most commonly accomplished by circulating water through heat exchangers. The water thus heated, if conserved and reused, must be cooled, and this is accomplished in the water-cooling system. In actual practice the cycle is continuous, and the heat added to the water in the heat exchangers equals the heat transferred from water to air in the water-cooling system. Cooling and reusing water is quite popular and offers many advantages over the use of water from wells, lakes, or streams.

TYPES OR CLASSES

There are many styles of water-cooling systems. One general classification is the spray-pond type, and another is the water-cooling tower. The latter can be classed as natural or mechanical draft, depending upon whether fans are or are not used for moving air through the structures. Atmospheric water-cooling towers fall in two general classes, *viz.*, the spray tower and the deck-type tower. Mechanical-draft towers may be classed as forced or induced draft, depending upon the location of the fans. Nearly all industrial towers are of wood construction, whereas those located in large cities and restricted fire zones must be noncombustible and therefore of steel or masonry.

THEORY OF PERFORMANCE

The generally accepted theory of the cooling of water assumes that heat is transferred from water to air both by convection (sensible heat) and evaporation (latent heat). The scientific explanation generally accepted was well offered by Walker, Lewis, and McAdams[1]

This theory was further developed by Merkel in 1925 and by many others since. The basic equation can best be expressed as follows:

$$L\,dT = Ka\,dV\,(h'' - h) \qquad \text{or} \qquad (KaV/L) = \int_{T_1}^{T_2} [dT/(h'' - h)]$$

where K = mass-transfer coefficient based on vapor-content potential
a = sq ft of exposed water surface per cu ft of tower
V = active tower volume, cu ft per sq ft
L = water rate, psf
T = water temperature
h'' = enthalpy of saturated air at water temperature
h = enthalpy of main air stream

This equation offers a basis for selecting the difference in enthalpies as the driving force to account for the transfer of both sensible and latent heat in cooling-tower performance and also shows why performance is determined by wet-bulb temperatures.

The left-hand side of the equation (KaV/L) represents the tower coefficient, while the mechanical or graphical integration of the right-hand side gives an evaluation of the performance conditions.

DESIGN AND APPLICATION ENGINEERING

Wet-bulb and Dry-bulb Temperature. The dry-bulb temperature is that temperature which is ordinarily read on any (dry) commercial thermometer. The wet-bulb temperature is that lower temperature to which air can be cooled when fully saturated with water vapor. The wet- and dry-bulb temperatures are equal when air is fully saturated. Relative humidity is a measure of the actual per cent of moisture in air by weight to the total amount possible. The relationship between wet bulb, dry bulb, and relative humidity is given in Table 8-54.

Table 8-54. Per Cent Relative Humidity (Barometric Pressure 29.92 in. Hg)

Total Heat of Air. At any given wet-bulb temperature the total heat of air remains constant regardless of humidity or dry bulb. With ingoing and outgoing wet-bulb temperature known, the total heat carried off by each pound of air can be calculated for any given heat load if ingoing and outgoing wet bulbs are known. The properties of air are shown in Table 8-55.

Design Wet Bulbs. Water can be cooled only to the wet-bulb temperature after which no heat transfer can take place. The commercial cooling system never cools to that theoretical limit but is designed to accomplish a portion thereof. Accurate information on weather and design wet bulb is necessary in connection with water-cooling problems. Suggested safe design wet bulbs are given in Table 8-56. Two

columns of wet-bulb figures are shown. The first is recommended for average year-round industrial use, and the second is for freon air conditioning which must produce maximum load during hottest weather. For steam-jet refrigeration even higher wet bulbs are recommended. Factors affecting actual wet-bulb choice are many, and they include (1) operating load factor, (2) total annual days of operation, (3) capital costs, (4) elevation above sea level, (5) overload protection, and added minor influences.

Pipe Sizes for Circulating Water. Two factors must be taken into consideration when determining the size pipe to use in distributing water. The larger the pipe, the more the initial expense and the less the friction loss.

If the distribution system is of considerable length and required to operate over long periods, larger pipe should be used as the pumping costs will thus be low. If the system piping is short and if the operating season is brief, then the smaller pipe sizes are recommended.

Some suggested pipe sizes and capacities are given in Table 8-57. Column A should be used for a continuous distribution system, Column B for an intermittent use, and Column C for a water-distribution system that only operates a small part of the time, *e.g.*, an air-conditioning layout.

Table 8-57. Pipe Sizes and Allowable Gpm—Standard-weight Steel Pipe

Sound. Sound-level measurements and noise control have become increasingly important. Cooling towers installed in industrial locations seldom present a serious problem since the ambient or background sound level is usually of about equal magnitude to that of the cooling tower. This is not true of cooling towers located in congested downtown, business, or hotel districts or in residential areas.

The response of the ear to sound is not proportional to the intensity but is more nearly proportional to the logarithm of the intensity as is shown in Fig. 8-189. The characteristic would be a straight line if the response of the ear were strictly logarithmic. Figure 8-189 also shows the loudness levels of familiar sounds.

The decibels scale, which is logarithmic, has been widely used for measurements in electrical communication, and it has logically been adopted for sound measurements. A decibel number represents a ratio rather than a definite quantity, so some reference point is necessary. This value for sound measurements is 10 watts per sq cm at a frequency of 1,000 cycles and actually represents approximately the threshold of hearing for a person whose ears are slightly more sensitive than average.

A decibel rating represents a ratio of powers which may be expressed by the equation

$$db = 10 \log (P_2/P_1)$$

where P_2 and P_1 represent the two powers being compared, and the decibel rating of two sound levels is not the sum of the two components.

The noise produced by a cooling tower is caused by the falling water and also by the fan on mechanical-draft towers. Fan noise may be minimized by installing oversize fans operating at lower speeds. Baffles constructed of sound-absorbent material may be used to absorb the sound or to deflect it.[2,3]

Delignification of Wood. The presence of sodium carbonate in the circulating water results in delignification of the wood structure of the tower. This is because the lignin which binds the wood fibers together is dissolved by the sodium carbonate, leaving the wood surface in a white, fibrous condition. Prolonged exposure reduces the structural strength of the wood. The rate of delignification is roughly proportional to the concentration of sodium carbonate present, and a concentration of 200 to 300 parts per million will result in damage to the wood structure and fill.

Delignification appears first on those parts of the tower which are alternately wet and dry since the evaporation at such points rapidly increases the concentration of dissolved solids. For this reason the action is far worse in atmospheric towers. Wood parts in mechanical-draft towers are continuously wet, and delignification is thus much slower.

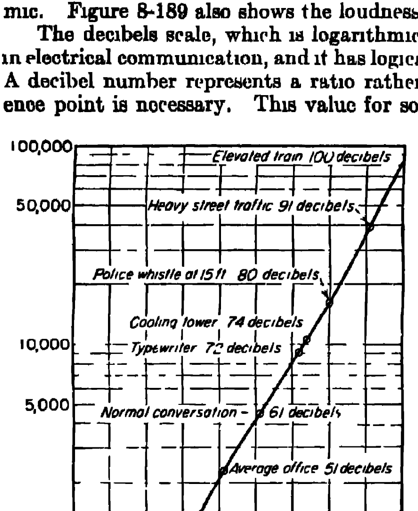

Fig 8-189 Loudness level in decibels for various sounds

The presence of sodium carbonate in harmful amounts is usually indicated by a high pH reading of 9 to 11. It should be understood, however, that the delignification is caused by the presence of sodium carbonate and not by the high pH value of the water. The sodium carbonate may be neutralized by the use of sulfuric acid which converts it into sodium sulfate. Such a treatment lowers the pH value of the water which should be maintained at 7.3 to 7.5.

Sodium carbonate seldom occurs naturally in the make-up water but is a product of water treatment. High concentrations are usually found when a zeolite water treatment is used It is therefore important to use sulfuric acid in connection with sodium zeolite water treatment to prevent delignification of the wood

Steam Condensing. When steam is condensed, the latent heat must be removed. This amounts to 960 Btu per lb of dry saturated steam. In actual operation the total heat may be more or less, depending upon the steam condition, as due allowance should be made for moisture or superheat being present

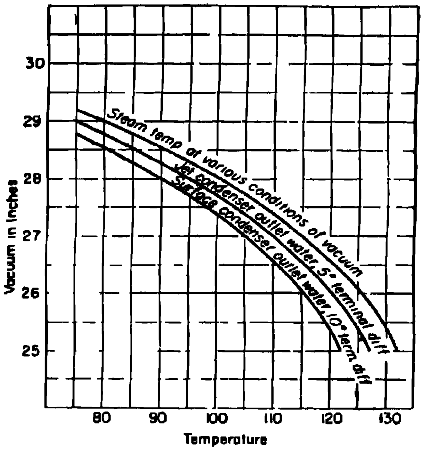

Fig 8-190 Relation between vacuum and temperatures for steam condensers.

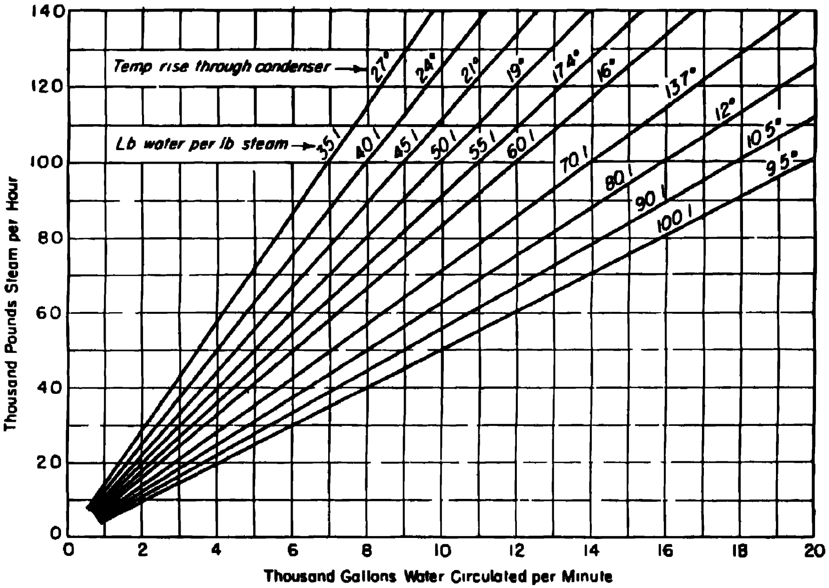

Fig 8-191 Flow relationship of steam to water for steam condensers, based upon 960 Btu per lb of steam

Allowable hot-water temperature leaving the steam condenser must be somewhat less than the condensing steam temperatures This is known as the "terminal difference" (Fig 8-190) For reciprocating-steam-engine work, a vacuum of 26 in is practical, and for steam-turbine operation vacuums of 27 to 28 in. are practical. When jet-type steam condensers are used, the outgoing hot water should be approximately five degrees cooler than the exhaust steam. When surface-type condensers are used, a difference of 8 to 10° is considered good practice (Fig. 8-191).

Excessive terminal difference indicates one of several things, including

1. Air or other noncondensable vapors in the condenser
2. Dirty or scaled-up cooling surface
3. Insufficient water velocity which reduces the heat-transfer rate
4. Too small a condenser

WATER-COOLING SYSTEMS

Spray Pond. The spray pond (Fig. 8-192) requires large areas and is practical only where ground is cheap and where drift is not objectionable to surroundings. If the soil is such that a concrete basin is required, the cost is prohibitive. If surroundings and drift conditions force the use of a louver fence, the spray pond is not recommended. Ponds are very low in first cost, and maintenance over a period of years is almost negligible. No serious icing problems occur in winter.

FIG. 8-192. Typical spray pond for cooling water with atmospheric air.

Systems are usually designed for from 5 to 6 lb pressure at the nozzles, and nozzles are elevated about seven feet above the surface of the water. Total pumping head required averages 25 ft on smaller systems and upward to 30 ft on large ponds.

For good practice space requirements will approximate 1.3 to 1.6 sq ft per gal of water sprayed. Large ponds should be relatively long and narrow. Actual width of the spraying section should be 25 ft for small single-run spray systems and should be held to not over 100 ft in large systems. An added clearance area of 15 to 20 ft on all sides should be allowed for drift prevention (Fig. 8-193).

Table 8-58. Recommended Spray-pond Standards

Wet bulb	Vacuum, in. Hg	Steam temperature	Surface condensers				Jet condensers			
			Hot water	Cold water	Range	Ratio lb H_2O/steam	Hot water	Cold water	Range	Ratio, lb H_2O/steam

The water is broken up into droplets only once in a spray pond and falls through a relatively short distance. This limits the practical cooling efficiency and usually results in more water being circulated than in a cooling tower.

Maximum practical cooling efficiency does not exceed 60 per cent in small single-run systems and seldom exceeds 50 per cent in large ponds if we consider performance to be measured as follows:

$$\text{Cooling efficiency} = \frac{\text{hot water} - \text{cold water}}{\text{hot water} - \text{wet bulb}} = \frac{\text{actual cooling range}}{\text{max poss. cooling range}}$$

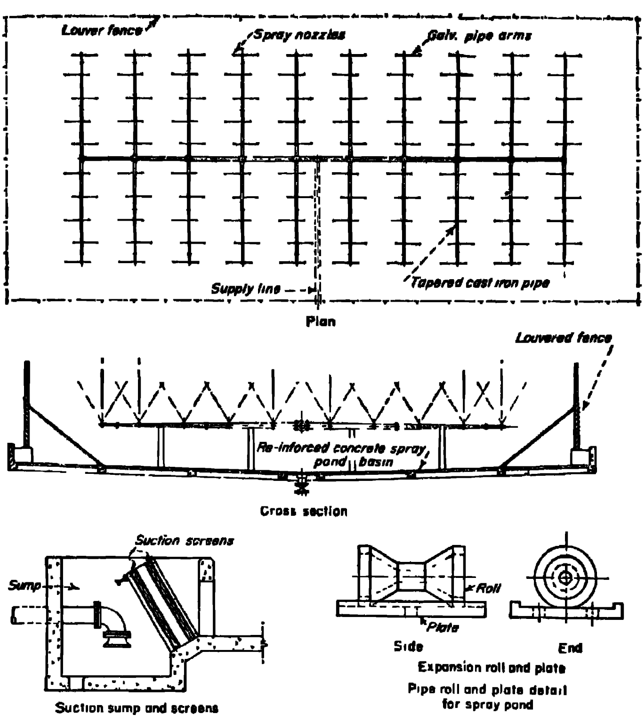

FIG. 8-193. Arrangement of spray pond showing piping, nozzles, louver-fence, water-sump, and pipe-expansion details.

Some recommended spray-pond standards for steam condensing are indicated in Table 8-58.

Atmospheric Spray Tower (Fig. 8-194). The atmospheric spray tower is very popular and practical in smaller sizes only. It is simple in design and easily erected by the average engineer or mechanic. A factory superintendent is not required to install it. Performance possibilities are limited to much the same as for a spray pond. Initial cost is low. Maintenance is easy, and repairs are negligible. Total pumping head is from 20 ft on the smaller units to 26 ft on larger sizes. Drift can be objectionable in high winds. When installed upon building roofs, it should be set back from the sidewalks to prevent drift on streets or other surroundings below.

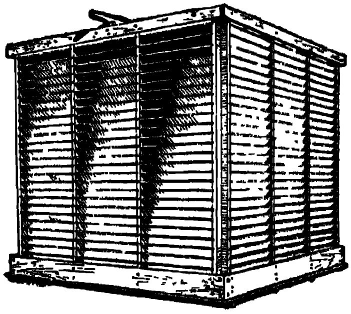

FIG. 8-194. Atmospheric-spray water-cooling tower.

Atmospheric Deck or Tray Tower (Fig. 8-195). In the atmospheric-deck type of cooling system, the hot water is introduced across the top by suitable distributing nozzles or flumes. It then cascades downward, splashing and dripping from deck to deck. Air passes horizontally through the structure, dependent upon existing breezes.

The effective width is usually about twelve feet, and height ranges from 28 to 36 ft. The total pumping head varies from 30 to 40 ft. Inclined louvers are required on all sides to prevent excessive drift. Velocity of the air through a well-designed unit will not exceed one-quarter to one-third the existing breeze available at the site. During periods of zero wind, some air moves vertically upward if the oncoming water is hotter than the air.

This style of tower performs well during periods of good breeze, but results are very poor during low-wind periods or with wind direction lengthwise rather than crosswise. Good exposure to prevailing breezes is essential.

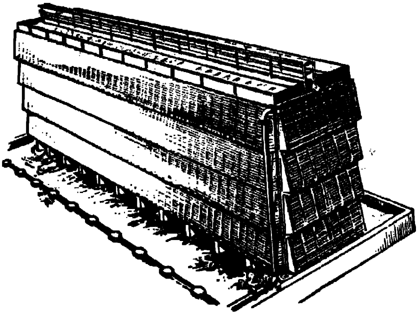

FIG. 8-195. Atmospheric-deck water-cooling tower.

Plan area required is a minimum for atmospheric towers. While very popular for many years, atmospheric towers are fast being outmoded by the modern improved mechanical-draft tower.

Table 8-59. Approximate Effective Areas Required for Atmospheric-deck Type of Cooling Towers

Cooling range, degrees	Square feet per gallon, approach to wet bulb		
	5°	10°	15°
5	0.864	0.312

14	1.61	0.952	0.576
15	1.66	1.00	0.624
16	1.70	1.04	0.656
18	1.77	1.10	0.724
20	1.83	1.18	0.780

Table 8-59 gives a rough approximation of the size or sectional area of tower required per gallon of water circulated. For instance, with a 15° range and 10° approach, 1 sq ft is required. A 2,000-gpm tower would require 2,000 ft of exposed area, and if the tower is 30 ft high, the length would be between 65 and 70 ft. Effective area is measured by height times length inside the louvers. The above table is for 70° wet bulb. With higher wet bulbs a reduced area is required for a given range and performance. With lower wet bulbs an increased area is required. Actual areas and wet-bulb correction factors vary considerably from the above figures, depending upon the make and style of tower being considered.

The Mechanical-draft Water-cooling Tower. Mechanical-draft water-cooling towers can be divided into two general classes. Forced draft pushes air into and through the tower, whereas induced draft pulls air from the tower. Most manufacturers prefer to build the induced-draft style. Mechanical-draft towers can also be classed as counterflow or crossflow, depending upon the direction of air flow as it passes through the active cooling surface.

Mechanical-draft towers have nearly constant air-to-water ratios and give uniform cooling results regardless of direction or velocity of wind. Performance tests can be easily conducted, whereas it is very difficult to test a spray pond or an atmospheric cooling tower because of variation in wind velocity and direction.

Mimimum space is required for mechanical-draft towers. Their external appearance is excellent, and there is no free moisture or drift loss to wet the surrounding ground or buildings. Because of drift elimination, they can usually be located much closer to the equipment they serve, thus reducing the cost of water lines to and from the equipment.

Table 8-60. Recommended Mechanical-draft Tower Standards

Wet bulb	Vacuum, in. Hg	Steam temp.	Surface condensers				Jet condensers			
			Hot water	Cold water	Range	Ratio	Hot water	Cold water	Range	Ratio
80	27.0	114.8	104	90	14	68	109	95	14	68
80	27.25	111.8	102	89	13	73	107	94	13	73
80	27.50	108.4	100	88	12	80	105	93	12	80
75	27.25	111.8	101	86	15	63	107	92	15	63
75	27.50	108.4	99	85	14	68	105	91	14	68
75	27.75	104.8	97	84	13	73	103	90	13	73
70	27.50	108.4	98	82	16	60	105	89	16	60
70	27.75	104.8	96	81	15	63	103	88	15	63
70	28.00	100.8	94	80	14	68	101	87	14	68

Table 8-60 indicates some suggested practical performance standards for steam-condensing operation. Three different vacuum conditions are indicated for each of three wet bulbs. The higher wet bulb is suggested for the Gulf Coast areas; the intermediate wet bulb is satisfactory for the central part of the United States; and the lower wet bulb is for northern locations.

Table 8-61. Approximate Effective Areas Required for Mechanical-draft Towers

Cooling range, degrees	Approach to wet bulb		
		10°	15°
5	0.313	0.174	
7½	0.412	0.237	0.154
10	0.489	0.287	0.195
15	0.598	0.373	0.200
20	0.670	0.438	0.311

Table 8-61 gives a rough approximation of the size or sectional area of tower required per gallon of water circulated. For instance with a 15° cooling range and a 10° approach 0.373 sq ft is required per gallon. Thus for a 10,000-gal tower, 3,730 sq ft are necessary, and if the tower picked has a width of 40 ft, the length must be somewhat over 90 ft, the exact dimension depending upon the manufacturer's standards.

Table 8-61 has been prepared for a 70° wet bulb. With higher wet bulbs a reduced area is required for a given range and performance. With lower wet bulbs an increased area is required. Actual areas and wet-bulb correction factors vary considerably from the above figures, depending upon the make and style of tower being considered.

Crossflow Water-cooling Towers. In the crossflow style (shown by Fig. 8-196) the water falls vertically downwards, and the air flows horizontally across the cooling section of the tower, whereas in the counterflow style of tower the air flows vertically upward. The crossflow principle has been popular in European practice for many years in both atmospheric and mechanical-draft equipment. In 1938, the first large-capacity crossflow cooling tower was introduced into American practice, and in a short time its popularity was unquestioned. In the larger industrial towers, instead of a single cooling tower per fan, the customary practice is to use one fan for each two cooling units. This results in what is known as the double-flow cooling tower shown by Fig. 8-197. The crossflow style of tower includes practically all the advantages but none of the disadvantages of counterflow towers.

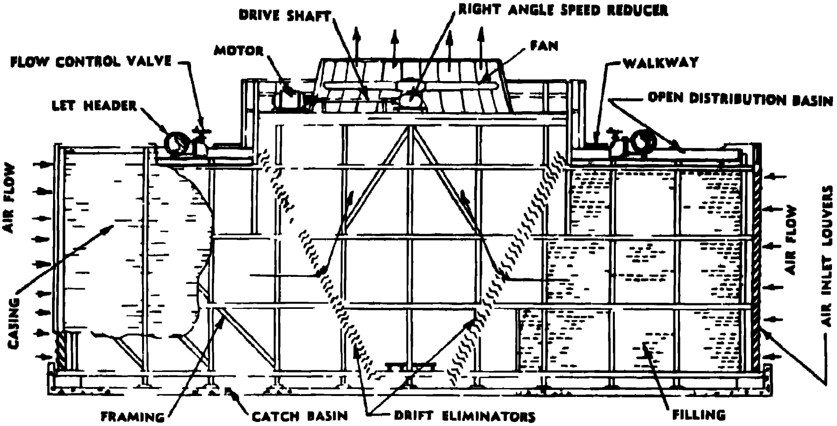

FIG. 8-196. Sectional elevation of a crossflow, also called double-flow, cooling tower.

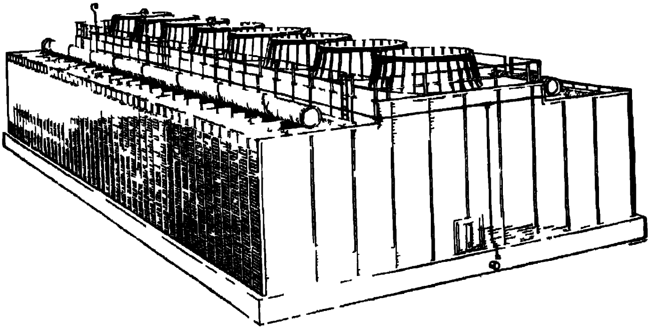

FIG. 8-197. Perspective view of a double flow water-cooling tower.

The crossflow tower is of minimum height and required pumping head. Being low and wide, it is easy to brace structurally for winds and earthquake. Accessibility to the mechanical equipment upon the top of the tower is easier than with conventional higher designs. Distribution of the hot water to the cooling surfaces of the tower is accomplished with a total head of only 6 to 8 in. of water.

The water-distributing system can be easily inspected at all times and while the tower is in operation. Mud can easily be removed, clogged nozzles can be cleaned, and most important of all, it is easy to adjust the float-control valves to make each tower cell take its proportionate quantity of water. These features are not possible in towers of counterflow design.

In conventional towers, the wider the framework, the higher must be the structure, and because of practical limits in the extreme larger sizes, two rows of fans are required, whereas with the crossflow tower the two cooling-tower cells may be set at any distance apart, and there is no limit to the maximum diameter of fans which can be used. Larger fans mean larger cells with fewer inlet water lines and fewer sets of electrical wiring and starting equipment, thus simplifying operation and maintenance. An extremely low draft loss is claimed for this style of tower because of less resistance to air flow past the slat fill as compared to the vertical or counterflow principle. The drift eliminator also provides a smaller draft loss because the eliminator area is much larger than the actual air-flow section of the tower proper. Because of the low draft loss, greater air per horsepower input to fans is obtained than with conventional towers.

OPERATION AND MAINTENANCE OF WATER-COOLING SYSTEMS

Spray pond, atmospheric towers, and mechanical-draft towers all require a regular maintenance schedule to keep them operating efficiently. The water-distribution problems are about the same in any water-cooling system.

Starting. When first starting operation or after a shutdown all water basins should be clean and free of any dirt or foreign matter, and they should be watertight. All pipe connections, valves, and nozzles should be checked to make certain they are in good working order. The cold-water basin should be filled with water, and then the system should be started operating. The water-distribution system should be inspected regularly to make certain the nozzles are spraying properly and that the evaporation and drift loss are not excessive. Low nozzle pressure indicates insufficient water, whereas high nozzle pressure indicates excessive water.

Make-up Water. Make-up water must be added continuously to a cooling system while in operation. Two different losses occur: (1) the loss due to evaporation and (2) the loss due to drift or free-moisture removal.

Evaporative Loss. Evaporative loss cannot exceed 1 per cent for each 10° of cooling. This assumes full heat dissipation by evaporation, which never occurs as part of the heat is dissipated by convection. In practice, evaporation dissipates from 50 to 90 per cent of the total heat. The evaporative portion is greatest in hottest weather and with longest cooling ranges.

Drift Loss. Drift loss or carry-over of entrained free moisture of any one standard of design varies through wide ranges in atmospheric cooling systems, depending upon wind velocity, wind direction, and structural design. Well-designed spray ponds will show no loss at zero winds and 3 to 4 per cent at extreme winds. They will average less than $\frac{1}{2}$ of 1 per cent. Deck towers will come within these limits, but 5 to 8 per cent maximum drift loss in high winds is not uncommon with older designs. In mechanical-draft towers the drift loss remains fairly constant. Well-designed units will average about $\frac{1}{10}$ of 1 per cent loss, and when the loss exceeds $\frac{2}{10}$ of 1 per cent, drift becomes objectionable. Drift-loss comparisons are shown by Fig. 8-198.

Algae. Algae can be expected to grow in almost all basins, especially those which are exposed to sunlight. If algae that have formed on basin floors and walls become too thick, they will break loose to the surface and clog the water-distribution system. By using chlorine, copper sulfate, potassium permanganate, or some other suitable chemical, algae may be minimized or completely eliminated. A reliable water-treatment engineer should be consulted for the proper treatment.

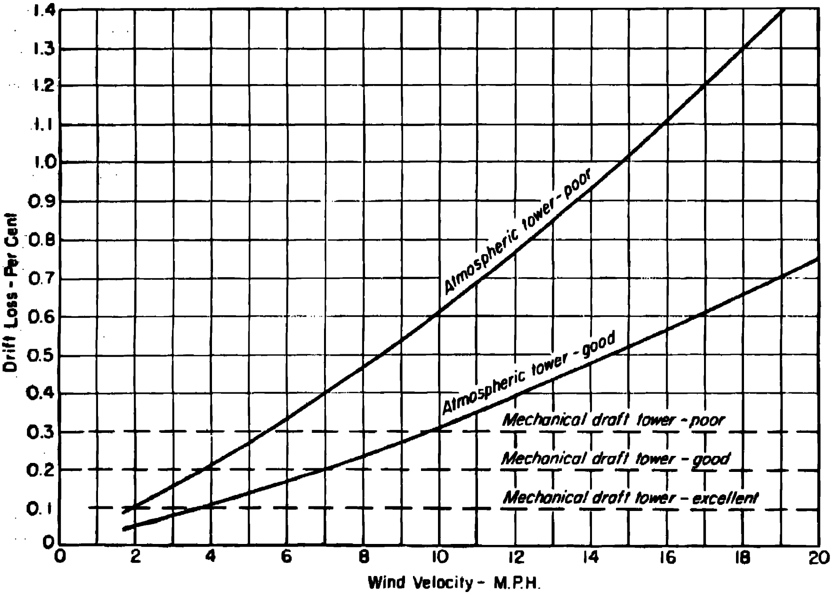
Scale. Scale-forming materials are found in practically all water. Scale will reduce heat-transfer rates, and scale forming in pipes and nozzles will reduce the effectiveness of water-cooling systems. A water-treatment engineer should be consulted to keep scaling at a minimum. Scale should be removed at regular intervals.

Concentration. As water is evaporated from the system the soluble solids remain in the water and increase in concentration. These solids will hamper the efficiency of the cooling system. Solution wet bulbs will be raised, and the system efficiency can be seriously reduced. Concentrations of solids can be controlled either by "blowing down" or by a "continuous overflow" to the sewer. A good water-treatment engineer can recommend the best way to control these solids.

Water Flow. The amount of water being circulated should be checked occasionally. Water flow can be checked by means of orifice meter, weir, pitot tube, pump characteristic curves, or spray-nozzle capacity curves. Reduced water quantities may indicate clogged or worn pumps, clogged nozzles, scaled-up tubing or piping.

When shutting down it should be made certain that all parts are properly drained and that the distribution system is protected from freezing and corrosion. While shut down, the entire system should be thoroughly inspected and repaired if necessary so it will be ready for immediate operation.

Structural Maintenance. When the system consists of a cooling tower, a careful maintenance and inspection schedule should be maintained to make certain that the structure is always in first-class condition. The following comments apply to both atmospheric and mechanical-draft units.



. 8-198. Drift-loss comparison of atmospheric and mechanical-draft towers.

Before starting all corrosive parts should be cleaned with special corrosive-resistant paint.

Any weak, broken, or warped lumber or structural members should be replaced.

All loose bolts should be tightened. Bolts in wood structures should not be pulled up too tightly as some allowance must be made for swelling of wood when wet.

Any loose, dry algae from hot-water basins or troughs and also from drift eliminators, deck filling, or air-inlet louvers should be removed.

All parts of hand rails, ladders, or stairways should be carefully examined or inspected.

Any painting of the exterior should be done while the structure is thoroughly dry. Painting of wood is not recommended as a preservative but for appearance only. Steel-cased towers should be painted annually.

Slat filling should be checked carefully, as any sagging of the deck slats or their support framing results in serious loss of cooling efficiency. Accurate spacing and position of slats is important.

Any possible structural failures of wood or hardware should be checked for, and wood should be examined for any signs of delignification.

If the system is in continuous operation, periodic inspections at intervals of 2 to 3 months apart are recommended.

Maintenance of Mechanical-draft Equipment. Where mechanical-draft equipment is used, a more rigid system is required, and attendants should inspect all moving machinery at least once per 8-hr shift.

Motors should be greased, painted, or otherwise maintained in accordance with the motor manufacturer's written instructions.

The alignment of motors, drive shafts, and gearboxes should be carefully checked at established intervals. Slight misalignment results in rapid failure of universal joints and is frequently the cause of excessive vibration. Universal joints should be oiled or greased as recommended, and drive shafts should be properly protected with guards to prevent damage to fans in case of failure.

Gearboxes should be drained and old oil replaced at intervals as recommended by the manufacturer. The instructions on the gear box should be followed. Too much end play of shafts indicates excessive bearing wear, and worn bearings should be replaced. Removable shims are usually provided to permit take-up of bearings if end play develops. Air vents should be kept open, and any water which may have accumulated in the gearbox should be drained off.

Table 8-62. Some Trouble Tips

Trouble	*Possible causes*
Unusual noise or vibration	Bad motor bearing
	Worn universal joint
	Loose motor or gearbox yoke
	Motor and gearbox not aligned
	Bad bearing in gearbox
	Loose fan hub
	Loose bolts in fan cylinder
	Loose bolts in tower structure
	Fan blades pitched unevenly
Excessive drift	Warped, broken, or missing eliminators
	Clogged or worn nozzles
	Excessive nozzle pressure
	Basin too full
	High winds
Increased temperature range	Decreased water circulation
	Dirt, algae, scale, or mud
	Valves partly closed
	Clogged strainers
	Worn pumps
Higher water temperatures	Reduced air flow—restrictions nearby
	Worn or dirty nozzles
	Extreme wet bulb conditions
	High concentration of solids
	Sagging of fill slats
	Algae on eliminators or decking
Rotting or disintegration of tower	Wood decay due to presence of fungi
	Insect attack
	Delignification
	Age
Poor vacuum	Mud or scaling in condenser
	Noncondensible vapors in condenser
	Reduced water quantity

Fans should be repainted as often as the need arises. The pitch of the fan blades must be uniform and should be carefully checked. A fan out of balance should be rebalanced at once. Fan cylinders should be kept painted if made of metal. All bolts should be tightened. The fan cylinder or ring requires frequent inspection and tightening. Clearance between fan ring and blade tips should be checked periodically.

In general, the greatest maintenance difficulties lie in the mechanical parts of the tower. Costly repairs and shutdowns can be prevented by a strict inspection and maintenance schedule. Spare mechanical parts should be carried in stock. All spray

ponds, atmospheric deck, or mechanical-draft towers require much the same operation and maintenance technique. However, individual instructions issued by the manufacturers for each type of water-cooling system should be carefully followed for the best results.

Winter Operation. Freezing weather demands extreme care and watchfulness to prevent serious damage. For atmospheric-deck-type towers a winter distributing header is recommended and is installed at a lower elevation. Ice accumulates on louvers and decks especially in the lower tower section and on the air-inlet side. Serious structural overloads occur, and resultant damage can easily occur.

Mechanical-draft towers have serious icing difficulties, but these can be eliminated or controlled by proper operation. Two-speed motors equipped with reversing switches should be standard equipment. Fully enclosed or splashproof motors are recommended. Splashproof motors equipped with space heaters provide good results.

Most forced-draft towers accumulate ice about the fans or fan rings due to moisture or spray. Serious damage to the mechanical equipment results if ice is not caught in time. Induced-draft towers cannot ice up the fans, and ice accumulation is confined to the inlet louvers or adjacent fill thus at least protecting the mechanical equipment.

It is practical to operate fans at one-half speed from fall to spring with a great saving in horsepower. During extreme freezing weather fans may be shut down continuously or intermittently as load conditions require. If ice still accumulates, fans may be reversed for short intervals, thus melting the ice.

If operating troubles develop, several sources should be investigated. Most probable of these are included in Table 8-62.

EVALUATING A WATER-COOLING TOWER

When cooling-tower manufacturers submit proposals to a buyer, the purchaser is confronted with various types of towers and various-priced towers. Each tower is said to give a certain performance. While almost all plant engineers know something of water-cooling towers, too often they have nothing too tangible to use as a guide in selecting the best cooling tower. The following material suggests some items that should be taken into consideration when purchasing a cooling tower.

Structural Theory. Structurally, a cooling tower may be considered as a shell or housing enclosing apparatus for mechanically forcing air through droplets of water for the purpose of cooling water. The housing must be capable of supporting

1. Internal loads of water passing through or being cooled in the cooling tower, the piping and tower filling (multiple strips used to mix mechanically the falling water with the air so as to facilitate heat transfer), the fans for forcing the air through the tower

2. External loads of wind, earthquake accelerations, and temperature effects; wind loads are usually assumed as (*a*) 20 psf of exposed vertical surface for cooling towers located on or near the ground level; (*b*) 30 psf for cooling towers located on roofs or other exposed locations. Earthquake loads are usually considered as horizontal forces (acting in any direction) equal to 0.1 of the vertical loads at or above the points or level of the structure under consideration.

The structural framework of a cooling tower consists of a series of framed bents (running both longitudinally and transversely in the tower). The horizontal ties or beams of these bents support the filling, water-spray or -distribution system, fan enclosure, and drift eliminators. The vertical posts act as supports for the beams and as struts in the wind or earthquake bracing system of the bent. The external casing and air-inlet louvers are usually attached to and supported by the exterior posts.

Any ordinary structural material that can be properly protected or is inherently resistant to decay when subjected to constant immersion in water (or alternate wetting and drying) can be used for cooling-tower construction. Redwood, cypress, Wolmanized fir, steel, and concrete are all used in varying degrees for that purpose.

Redwood[4] and cypress[5] (heartwoods) are the most commonly used materials because these timbers are impregnated with natural toxic ingredients which protect them from decay and insect attack. Since redwood is more generally used, its properties will be discussed briefly.

Redwood has a relatively high strength-weight ratio. It is highly resistant to warping and curling because of its low shrinkage and expansion with change of moisture content. Select heart redwood is usually used for the structural framework. Clear heartwood is used for exterior casing, louvers, trim, and other parts requiring good appearance and watertightness. Working stresses used in the design of cooling-tower structures for the grades of redwood outlined above are as shown in Table 8-63.

Table 8-63

Extreme fiber in bending	960 psi
Tension	960 psi
Compression with grain	800 psi
Compression across grain	250 psi
Horizontal shear	56 psi
Modulus of elasticity	1,200,000 psi

Since the cooling-tower frame is subject to severe exposure and possible vibratory loads, the connections or joints must be structurally adequate and designed for long life. These requirements dictate that bolted joints must be used throughout the framework with approved timber connectors[6] (such as the Teco ring type) used at all joints carrying horizontal loads. The nailing of the cooling-tower structure does not guarantee permanency and should not be used. Hardware should be of cast iron, bronze, or other corrosion-resistant material to ensure a well-balanced, long-lasting cooling tower.

Detailed Specifications for Mechanical-draft Towers. When requesting proposals from manufacturers be sure to include the following data:

1. Description of service intended
2. Location of installation or desired wet bulb
3. Total load in Btu or pounds of steam
4. Desired vacuum and style of condenser
5. Capacity in gallons per minute
6. Allowable hot- and cold-water temperatures
7. Characteristics of electrical current or power available
8. Cost of electricity or other power if any
9. Space limitations if any
10. Class of erection labor required
11. Desired delivery and erection schedule
12. Is location on ground or roof
13. Is railroad siding available
14. Must any local codes be adhered to such as fire or earthquake
15. Will electric power and water be available at site
16. Distance from site to nearest town
17. Specify whether bronze or galvanized bolts and nails
18. Specify who will furnish
    - *a.* Receiving and unloading
    - *b.* Erection supervision
    - *c.* Erection labor
    - *d.* Foundation and anchor bolts
    - *e.* Water piping and valves to tower
    - *f.* Electrical wiring and starters
    - *g.* Painting if any

Suggested General Specifications for Purpose of Purchase.

1. All lumber shall be of heart California redwood, free from sap and any serious defects. It shall be equal to No. 1 heart common or better as graded by the California Redwood Association.

2. The successful bidder will furnish a stress diagram. He will furnish detailed information of all joints and sizes of main frame members and bolts and also details of all load calculations.

3. Structural timber members shall be designed according to the basic unit stresses (reduced 30 per cent for continuously wet operating conditions) as established in the chapter on Structural Timbers, pages 99 *ff.* of the "Wood Handbook" of the Forest Products Laboratory, edition of 1935. Connections shall be designed to develop the stresses in the members with no allowance for nails or spikes. All dependence for the developing of the joints shall be upon the bolts or ring connectors. The strength of the bolted or ring connector joints shall be determined by the procedure and values established in the chapter on Timber Fastenings, pages 119 *ff.* of the aforementioned "Wood Handbook." The general design of the timber frame shall be according to the chapter on Wood Beams, Columns and Arches, pages 149 *ff.* in the above-mentioned "Wood Handbook."

4. Concrete members shall be designed according to the recommendations of the latest edition of Joint Code of Building Regulations for Reinforced Concrete Structures of the American Concrete Institute.

5. Cast iron used structurally shall conform to the standard specifications for gray iron castings, serial designation A-48-32-T, of the American Society for Testing Materials.

6. Cast steel used structurally shall conform to the standard specifications for steel castings, serial designation A-27-24, of the American Society for Testing Materials.

7. Unit stresses for combined dead and live loads and wind may be increased 33⅓ per cent over the provisions stated above for static loading conditions, provided that the section obtained thereby is not less than that required for dead and live loads along with the static unit stresses.

8. Cooling towers shall be designed to withstand a wind pressure of 30 psf, acting from any direction. Adequate anchorage shall be provided for uplift either during construction or in the completed tower.

9. If installed upon a roof, a ladder with guard will be provided. If installed upon the ground, a stairway will be provided. If in excess of 100 ft in length, two stairways will be provided, one to be at each end of the tower.

10. Deck-fill slats (flat side horizontal), if of ½-in. nominal thickness, shall be supported at intervals of not less than 18 in. If of 1-in. nominal thickness, they shall be supported at intervals of not less than 36 in. Allowable span for inlet louvers and eliminator slats may be double this amount where inclined at not less than 45 deg to the horizontal.

11. Motors shall be of the splashproof type unless otherwise required.

12. A speed reducer using spiral bevel gears is preferred. This shall be contained in a cast housing, oil-lubricated and with antifriction roller-type bearings.

13. All material and workmanship shall be guaranteed for a period of 1 year, and manufacturer will replace free of charge f.o.b. shipping point any defective part.

14. A performance acceptance test may be conducted at any time within 1 year after completion of erection. The manufacturer may have a representative present. Test will be conducted at purchaser's expense, and readings shall be taken in accordance with the ASME code for water-cooling equipment.

15. The purchaser may employ a competent licensed professional engineer at his expense to check structural drawings furnished, and successful bidder agrees to alter his structural design to meet the specifications of the purchaser if found necessary.

16. Casing shall be not less than 2 in. (nominal) in thickness. It may be of single- or double-wall construction.

17. Fill or deck slats of interlocking nailless design are to be preferred.

18. The cooling tower shall have a guaranteed drift loss of not exceeding 0.2 of 1 per cent under condition of 5-mph wind if of atmospheric design or under any and all conditions if of mechanical-draft design.

19. Hot-water-flow control valves shall be furnished for each section or cell of the tower.

20. The successful bidder shall furnish a printed manual with full instructions for care, operation, and maintenance of the tower.

HYDRAULIC TURBINES

BY FRANK H. ROGERS

Consulting Sales Engineer, Hydraulic Turbines, The Baldwin Locomotive Works, Eddystone, Pennsylvania

The national importance of water power in the United States to supply the needs of industry, transportation, and domestic use is indicated in Fig. 8-199. It will be noted from this chart that, until 1895, the hydraulic-turbine industry was small and of little national importance. In that year, however, the first large water-power development at Niagara Falls was started; and since that time, the demand for water power has progressed at a rapid rate. From 1922 to 1931, installed horsepower increased at the rate of about 800,000 hp per year The slope of the curve rises to a still higher rate of about 870,000 hp per year from 1937 to 1945. Because of conditions growing out of the Second World War, only about 15,000 hp of new capacity

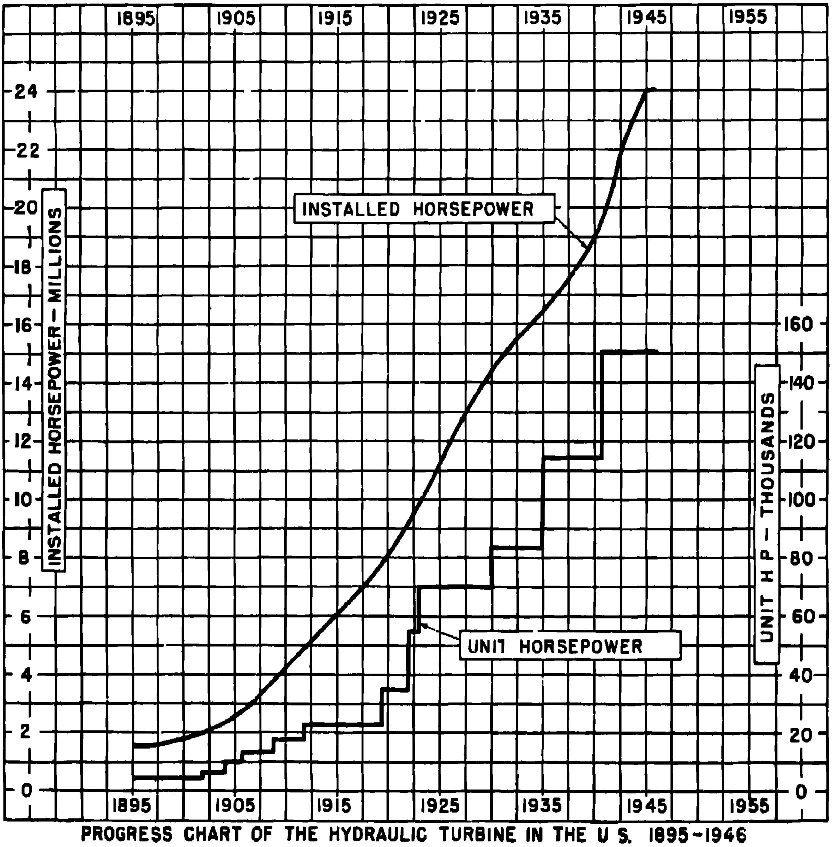

FIG. 8-199 Progress chart of the hydraulic turbine in the United States, 1895 to 1946. (*Federal Power Commission.*)

went into service in 1946; but from present data available about 500,000 hp went into service in 1947 and over a million horsepower is expected in 1948.

The increase in output from single units (unit horsepower) has been very great, starting in 1900 with the 5,000-hp units installed in the original Niagara Development and progressing to the 150,000-hp units first installed in the Grand Coulee Station on the Columbia River in Washington in 1941. These are the most powerful units in the world. Nine units are now in operation, and six additional units are under construction. In comparing hydroelectric power with steam-electric power, the important role played by the former is shown by the fact that, of the total power generated in central stations, about 35 per cent is furnished by hydroelectric plants as compared to 65 per cent from steam plants.

TYPES OF HYDRAULIC TURBINES

There are two general types of turbines, impulse and reaction. In the impulse type, all the energy contained in the water is converted to velocity head at the nozzle, where the buckets of the wheel receive the jet and convert the velocity in the jet to mechanical power by impulse action. In the reaction-type turbine, the energy is converted to power in the runner by means of vanes turning the water, thus causing a high pressure on the face of the vanes and a lower pressure on the back, causing a reaction. The reaction type is further subdivided into the following classifications:

1. *The Francis turbine* is of the mixed-flow type in that the water enters the runner in a radial direction and discharges the water in an axial direction. Such runners are usually constructed with from 12 to 19 vanes supported by the crown of the runner which is connected to the turbine shaft and guided by the band near the discharge side of the runner.

2. *The propeller turbine* also belongs to the reaction type but consists of from three to eight blades, the flow through the runner being in a general axial direction both at inflow and discharge. The runner blades are supported by the hub and have no band, thus in general resembling a ship propeller, from which it derives its name. Turbines of this type, having fixed blades, are usually referred to as propeller turbines.

3. *Kaplan turbines* are similar to fixed-blade propeller turbines, except that the blades are automatically adjusted during operation in order to develop high efficiencies over a wide range in loads.

Specific speed. As the head, horsepower, and speed may differ widely in different installations, a comparison of the various types of hydraulic turbines may best be made by comparing their specific speeds. Specific speed is the speed in revolutions per minute at which any turbine would operate at its best efficiency if the dimensions of such turbine are geometrically reduced so that the turbine would develop 1 hp under a net head of 1 ft. As a formula

$$N_s = \text{rpm} \times \sqrt{\text{hp}}/H^{5/4}$$

where N_s = specific speed
rpm = revolutions per minute
hp = horsepower developed
H = net effective head

The specific speed of the runner selected depends on the head. For high-head developments, low-specific-speed runners are used; and as the head decreases, the specific speed may be increased. An approximate formula to determine the specific speed for various heads is as follows:

For Francis-type turbines:

$$N_s = 660/\sqrt{H}$$

For propeller-type turbines:

$$N_s = 6{,}750/H$$

The size and shape of runners of different specific speeds differ materially as indicated by Fig. 8-200, which shows a comparison of five runners of different specific speeds. All these runners are drawn to the same scale, and each runner would develop the same horsepower output under the same net head but would operate at speeds proportional to the specific speeds indicated. The runner shown at the top, having a specific speed of 20, would be suitable for heads up to about 1,000 ft; the second runner, having a specific speed of 35, for heads up to about 300 ft; the third runner, having a specific speed of 53, for heads up to about 150 ft; the fourth runner, having a specific speed of 85, for heads up to about 60 ft; and the fifth runner, of the propeller type, having a specific speed of 143, for heads up to about 48 ft.

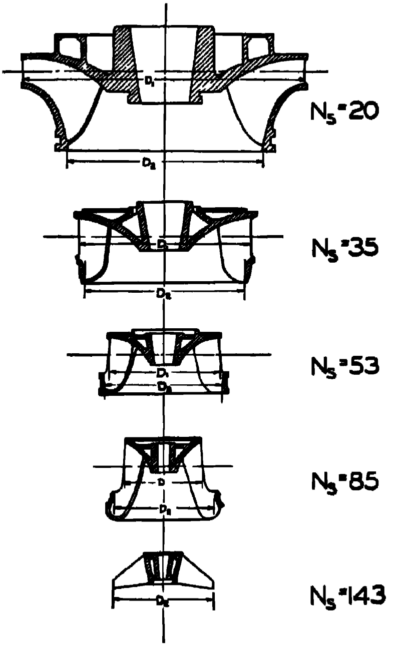

Fig. 8-200. Runners of equal power but with different specific speeds.

It is a characteristic of design that, as the specific speed of a runner increases, the horsepower-efficiency curve becomes steeper, *i.e.*, the part-load efficiencies decrease. This characteristic is indicated by Fig. 8-201, which shows typical horsepower-efficiency curves for the same runners indicated in Fig. 8-200. It may be noted from these curves that for high-head plants with runners of low specific speeds, flat horsepower-efficiency curves are obtained; whereas for the runners that would be used in low-head plants, where higher specific speeds are used, steep horsepower-efficiency curves result. Thus, in the case of the fixed-blade-propeller runner, the horsepower-efficiency curve is quite steep, and low efficiencies are obtained at part loads. In order to correct this inherent weakness in the characteristics of fixed-blade-propeller turbines, the Kaplan adjustable-blade turbine is used. This runner was named after Victor Kaplan of Austria, who first suggested it. It consists of runner blades supported in bearings in the runner hub. The blades can move while the turbine is in operation by means of an operating gear within the runner hub. This gear is connected by an internal shaft within the main turbine shaft, and the internal

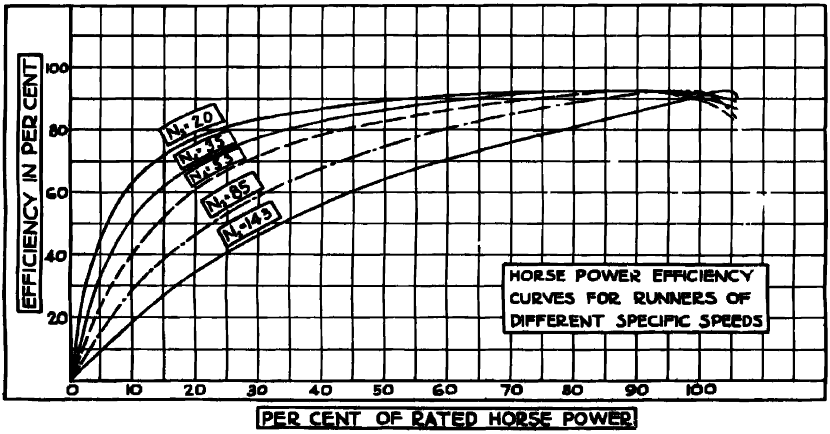

Fig. 8-201. Horsepower-efficiency curves for runners in Fig. 8-200.

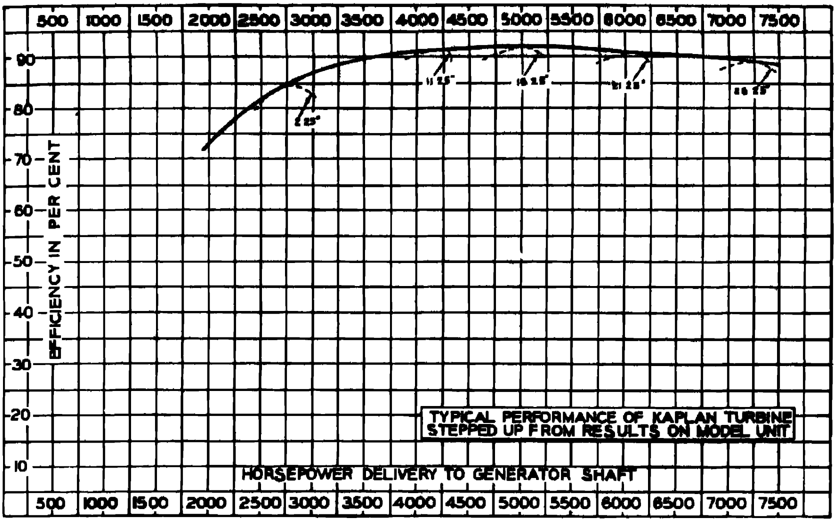

FIG. 8-202. Horsepower-efficiency curve for Kaplan-type turbine.

shaft is connected to a piston in a servomotor revolving with the main shaft. Oil pressure controlled by the governor is admitted to the revolving servomotor in order to adjust the runner blades. These runner blades and the turbine guide vanes are automatically and simultaneously adjusted in accordance with the load demand on the unit in order to provide the best possible hydraulic relation between the guide vane opening and the runner blade position. A typical horsepower-efficiency curve for the Kaplan-type turbine is shown in Fig. 8-202. Each of the dotted lines shows the performance of the unit if operated as a fixed-blade runner at the blade angle indicated. By automatically moving the runner blades at the same time as the guide vanes, the unit may be operated at the peak of each separate efficiency curve, so that the envelope curve (shown solid) becomes the actual operating curve of the unit. The Kaplan-type turbine, therefore, permits the adoption of high speed, yet maintains the high efficiencies over a wide range in load.

ACTUAL INSTALLATIONS OF DIFFERENT TYPES OF TURBINES

Impulse Type. Figure 8-203 shows a runner of a very large impulse turbine installed in the Big Creek No. 2-A Development of the Southern California Edison Company. The runner illustrated develops 35,000 hp under a net head of 2,200 ft at a speed of 250 rpm. A single unit consists of two overhung runners, each runner being provided with a single nozzle, so that the complete unit develops 70,000 hp.

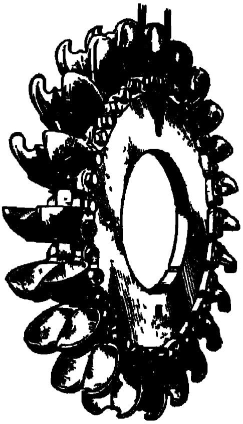

FIG. 8-203. Impulse runner, Big Creek 2-A Development of the Southern California Edison Company.

High-head Francis Type. Figure 8-204 is a shop view of an assembled turbine built for the Hoover Dam Plant of the U.S. Bureau of Reclamation, located on the Colorado River between Arizona and Nevada. Each unit is designed to develop 115,000 hp under a net head of 480 ft at a speed of 180 rpm. Twelve units of this size are now installed in the Hoover plant, together with one smaller unit of 55,000

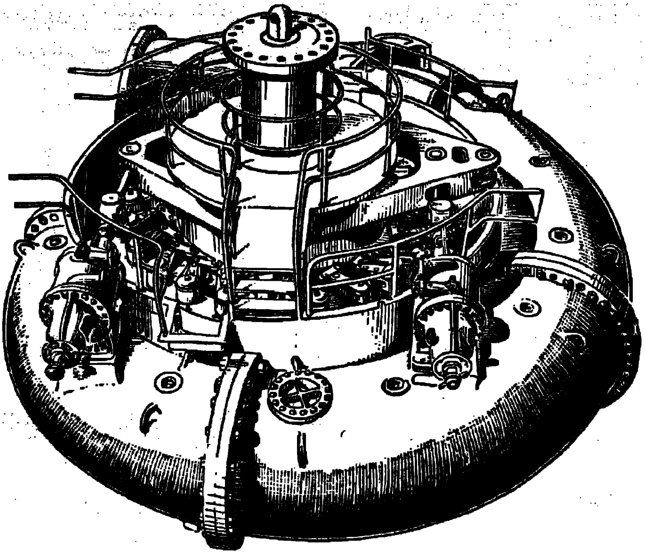

FIG. 8-204. Hoover Dam turbine, 115,000 hp, in shop.

hp. There is still space in this plant for installing three additional main turbines and one additional unit of the smaller size.

Medium-head Francis Type. An example of the Francis-type turbine operating under a medium head is given in Fig. 8-205, a shop view showing runner and shaft being lowered into the unit. This turbine was built for the Loup River Public Power District, Columbus Power Plant, Nebraska. Three units are now in operation, each designed to develop 18,000 hp under a net head of 112 ft at a speed of 150 rpm. The illustration shows only the assembled guide vanes and head cover, but this unit is provided with a plate-steel volute-type casing.

Low-head Propeller Type. As an example of a low-head development, Fig. 8-206 shows the runner of a fixed-blade

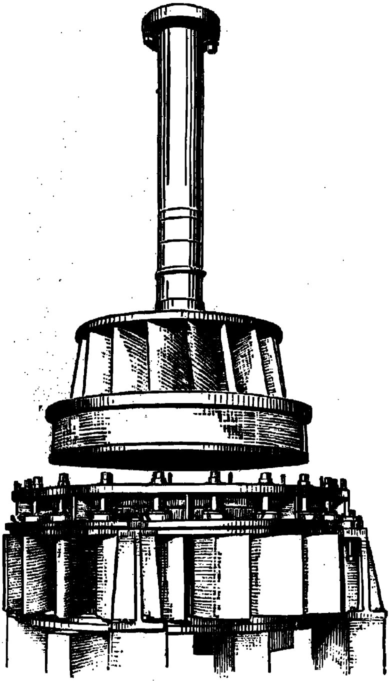

FIG. 8-205. Turbine of 18,000 hp capacity, Loup River Public Power District.

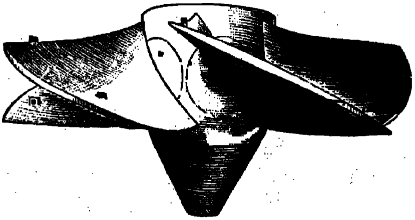

FIG. 8-206. Propeller runner, 45,000 hp, fixed-blade type, Wheeler Dam Development of Tennessee Valley Authority.

propeller-type turbine built for the Tennessee Valley Authority, Wheeler Dam Plant, on the Tennessee River in Alabama. Six units are now installed in this plant, and two additional units are under construction. Each unit is rated at 45,000 hp under a head of 48 ft at a speed of 85.7 rpm. The runner illustrated has an outside diameter of 22 ft.

As an example of a Kaplan-type turbine for low-head operation, Fig. 8-207 is a sectional view through one of the turbines built for the Tennessee Valley Authority, Watts Bar Dam, on the Tennessee River in Tennessee. Five of these turbines are now in operation, each unit developing 42,000 hp under a net head of 52 ft at a speed of 94.7 rpm.

LABORATORY TESTING

Research work is carried on by all the turbine manufacturers in specially designed hydraulic laboratories in order to be able to predict the performance of the large units in the field. Models exactly homologous to the large units, including the intake, casing, and draft tube, are tested over a wide range in power and speed. The model runners are usually from 10 to 16 in. in diameter. During the testing program, changes can readily be made in the runners, guide vanes, casing, and draft tube in order to obtain the best possible combination before starting construction of the large units. From the test data secured in the laboratory, the performance of the large units in the field can be accurately predicted. From the tests made on the models, curves may be plotted between the speed factor phi and unit horsepower (the power the runner would develop under a 1-ft head and a 1-ft runner diameter) and between phi and efficiency for various gate openings. The speed factor phi is the ratio of the peripheral speed of the runner to the spouting velocity of the water under the full head, or expressed as a formula

$$\phi = (D_2 \times \text{rpm})/(1{,}836 \times \sqrt{H})$$

D_2 represents the diameter at the throat of the runner in inches, and H is the net effective head on the unit

The model results can be stepped up to the field conditions by the following formulas at the phi selected for the field conditions:

$$\text{hp}_2 = \text{hp}_1 \times (D_2/D_1)^2 \times (H_2/H_1)^{3/2}$$

where hp_2 = expected horsepower from prototype or large unit
hp_1 = horsepower developed by model
D_2 = runner throat diameter for prototype unit
D_1 = throat diameter of model
H_2 = net effective head on prototype unit
H_1 = net effective head on model

The efficiencies of the prototype will be higher than the model efficiencies because of the smaller internal losses of the water flowing through the larger passages. The

Moody formula, which is generally accepted. may be used to determine expected field efficiencies as follows:

$$E_p = 100 - (100 - E_m) \times (D_m/D_p)^{0.20}$$

where E_p = expected efficiency of prototype
E_m = maximum efficiency obtained on model at its best phi
D_m = throat diameter of model
D_p = throat diameter of prototype

The gain in efficiency for the prototype unit, or $E_p - E_m$, is then applied to the efficiency of the model at the phi selected for the prototype unit. The performance of the unit in the field for various heads can be predicted in the same manner by using the phis corresponding to the heads considered.

CAVITATION

Cavitation research is of vital importance both to the turbine industry and to the operating companies, and specially equipped laboratories are used for these studies. Cavitation may be defined as the formation of vapor-filled cavities at points on the runner blades or at any point within the water stream which disturbs the continuity of flow or causes the water to leave the blade surfaces. Cavitation reduces both turbine output and efficiency, and because of the collapse or "implosion" of the cavities where the flow reaches points of higher pressure, it causes pitting of the runner or adjacent parts.

At a given elevation above sea level and a given water temperature, the absolute pressure available is the water barometric pressure. At the runner discharge, this pressure is reduced by

1. The elevation of the runner above tail water
2. The velocity head
3. The curvature of the flow lines

This third element is dependent upon the runner design, particularly on the proportional magnitude of the blade area and the blade spacing, and may differ materially on two runners of the same specific speed. Hence, for any given runner, it is necessary to determine the correct elevation with respect to tail water so as to assure sufficient absolute pressure at the discharge of the runner blades under the required head to avoid cavitation. In the special cavitation laboratories, the elevation of the tail water can be varied while the total head on the model turbine is maintained constant. As the tail water is lowered, observations are made of the discharge, power output, and efficiency; and the break in these curves indicates the cavitation limit. The cavitation coefficient is known as sigma and is given by the formula

$$\sigma = (H_b - H_s)/H$$

where H_b = height of water barometric column at proper elevation above sea level and normal water temperature
H_s = greatest elevation of runner above tail water at which cavitation does not occur with turbine operating at its rated capacity
H = total effective head on unit

It is to be noted that, if cavitation begins while the runner is still below tail water, H_s is negative and represents the least depth of runner below tail water at which cavitation does not occur.

Values of sigma must be determined over the entire range of power and head through which the runner is to be operated. In fixing the elevation of the runner in the field, a factor of safety of from 3 to 4 ft should be allowed, *i.e.*, the value of sigma used in the field should be well above the actual value determined in the laboratory.

From studies made of the behavior of various installations in operation, with particular reference to the avoidance of pitting, the curves shown in Fig. 8-208 may be used as a general guide to the selection of plant sigma values. This curve is presented as an approximate method of determining the elevation of the runner for a proposed installation; but the final elevation should be fixed from the results of cavitation tests made on the model of the runner to be used in the actual installation. As an example for the use of this curve, if we assume a hydroelectric installation where the elevation above sea level is 1,000 ft and the net effective head on the turbine is 300 ft, we can arrive at the approximate elevation of the runner above the low tail-water level in the following manner.

From the approximate formula for determining specific speed as shown on page 579, it will be noted that, for a head of 300 ft, the specific speed should be about 38. For this specific speed, from curve shown in Fig. 8-208, it is noted that the plant sigma should be 0.09. For this elevation above sea level and assuming a water temperature of 70°F, the value of the water barometer H_b is 31.6; and from the formula for sigma shown on page 584, the distance of the runner above tail water H_s is obtained as follows:

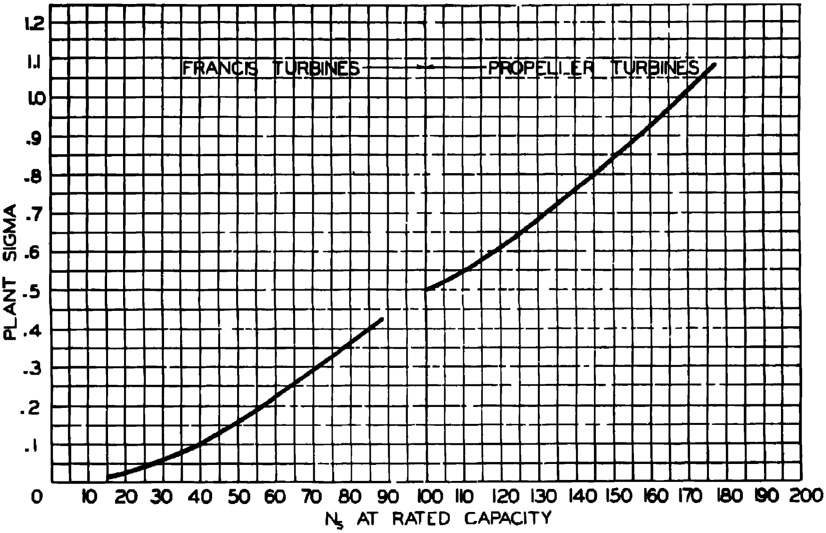

Fig. 8-208. Plant sigma vs. specific speed.

$$H_s = 31.6 - 0.09 \times 300 = 4.6 \text{ ft}$$

In a similar manner, if we assume the installation of a Kaplan-type turbine where the total net head is 48 ft and the plant is located 1,000 ft above sea level, a specific speed of 141 could be used; and using the same formulas, it is found that the runner should be located about five feet below low tail-water elevation.

FIELD TESTING

It is desirable, when possible, to conduct performance tests of turbines at site, as the data thus obtained permits the most economical operation of the units for the various flows and heads to be encountered. Field tests are usually conducted in accordance with the Test Code for Hydraulic Prime Movers of the ASME, originally issued in June, 1938. The present treatise will, therefore, only briefly describe the values to be measured in order to determine turbine efficiency.

The turbine efficiency is the ratio of the brake horsepower delivered by the turbine to the water horsepower available, or

$$E = \text{bhp}/\text{whp}$$

Water horsepower is given by the formula

$$\text{whp} = (Q \times w \times H)/550$$

where Q = flow, cfs
w = weight of water, lb per cu ft
H = effective head, ft

In the case of hydroelectric units, the brake horsepower is determined from the generator output divided by the generator efficiency. The generator efficiency may be determined by tests made in the shops of the builder or after installation, either by direct measurement of input and output or by the separate loss method.

The effective head on the turbine is the difference between the total energy contained in the water immediately before its entrance into the turbine and the total energy in the water immediately after its discharge from the draft tube. As the total energy at any point is the pressure head plus the velocity head, the net effective head on the turbine is given by the following:

$$H = H_p + (V_1^2/2g) + D - (V_2^2/2g)$$

where H_p = pressure head measured at casing intake, ft
V_1 = velocity at point where pressure head is measured, fps
D = distance from point of measurement of pressure head to elevation of the water in the tailrace near the draft-tube discharge at points reasonably free from local disturbances, ft
V_2 = velocity at the section of measurement in the tailrace, fps

The pressure head H_p is usually obtained from calibrated pressure gauges or direct-reading U tubes or elevation tubes. The velocity V_1 is determined by dividing the total flow in cubic feet per second by the area in square feet at the point of measurement, and the velocity V_2 is determined by dividing the total quantity in cubic feet per second by the area of that part of the tailrace channel which may fairly be charged to the unit under test.

The measurement of flow in cubic feet per second is usually considered the most difficult of all factors to be determined. Many different methods of quantity determination have been used, depending on local conditions, such as the Venturi meter, weir, pitot tube, current meters, salt velocity, and Gibson methods. The last two methods have been in general use for a number of years and are considered the most accurate for determining the flow of water. Therefore, a brief description will be given herein in connection with each of these two methods.

Salt-velocity Method. The salt-velocity or Allen method for measuring the flow of water was developed by Professor Charles M. Allen of Worcester Polytechnic Institute, Massachusetts. This method has been very widely adopted in a large number of tests made in this country and many foreign countries. The method is based on the fact that salt in solution increases the electrical conductivity of water. The salt solution is introduced near the upper end of the conduit, and the passage of the solution across one or more pairs of electrodes at other points in the conduit is recorded graphically by electrical instruments. The passage of the salt solution between two points is accurately timed, and the volume of the penstock between the same points is accurately measured. The discharge in cubic feet per second is then equal to the volume of the penstock in cubic feet divided by the time in seconds.

In making such a test, it is necessary to provide for the introduction of the salt solution and for two sets of electrodes and a source of electrical energy, generally 110 volts direct current or alternating current. A recording ammeter or wattmeter is connected in the circuit of the electrodes; and before the salt solution is introduced, the initial steady reading of the meter will be from ½ to 1 amp. When the salt solution reaches the first set of electrodes, the current passing between the bars increases (owing to the greater conductivity of the water), reaches a maximum value, and decreases again to normal as the charge of salt passes by, thus producing a humped curve on the chart. A similar curve is drawn by the meter when the salt solution passes the second set of electrodes. The time is also recorded on the same chart by a clock or seconds pendulum connected electrically to a pen or by a hot spark. The time between the centers of gravity of the two curves produced is the average time it has taken the water to travel the distance between the two sets of electrodes. The volume in cubic feet between the two sets of electrodes is accurately determined by physical measurements, and the quantity flowing in cubic feet per second is the volume divided by the time.

Gibson Method. The Gibson method of water-flow measurement was developed some years ago by Norman R. Gibson, Consulting Engineer for the Niagara Falls Power Company. This method makes use of two well-known principles, the first of which is Newton's second law of motion, that the force is equal to the product of the mass and the rate of change of velocity of that mass, or

$$F = M(dv/dt)$$

This equation may also be written $F\,dt = M\,dv$, which expresses the fact that the impulse or product of force by time is equal to the change in momentum or the product of the mass by the velocity change.

The second principle is the corollary of the first, *viz.*, the relation between the change of pressure and the change of velocity of a column of water expressed in terms of velocity of the pressure waves which are propagated during the change from one end of the column to the other.

To apply this principle to the determination of water quantity flowing in a pipe of uniform cross section, the gates of the turbine at the lower end are closed gradually in a given time, so that the velocity of the water in the pipe is diminished and is finally stopped when the turbine gates are fully closed. During this closure, the pressure in the pipe rises, and this pressure rise is the manifestation of the force exerted to stop the flow of the mass of water in the pipe. From the fundamental impulse equation given above, if the mass of water in the pipe is known and the time taken to stop its flow and the average force exerted in doing so are measured, the velocity of the water prior to the interruption of its flow may readily be determined.

Thus

$$PwaT = (Law/g) \times V$$

from which

$$V = gPT/L$$

where a = area of pipe, sq ft
L = length of pipe, ft
V = velocity of water, fps
T = time to stop flow, sec
P = average pressure rise during time T, ft
w = weight of water, lb per cu ft
g = acceleration due to gravity

The average pressure rise P and the time T are recorded by specially designed Gibson apparatus so that it is necessary only to measure the length L of the penstock to determine the velocity V.

In practice, the test procedure consists of placing the desired amount of load on the unit and, for a period of time, observing the head water elevation, tail-water elevation, casing pressure, speed, gate opening, and the various electrical measurements necessary to obtain the generator output. At a given signal, the turbine gates are closed at a slow rate, and the load is taken up by another unit operating in synchronism with it. The rate of closure need not be uniform, although this operation should take place as smoothly as possible. During the closure, the flow in the penstock is being retarded and produces a change in pressure. A continuous record of this pressure change and the time of closure is made by the Gibson apparatus.

In most installations, the sections of the penstock are not of uniform area, but the penstock is made up of a series of sections of different lengths and different areas. The formula is, therefore, usually expressed in terms of discharge, the net area of the pressure-time diagram, the constants of the apparatus, and the physical dimensions of the penstock, by the following formula:

$$Q = K_g A_d / SF$$

where Q = discharge, cfs
K_g = calibration constant of recording apparatus = g/y

y = vertical height, in., on diagram corresponding to 1 ft of pressure change in the penstock

A_d = net area of pressure-time diagram, sq in.

S = time constant of diagram = horizontal length, in., corresponding to 1 sec of time

F = constant of the penstock. If pipe is of uniform cross section, $F = L/a$. If penstock is of nonuniform cross section, F is the integration of length divided by area

Because of the fact that some leakage always occurs through the turbine guide vanes when in their closed position, this leakage quantity is not cut off by the closure of the gates. The total turbine discharge obtained by the above formula must therefore be corrected by adding the amount of such leakage.

OPERATION OF UNITS IN THE FIELD

Field tests as previously described are of very considerable value to the operating forces at the plant, as from such test data the units can be operated as near their points of maximum efficiency as permitted by the loading. Curves of power discharge may be plotted so that the turbine itself may be used as a measuring device or indicating flowmeter. It is also possible, when making the field tests, to calibrate a flowmeter consisting of a closed U tube, each arm of which is connected by piping to a piezometer in the water passage, where the velocities differ by a reasonable amount. Readings are taken during the efficiency tests on the turbine, and curves may be plotted between the total deflections of the U tube and the discharges determined during the test. Such a calibration curve may be used in station operation for determining quite accurately the flow under any load condition and whether the efficiencies are being properly maintained. A drop in efficiency might be due to wear at the seal rings between the runner and stationary parts or possibly to foreign material wedged in the runner vanes to such an extent as to decrease the flow at a given gate opening.

The data obtained in field tests are also of value in setting the gate limits on the turbine to prevent overloading If turbines are operated appreciably beyond their rated horsepower, there is a drop in efficiency and an increase in discharge beyond the full rated flow. This practice results not only in loss of efficiency but also in pitting on the turbine runners and adjacent parts due possibly to exceeding the cavitation limits.

INSPECTION AND LUBRICATION

Regular inspections of the visible parts of the turbine are usually made once each day or preferably once each shift. Such inspections cover shaft swing, bearing feed, stuffing box, and operating gear.

If the shaft swing increases appreciably, it may be due to bearing wear from lack of proper lubrication or to unbalance in the generator or turbine. Oil-type bearings are usually supplied by two motor-driven pumps, the regular pump being driven by an a-c motor and the emergency pump by a d-c motor from the storage battery. In case of failure of the a-c motor, the d-c motor pump should automatically start up. These controls should be carefully checked at each regular inspection.

In many installations of vertical-shaft turbines, water-lubricated bearings are used. Such bearings consist of strips of lignum vitae or compressed phenolic materials driven into slots in the bearing housing and then bored or ground to the finished diameter to give proper clearance on the shaft. Where the available water supply is reasonably free of foreign materials, such water-lubricated bearings are entirely satisfactory and require less auxiliary equipment than the oil-type bearings. The main stuffing box may be located above the bearing and is, therefore, more accessible for inspection and adjustment than the stuffing box with the oil-type bearing, which must be located below the bearing Furthermore, for water-type bearings, no oil pumps or sump pumps are required One very important consideration, however, for an installation with water-lubricated bearings is an assured water supply at all times. The water may be taken from the ordinary station system if reasonably clear. Otherwise, filtered water should be used. A flowmeter is installed in the feed line with a low flow alarm connected electrically to the station switchboard so as to give the operator immediate notice of water supply below normal. In such an event, the unit should be shut down, either manually or preferably automatically, to prevent damage to the bearing.

Excessive shaft swing may also be due to unbalance in the turbine runner. The runner is usually balanced in the manufacturer's shops before shipment, so when first installed it should operate smoothly. Unbalance at a later date may be due to foreign material becoming wedged between the vanes.

In the main stuffing box, the packing should be adjusted to allow a small leakage at all times to prevent the packing from cutting the shaft sleeve.

The operating gear, consisting of all pins, levers, and links connecting the operating ring to the servomotors, should be free of lost motion due to wear; otherwise the speed regulation will be impaired. If such wear is discovered, the pins and bushings should be repaired or renewed.

Lubrication. The guide-vane bushings and all pin connections between the levers, links, and operating ring are lubricated by a high-pressure grease system. This usually consists of a high-pressure grease gun, operated by air pressure from the station system and connected through reinforced flexible hose to a hand-operated measuring valve and trigger control. Connection is made by the operator to special fittings at each bearing or sliding contact, and a measured amount of grease is forced to each point requiring lubrication. In some plants, automatic lubrication is provided by piping the grease gun to all points and automatically greasing at fixed time intervals.

It is recommended that all parts of the operating gear be lubricated at least once a day and preferably once every shift.

For Kaplan-type turbines, the runner hubs are filled with oil to lubricate the blade-shank bearings. The oil is carried up through a central hole in the turbine shaft to a revolving oil chamber so as to maintain sufficient oil pressure in the hub to prevent leakage of water into the hub. The oil level at the revolving oil chamber should be checked at regular intervals. A falling of this oil level shows loss of oil from the hub, which should be replaced. If such loss is excessive, the unit should be shut down, and the packing at the runner blade shanks adjusted or replaced.

A rise in the oil level at the revolving chamber indicates that water is leaking into the runner hub and forcing the oil up through the shaft hole. Such a mixture of oil and water in the hub would cause damage to the blade-shank bearings, and the water should be drained or forced out of the hub by adding more oil at the filling valve in the shaft.

Inspection of Internal Parts. The first inspection of the internal parts of the turbine should be made within 6 months after starting the machine in initial operation, and thereafter complete inspection of internal parts should be made at least once a year.

The clearance between the runner seals and stationary seals should be checked with feelers. This is of particular importance in connection with high-head turbines, as excess clearance at the runner seals would result in considerable loss in efficiency. Such wear is of less importance in connection with low-head turbines.

Of particular importance in connection with these inspections is the pitting which may occur in connection with the runner and other parts. In the case of Francis-type turbines, such pitting will usually be found just beyond the discharge orifice of the runner vanes, or what is usually known as the "spoon" of the vanes. This is due to the fact that, when the water has left the discharge orifice, it is no longer guided, and the water may leave the back of the vanes, causing points of high local vacuum, resulting in pitting. In connection with Francis-type turbines, it is also found that pitting will sometimes occur on the back of the vanes near the intake edge and extend onto the runner band. This is due very often to the rapid curvature of the runner band near the entrance edge of the vanes.

In the case of propeller-type turbines, pitting is apt to occur on the back of the blades near the outer periphery and toward the trailing edges of the blades. Pitting also occurs in this type of turbine near the runner hub where the blades must be of considerable thickness to transmit the load to the hub.

Pitting also sometimes occurs on the stationary parts near the runner discharge where the velocity is extremely high. Pitting or mechanical wear is also sometimes found on the distributor plates immediately above and below the guide vanes and also on the guide vanes themselves. Such wear is more apt to occur if units are operating at small loads or as synchronous condensers with the casing full of water.

If pitting or wear of the internal parts is severe, repairs should be made by chipping the pitted areas to clean metal and welding with stainless steel. It has been found from experience that stainless steel will resist pitting for a considerably longer period than ordinary cast steel or plate steel. It is for this reason that in many turbines the parts of the runner vanes or blades most likely to pit are prewelded in the shop with stainless steel.

When inspections are made of the internal parts, it is also advisable to check any possible wear in the guide-vane bushings by means of feelers. Such wear is due to the thrust of the water against the guide vanes in the direction toward the center of the unit, or possibly may be due to lack of proper lubrication of these parts.

At the time of these yearly inspections, a complete record should be kept of the wear at the various points and particularly of any pitting which is occurring on the runner vanes or other parts. It is advisable to number the runner vanes and to make sketches showing the location of the pitting and its depth on each vane, so that, in future inspections, comparisons may be made of the increase in pitting or wear each year.

MECHANICAL-DRIVE TURBINES

BY H. D. BEVAN

Philadelphia District Manager, The Terry Steam Turbine Company

PRINCIPLE

The mechanical-drive turbine operates on the same basic principle as the turbine of a large turbogenerator unit. It converts heat energy into mechanical energy. In its simplest form it consists of a single wheel with blades or buckets mounted on the periphery. Steam is expanded through accurately proportioned nozzles which convert the energy in the steam into velocity energy. The high-velocity steam then strikes the blades and causes the wheel to rotate. Figure 8-209 shows the action of the steam in two types of single-stage mechanical-drive turbines. These units, and practically all mechanical-drive turbines, are of the impulse type.

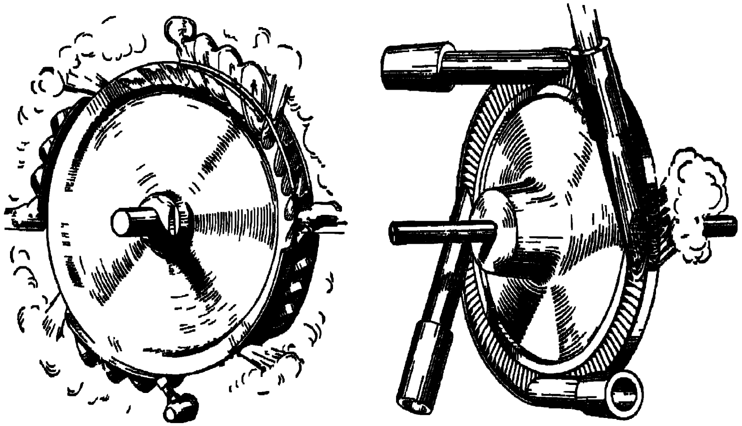

FIG. 8-209

DETAILED DESIGN

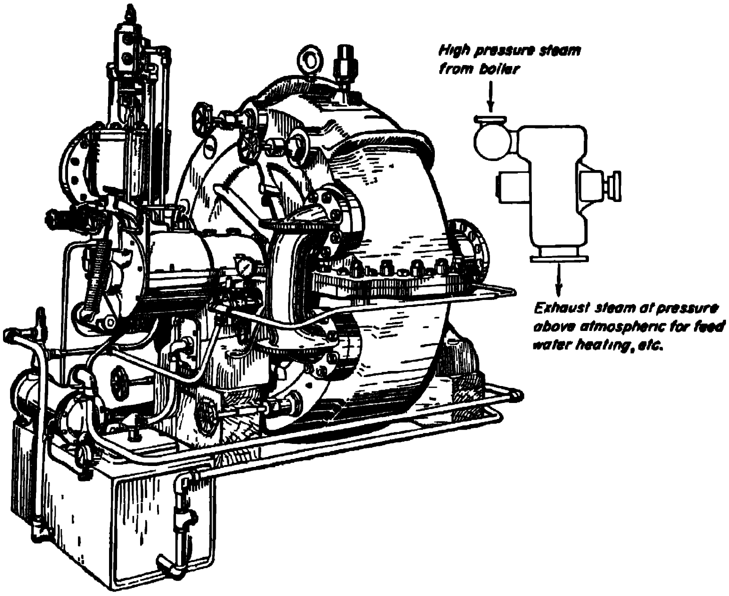
Turbine designs are flexible, and more or less standard machines are built for a wide variety of drives and steam conditions. The design and the cost of a mechanical-drive turbine depend upon the conditions under which it will be used. To submit figures on a turbine, the manufacturer must know:

1. Horsepower required and type of driven machine.
2. Steam pressure which will be available at the turbine inlet and condition of steam at inlet, viz., whether it is dry and saturated, moist and per cent quality, or superheated and deg F.
3. Pressure at turbine exhaust.
4. Speed at which the driven machine will operate and type of governor or control mechanism that will be required.

If occasional low initial pressure, high back pressure, or overload is likely to be encountered, these should be stated so the manufacturer will supply sufficient nozzle capacity. All these could be taken care of by one or more extra hand-valve-controlled nozzles which would permit the turbine to be designed for best efficiency at rated conditions.

If new boilers with higher pressure or temperature are likely to be installed later, consideration should be given to designing the turbine so it can be operated with the new conditions. Under some circumstances it is more practical to install new parts in the turbine when the future changes take place. The manufacturer can make recommendations if he knows the requirements.

5. Any other details or special requirements such as operation as a bleeder turbine, as a mixed-pressure turbine, maximum total steam consumption desired, etc.



High pressure steam from boiler
Exhaust steam at pressure above atmospheric for feed water heating, etc.

Fig. 8-210. Single-stage, back-pressure turbine with oil relay governor, forced-feed lubrication, and hand-valve-controlled nozzles

TYPES OF MECHANICAL-DRIVE TURBINES

Mechanical-drive turbines are used extensively in the boiler plants of all industries, in process plants, chemical plants, oil refineries, paper mills, breweries, etc. They commonly drive equipment such as

Centrifugal pumps—boiler feed, fuel oil, condenser circulating, hot well, fire, general service, etc.

Fans and blowers—forced and induced draft, gas, etc.

Electric generators—auxiliary exciters, emergency electric-generator units, etc.

Miscellaneous apparatus paper machines, coal pulverizers, line shafting, centrifugal compressors and exhausters, centrifugal refrigeration machines, etc.

Back-pressure Turbine. Most mechanical-drive turbines are of the back-pressure or reducing-valve type. They are used where there is a demand for low-pressure steam for feed-water heating, general heating, or for some commercial process.

In installations of this kind the turbine acts as a power-generating reducing valve It reduces the pressure of the steam from that in the boiler to that required for heating or process At the same time it skims off power as a by-product but in so doing extracts only a small percentage (about 10 per cent) of the total heat in the steam. The value of the steam as a heating medium is, therefore, not impaired, and it is not contaminated by oil. The steam charge for this by-product power is approximately 10 per cent of the steam passing through the turbine. This results in extremely high over-all thermal efficiency.

The smaller drives of this type are single-stage turbines (Fig. 8-210). If the heat balance of the plant requires a lower steam rate than is obtainable with a single-stage machine, the more efficient multistage turbine with two or more sets of expanding nozzles and corresponding wheels may be used for some of the larger drives. Figure 8-211 shows the steam path through a machine of this type.

Condensing Turbine. In the condensing turbine steam is expanded through the turbine to a condenser (Fig. 8-212). While the steam rate is lower, a large part of the heat in the steam is given up to the condenser, and heat returned to the boiler in the condensate is a relatively small part of the heat content of the exhaust steam. Figure 8-213 shows the relative heat recovery from a condensing turbine compared to that from a noncondensing or back-pressure turbine.

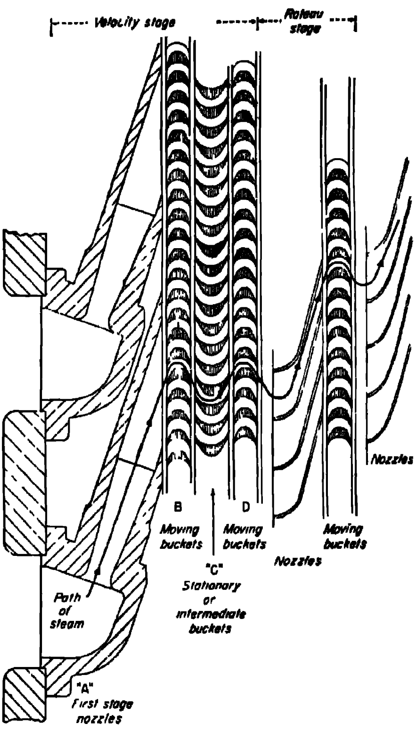


Fig. 8-211. Steam path through a multistage turbine.

Since the steam is expanded to a lower pressure in a condensing machine, there is more heat available for making power than with a back-pressure turbine. To utilize this energy efficiently it is generally necessary to use a multistage turbine. Such a turbine is considerably more expensive than a single-stage unit, and there is an added investment for a condenser, pumping equipment, etc., which is difficult to justify for small installations.

For installations where it is desirable to operate condensing at low first cost, single-stage condensing turbines may be installed. Care must be used in selecting a single-stage turbine for condensing operation, however, since the high heat drop and consequent high steam velocity through the turbine may cause rapid blade wear.

Condensing turbines are sometimes installed to operate in conjunction with back-pressure turbines. The back-pressure machine is operated when steam for heating is needed, and the condensing turbine is used when no exhaust steam is required.

Bleeder Turbine and Mixed-pressure Turbine. The bleeder turbine combines the advantage of the back-pressure turbine with that of the condensing turbine (Fig. 8-211). High-pressure steam is admitted to the turbine and, after being expanded to the required pressure through one or more stages and making power, is extracted from the turbine casing for process or heating. If the quantity of steam extracted is not sufficient to develop the full horsepower required, additional steam is expanded through the low-pressure stages of the turbine to a condenser, and this portion of the power is made with a low water rate. Such a machine will take care of plants where the power and process steam loads do not vary up and down together.

The bleeder turbine is fitted with a valve gear to maintain the required bleeder pressure automatically.

In some installations, instead of having a condensing low-pressure end, the bleeder turbine is built to exhaust at a back pressure above atmospheric but below bleeder pressure (Fig. 8-215). This type of turbine could be used in a plant requiring process steam at 75 lb gauge pressure, for example, but with an additional heating load at 5

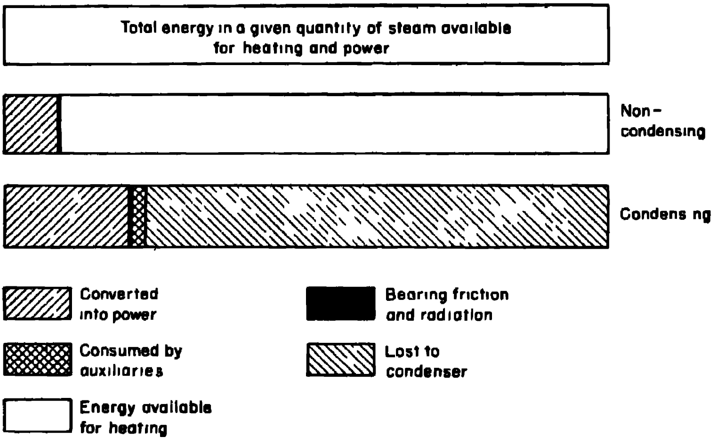

Fig. 8-213

lb gauge pressure Such a machine, however, would not be profitable for a bleeder pressure of 15 lb with a secondary requirement for steam at 5 lb For such conditions a straight back pressure turbine exhausting at 15 lb should be used

The bleeder turbine is not often built in sizes below 500-hp since its initial cost is too high when compared with the savings that can be obtained with lower horsepower ratings

The bleeder turbine is also built as a mixed pressure or mixed-flow unit (Fig 8-216) This is similar to the straight bleeder turbine, but in addition to bleeding steam, the valve gear is arranged to admit any surplus steam from the process line to the turbine low-pressure stages. With this flexible installation it is possible either to bleed steam to or absorb steam from the process line. The valve gear takes care of

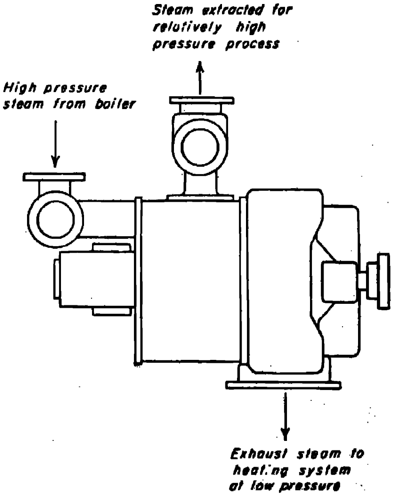
Exhaust steam to a condenser

FIG. 8-214. Partly assembled 12-stage bleeder turbine which bleeds steam after the fifth stage.

this extraction and absorption automatically. The steam passed in or taken out of the turbine is determined by the steam pressure in the process line.



Steam extracted for relatively high pressure process
High pressure steam from boiler
Exhaust steam to heating system at low pressure

Low-pressure Turbine. Low-pressure turbines, in general, operate with initial steam pressures at or slightly above atmospheric and exhaust to a condenser (Fig. 8-217). The energy available in 1 lb of steam at atmospheric pressure expanded to 28 in. Hg vacuum is approximately the same as for steam expanded from 150 lb gauge to atmosphere.

Plants with a reasonably constant amount of surplus low-pressure steam can convert it into mechanical power with this type of turbine. The turbine is much larger than a high-pressure machine, has more stages, and requires a condenser. Therefore, it has a high installation cost. It can often make very attractive savings in spite of this fact, however.

If the low-pressure steam supply is erratic, a mixed-pressure machine should be used. In the mixed-pressure turbine, low-pressure steam is absorbed and converted into power; if there is not enough low-pressure steam to carry the load, high-pressure steam is automatically admitted to the turbine to maintain the power output.

MAXIMUM PRESSURE AND TEMPERATURE CONDITIONS

Most steam turbines are so constructed that in emergencies they will withstand increased initial pressures of 10 per cent or 50 lb gauge, whichever is lower. They are also constructed so that in emergencies they will withstand increased initial temperatures of 25°F for periods not exceeding 15 min in duration and which do not occur more than twice in 24 hr.

Manufacturers design machines for various initial steam-pressure and temperature classifications as shown in Table 8-64.

Table 8-64*

Initial steam pressure, psi gauge	Initial steam temperature, deg F					
	Up to 500	501–600	601–750	751–825	826–900	901–950
250 and lower	x	x	x			
251 400	x	x	x	x		
401 600		x	x	x	x	
601 900			x	x	x	x
901–1500				x	x	x

PERFORMANCE

Water Rate. Steam-turbine performance is indicated by water rate (or steam consumption) which is expressed in pounds per brake horsepower per hour. Calculations usually involve total steam flow in pounds per hour, which is brake horsepower multiplied by water rate.

Manufacturers determine water rates from actual test data. Since steam conditions, horsepower, speed, and turbine type all affect water rates, no attempt is made here to indicate them. Manufacturers' data should be consulted for this information.

Heat in Exhaust Steam. For heat-balance calculations it is necessary to determine the Btu contained in the turbine exhaust steam. The amount of heat exhausted from a turbine cannot be determined directly from steam tables. The heat per pound of exhaust is equal to the total heat of the steam when it enters the turbine, minus the heat loss due to radiation and minus the heat utilized in making power. A convenient formula for determining the heat in the exhaust steam is

$$H_L = H_1 - \left(H_R + \frac{2{,}545}{\text{Water rate, lb/bhp-hr}}\right)$$

where H_E = Btu per lb of exhaust steam

H_1 = total heat of steam, Btu per lb at turbine-inlet conditions

H_R = heat radiated, Btu per lb

For H_R, a close approximation is 3 per cent of the difference between the total heat of the steam at the turbine inlet steam condition and the total heat at the turbine exhaust pressure after adiabatic expansion (constant entropy).

Temperature of Exhaust Steam. Turbine-exhaust steam temperature is determined on the Mollier chart at the intersection of the exhaust-pressure curve and Btu per pound of exhaust steam.

Efficiency. Theoretical water rate in pounds per horsepower-hour is equal to

$$2{,}545/(H_1 - H_2)$$

where 2545 = Btu equivalent of 1 hp

H_1 = total heat of steam in Btu per lb at turbine-inlet conditions.

H_2 = total heat of steam in Btu per lb at turbine-exhaust pressure after an adiabatic expansion (at constant entropy)

$$\text{Thermal efficiency} = \frac{\text{theoretical water rate}}{\text{actual water rate}} \times 100$$

Rated-load Water Rates. Water rates are usually given at rated-load and rated-steam conditions. Nozzles are selected for a steam-chest pressure which allows for the pressure drop through the turbine governor valve. Therefore, the steam-chest pressure is close to the inlet pressure when the turbine is operating at rated conditions, and high nozzle efficiency is obtained.

Partial-load Water Rates. At loads under rating the turbine will overspeed unless the steam flow is reduced by the governing valve. When the flow is reduced, the steam-chest pressure, the effective heat in the steam, and the nozzle efficiency are lowered, and water rate is increased at the lighter load.

Hand-valve Control at Partial Load. Hand valves to close individual nozzles can be supplied. Closing one or more of these valves at partial load reduces the total nozzle area, and therefore, more governor-valve opening is required. This raises the steam-chest pressure ahead of the nozzles so it is closer to the design pressure, and improved efficiency and water rate are obtained. A turbine can be designed with hand-valve-controlled nozzles to permit it to carry a peak load without sacrifice of efficiency at the lower normal load.

The dotted line in Fig 8-218 is a typical water-rate curve for a mechanical-drive turbine operating at constant speed with governor or throttling control. The effect of closing successive hand-valve-controlled nozzles is shown by the solid line

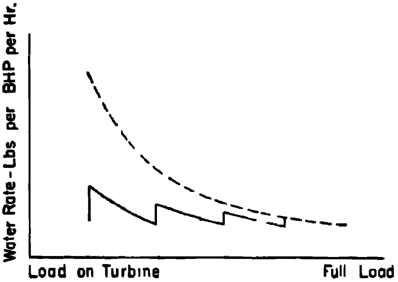

FIG. 8-218.

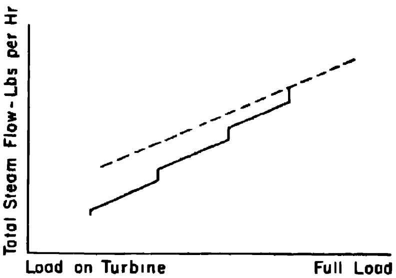

FIG. 8-219.

Figure 8-219 shows total steam flow for the same machine; solid line shows the effect of closing hand valves.

SELECTION

Heat Balance. Selection of a turbine generally depends on heat balance. Steam is required in all boiler plants for heating feed water Industrial boiler plants built to supply process steam can use turbines to drive auxiliaries such as boiler feed pump, forced- and induced-draft fans, pulverizers, etc. It is necessary only to choose turbines which will not supply exhaust steam in excess of feed-water heating or other process-steam requirements.

In chemical plants, oil refineries, etc., where initial steam pressures are 400 lb or above, mechanical drives are sometimes employed which exhaust to process-steam lines at pressures as high as 200 lb A single-stage turbine can be used, but since first cost is higher where back pressures are above 75 lb gauge, these types cannot be used economically, as a rule, in sizes below 200 hp

In plants of this type, fire hazard may be reduced by using turbine drive.

Starting and Emergency Drives. Central stations and industrial plants generating electric power frequently install steam-turbine drives for starting or emergency service These machines will not be operated for long periods, so water rate is seldom an important consideration. Such turbines may drive boiler feed pumps, emergency exciters, etc.

This type of drive should be simple, rugged, and capable of being started without preliminary warming up In general, all mechanical drives should be selected on this basis if possible, and the more complicated multistage type of turbine should be used only where a low water rate is required.

APPLICATION

Turbines are most efficient when operated at relatively high speeds. Standard designs range in speed from 1,000 to 5,000 rpm Below 1,000 rpm the ordinary mechanical governor furnished on a turbine will not control the speed closely. Also, at the lower speeds water rates are high In general, for slow-speed driven equipment it is necessary to use a high-speed turbine with a reduction gear. Turbine speeds above 5,000 rpm are common, but special construction at higher cost may be required.

Governors. Turbine speed is controlled by a governor that positions the turbine inlet or governor valve. Some driven machines run at constant speed, others operate at varying speed depending on load, etc. Different governors are available for taking care of driven-machine speed-control requirements.

Direct-acting Centrifugal Governor. This governor is of the flyball type and is commonly called a constant-speed governor (Fig. 8-220). It is standard equipment on most mechanical-drive turbines. It consists of governor weights A mounted on the turbine shaft. Centrifugal force of the governor weights is opposed by a spring. An increase in speed above that for which the governor is set causes the weights to move apart, and their movement closes governor valve B through the governor lever.

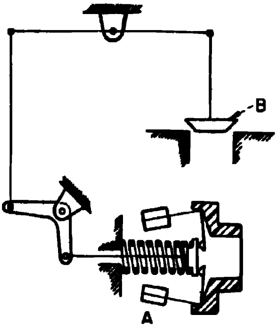

Fig. 8-220.

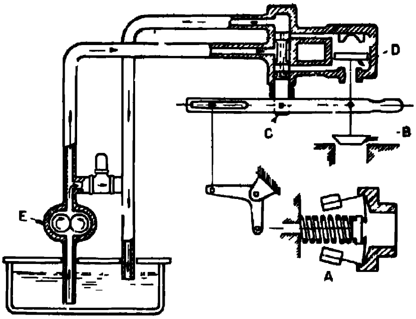

Fig. 8-221.

This governor is usually sufficient to control satisfactorily the smaller turbines that drive pumps, fans, pulverizers, etc.

Oil Relay Centrifugal Governor. The oil relay governor operates on the same principle as the direct-acting type (Fig. 8-221). However, instead of moving the governor valve directly, the governor weights actuate an oil pilot valve C which puts oil pressure on piston D to open or close governor valve B. As soon as the governor-valve position is changed, the pilot valve returns to its neutral position, and the governor valve does not move again until there is another impulse from the governor weights This compensation, together with the short travel of governor weights and pilot valve, results in speed regulation of about three per cent. In addition to being used where close speed regulation is needed, the oil relay governor is required on turbines with large governor valves and often for initial steam pressures above 650 lb.

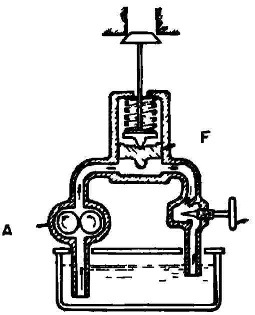

Fig. 8-222.

Oil pressure for operating this governor is supplied by a turbine-shaft-driven oil pump.

The direct-acting and oil relay centrifugal governors can be arranged to permit a small speed adjustment while the turbine is in operation, but this will not exceed 10 to 20 per cent.

Direct-acting Variable-speed Oil Governor. The direct-acting variable-speed oil governor is used on turbines driving machines that require variable-speed operation (Fig. 8-222). The speed of the turbine can be set at any operating point (within the speed range of the governor) while the unit is running. A turbine-shaft-driven oil pump A_1 supplies oil pressure to governor valve operating piston F and discharges back to a reservoir through adjustable orifice valve G. With the orifice valve set for the desired speed, the oil pump maintains just enough oil pressure at F to keep the governor valve sufficiently open to carry the load on the turbine. If the speed increases slightly, there is an immediate and corresponding increase in the oil pressure which causes the governor valve to close slightly and restore the speed. Speed is changed by adjusting orifice valve G.

Speed control may be obtained by the following methods:

Hand control as in Fig. 8-222
Motor-operated control from a remote point
Pressure-operated control by a regulator
Mechanical linkage control

Speed regulation with this type of governor is approximately ten per cent.

The direct-acting variable-speed oil governor can be arranged to permit a speed range as high as five to one, provided the turbine shaft speed is reasonable at the low operating point.

Oil Relay Variable-speed Governor. The oil relay variable-speed governor is used on turbines driving large centrifugal compressors, pumps, etc., where variable-speed operation is necessary and when close speed regulation is required (Fig. 8-223). The principle of operation is the same as that of the direct-acting variable-speed oil governor, but instead of moving the governor valve directly, piston *F* operates pilot valve *C* through which oil is applied to piston *D*. Two turbine-shaft-driven oil pumps are required by this governor. Methods of speed control are the same as for the direct-acting oil governor.

This governor can be built for a wider speed range than the direct-acting type.

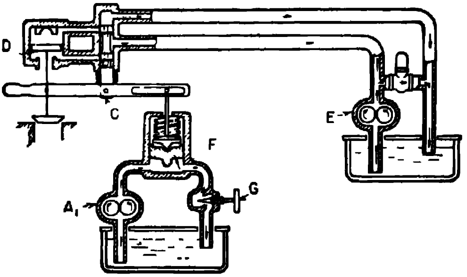

FIG. 8-223.

Emergency Overspeed Governor. All turbines should be equipped with an emergency overspeed trip to reduce the steam supply to the turbine and prevent overspeeding. Usually this governor is set to trip at 10 to 15 per cent overspeed.

When an oil governor is used, it is desirable to supply circulating oil to the turbine-shaft bearings from the governor oil pump.

Selection and application of mechanical-drive turbines vary according to driven-machine requirements.

Boiler-feed-pump Drive. The turbine should be simple, reliable, and capable of being started without preliminary warming up. Usually, efficiency is not paramount since exhaust steam will be utilized for heating feed water, or the unit will be an emergency stand-by to an electrically driven pump. The turbine drive should be rated a little above required pump brake horsepower to allow for gradual pump-impeller wear.

Hand Valves. In general, hand valves are not useful on boiler-feed-pump-drive turbines. These units operate over a wide load range, and an operator should not be expected to open and close hand valves whenever the load changes. Water rates at partial loads, therefore, should be figured without the use of hand valves. However, a hand valve may be justified for an infrequent overload condition. Also, there are installations where an extra hand-valve-controlled nozzle is necessary to develop the required power when starting the plant at low boiler pressure.

Control. The turbine should be equipped with a standard constant-speed governor, and it should also have an emergency overspeed trip.

Automatic control may be obtained by fitting the turbine with a differential pressure governor. This type of governor maintains a constant differential between discharge pressure of the boiler feed pump and steam pressure in the boiler. In principle, it consists of a diaphragm-operated steam-supply valve with pump discharge pressure connected to the upper side of the diaphragm and steam pressure connected to the lower side with a spring to balance the two pressures. An increase in pump discharge pressure on the diaphragm will tend to close the steam-supply valve and reduce turbine speed and, therefore, pump capacity. At loads under rating, the pump will require less power for a given capacity if the speed is reduced.

It is preferable that water and steam connections of the pressure governor be connected to water and steam lines close to the boiler in order to keep the differential as low as possible and to minimize the effect of pipe friction for varying boiler loads.

If a turbine-driven boiler feed pump feeds only one boiler, this governor may be connected across the boiler water-level control valve. The water side of the diaphragm would be connected near the valve inlet and the steam side between the outlet and the boiler.

With the three governors, the pump would be controlled by the differential pressure governor, the constant-speed governor would be set at a speed a little above the maximum required and the emergency overspeed trip about 10 per cent higher. If the differential pressure governor becomes inoperative and opens wide, the constant-speed governor will act as a speed limit and prevent the overspeed governor from shutting the unit down. The differential pressure governor can be built into the turbine, or it may be installed in the steam line ahead of the turbine.

Where a turbine-driven boiler feed pump is to operate in parallel with a motor-driven pump, the two units must run at approximately the same speed in order to divide the pumping load, and a differential pressure governor will not be useful on the turbine.

Boiler Fan Drive. Many forced- and induced-draft fans are turbine-driven. Where the exhaust steam can be used for feed-water heating or process work, turbines are economical drives. In addition, variable speed, which is usually essential, can be obtained easily with turbine drive by throttling the steam supply.

The drive must be selected for the horsepower and speed of the fan, and it must be capable of developing the required power with the low steam pressure which may prevail when the boiler is started. Also, it is frequently necessary to have additional capacity so that the fan unit will perform satisfactorily with lower than design air or gas temperatures.

Smaller fans, and particularly forced-draft fans, are often direct-connected to turbine drives. Induced-draft fan drives and duplex units with forced- and induced-draft fan wheels on the same shaft run at speeds around or below 1,200 rpm, and it is frequently necessary to use a high-speed geared turbine, so the steam required to drive the turbine will be within the heat balance limitation.

The reduction gear must be selected for the type of fan it is to drive. Induced-draft-fan-drive service is more severe than forced-draft-fan drive. When a coupled gear is used, turbine and gear should be mounted on a common base plate so that alignment will be maintained.

Hand Valves for Overload. One or more extra hand-valve-controlled nozzles can be provided to give the extra power required when the fan handles air or gas at low temperature and for starting with low steam pressure. This will permit good efficiency at the normal rating.

Partial-load Hand Valves. Most fans operate at loads under normal rating. Considerable steam saving can be made by closing hand valves at partial loads when the horsepower requirements are lower and fan speeds are correspondingly reduced.

Control. It is desirable to control fan capacity by varying the speed because at reduced loads the fan power requirement is less than if it runs at full speed with the control obtained by dampering. To lower the speed of a turbine it is necessary only to reduce the steam flow. This can be done by hand operation of a valve in the steam line, by combustion-control operation of a valve in the steam line, or by changing the speed setting of a variable-speed turbine oil governor by the combustion control. Usually hand control is used only on smaller installations. Satisfactory results are obtained with an automatic combustion-control valve installed in the steam line, but generally a damper is required also. Use of a damper is minimized with the variable-speed turbine oil governor because the combustion control sets the speed of the turbine directly, and steam flow to the turbine is controlled to maintain speed (within the capacity of the turbine) regardless of changes in load and initial steam pressure or back pressure. The variable-speed oil governor is relatively expensive and usually requires a fairly large drive to justify the extra expense.

Generally, it is not desirable to connect the combustion-control system direct to the main turbine governor valve. The travel of this valve is short, for the full speed range and lost motion in the connecting linkage will not permit the small valve adjustments required at light loads.

Some kind of control should be provided to shut off fuel in the event that the induced-draft fan stops. In general, the induced-draft-fan drive will be running as long as there is steam pressure in the steam chest ahead of the turbine nozzles. A pressure control can be connected to the turbine steam chest which will operate to trip the fuel supply if this pressure goes below a predetermined point.

Pulverizer Drive. Turbines that drive coal pulverizers are direct-connected or geared depending on the amount of exhaust steam that can be absorbed. When a geared unit is employed, the gear must be selected specifically for pulverizer drive since this is rougher than the usual drive. Furthermore, coal pulverizers require a drive with a high starting torque, and this starting torque should be specified.

Hand Valves. One or more extra hand-valve-controlled nozzles should be supplied. The high starting torque must be provided for, and furthermore, the turbine must be capable of developing this torque with low boiler pressure when the plant is started. These hand-valve-controlled nozzles allow best efficiency at the normal load and at the same time provide necessary overload capacity. Partial-load hand valves are not usually required.

Control. A pulverizer runs at constant speed, and usually a mechanical constant-speed governor and separate emergency overspeed trip are sufficient to control the driving turbine.

Provision should be made to shut down the pulverizer (and the forced-draft fan) in the event that the induced-draft fan stops. For the pulverizer turbine this may be accomplished by installing a valve in the steam-inlet pipe arranged to shut off the steam automatically when the induced-draft fan stops.

Auxiliary Exciter and Emergency Electric-generator Drive. Auxiliary exciter and emergency electric-generator drives usually are required only for emergency power. The turbine should be as simple as possible and should be capable of starting without preliminary warming up. A single-stage turbine should be used unless the unit is likely to be operated for considerable periods of time when excess exhaust steam might be a problem. A multistage turbine would not be used, ordinarily, on an exciter drive but might be used to drive an emergency electric generator. However, this type cannot be started so quickly as the simpler single-stage turbine. Some single-stage machines can be started automatically if necessary, with a solenoid valve in the steam line ahead of the turbine. For such an installation the exhaust valve should always be kept open and the casing and steam-inlet pipe drained at all times.

Hand Valves. These types of units may have to start and operate with reduced boiler pressure, so one or more extra hand-valve-controlled nozzles should be provided.

Control. A mechanical constant-speed governor is usually satisfactory for generator drives up to 50-kw capacity unless close regulation is required. For larger capacities, an oil relay governor is required in order to avoid excessive speed change and voltage variation with the heavier electrical loads.

Paper-machine Drive. Turbine units can drive either variable-speed or constant-speed paper-machine line shafts. The drive usually consists of a high-speed turbine connected to a reduction gear which can be coupled or belted to the line shaft. If belted, the driving pulley should be mounted on a separately supported jackshaft with a flexible coupling connecting it to the slow-speed gear shaft. This eliminates belt pull on the reduction-gear bearings. Sometimes a drive is installed in the middle of a line shaft with the slow-speed gear shaft of the drive unit extended in both directions. For small drives this type may be too expensive because the gear must have a large center distance in order for one slow-speed shaft to clear the turbine casing. This drive is simple, relatively inexpensive, and it supplies steam necessary for drying paper. When higher speed is contemplated on an existing paper machine, a new turbine is the least expensive drive, takes up little space, and a heavy foundation is not required. Turbine exhaust steam is as free of impurities as boiler steam, and an oil separator is not required.

Partial-load Hand Valves. Since the exhaust steam from the turbine is used for drying paper, the amount required (and also the mechanical load on the turbine) will vary for different grades of paper. The turbine should be equipped with partial-load hand valves, so best efficiency can be obtained for any weight of paper.

Overload Hand Valves. It is advisable to include one or more extra hand-valve-controlled nozzles for overload at starting or low steam pressure.

Control—Variable- and Constant-speed Line-shaft Drive. Variable-speed line-shaft drive requires close speed regulation to prevent paper thickness variation or possible paper break. An oil-relay variable-speed governor must be provided, and on most installations a governor adjustable over a six to one speed range will be satisfactory. The governor-speed setting should be adjustable by hand at the turbine itself, and if desired, the unit can be equipped with a remote push-button-controlled motor-operated speed-changing device.

A push-button-operated solenoid on the emergency overspeed governor can be supplied. This device permits shutting down the turbine in emergency from a remote operating point.

The less expensive oil relay constant-speed governor is sufficient to control the constant-speed line-shaft type of drive.

Centrifugal-compressor Drive. A turbine is efficient at usual centrifugal compressor or exhauster speeds, and these units are direct-connected. Compressor load varies with speed. Therefore, automatic control of a turbine-driven unit is relatively simple. These units require substantial power, and multistage condensing, bleeder, mixed-pressure, and low-pressure turbines, in addition to the back-pressure type, are economical drives in many cases.

Low-pressure condensing turbines can make power for summer air conditioning from low-pressure or exhaust steam that is wasted when there is no building heating load.

When more than one refrigeration compressor is required, as in a brewery or chemical plant, good heat balance may be obtained sometimes with one compressor driven by a single-stage reducing-valve type of turbine and a second compressor driven by a condensing mixed-pressure bleeder turbine. This type of installation permits efficient operation with the relatively steady compressor power demand but takes care of wide fluctuations in process-steam requirements. Both machines exhaust to the process-steam line, and if too much steam is supplied, the valve gear on the mixed-pressure bleeder turbine admits surplus to the low-pressure stages, and power is made with a low condensing water rate.

New centrifugal air-conditioning or refrigeration equipment adds considerably to the power load of any plant. A turbine drive for new equipment of this type should be considered when there is sufficient boiler capacity to take care of the added steam load and if electric drive will load plant-generating capacity so much that there is little margin for expansion. Turbine drives are much less expensive than new generating capacity.

Water is required by the condenser of a centrifugal-refrigeration or air-conditioning unit. Usually, the same water is sufficient to condense all exhaust steam when a condensing turbine is used.

Hand Valves. Partial-load hand valves should be supplied on all but low-pressure, bleeder, and mixed-pressure turbines. Bleeder and mixed-pressure turbines probably should be equipped with automatic nozzle control or sectional inlet valves, although this depends on the character of the process steam and refrigeration loads.

Control. An air-conditioning or refrigeration compressor-drive turbine should have a variable-speed oil governor. The unit can then be arranged so that refrigerant temperature will actuate a small control valve in the turbine-governor oil line to vary the turbine speed automatically and, therefore, the compressor capacity in accordance with refrigeration requirements.

Gas compressors and exhausters can be controlled in a similar manner when the driving turbine is equipped with a variable-speed oil governor.

Dual Drive. Oil-refinery pumps, exciters, etc., that must operate continuously are sometimes dual driven with a turbine at one end and an electric motor at the other. If power fails when the unit is electrically driven, the turbine automatically takes over the drive at slightly reduced speed.

Dual drive may be used for automatic heat balance since the driven load can be divided in any proportion between motor and turbine, depending on the amount of exhaust steam required.

A dual-drive turbine to be installed only as protection against motor failure can sometimes be selected for a capacity less than the rating of the driven machine. For example, an emergency turbine driving an oil-refinery pump could be designed to develop only enough power to maintain sufficient liquid flow to prevent damage to other equipment.

Control. The turbine must be equipped with a constant-speed governor which is adjustable during operation. With the motor driving, the turbine governor is set just below rated speed. On failure of the electric drive, the turbine-governor valve opens, and the turbine drives at slightly reduced speed. To restore speed, the turbine governor must be reset.

If required, the turbine governor may be solenoid-operated so it will take over the load at rated speed on failure of the motor.

It is usually necessary to bleed a small quantity of cooling steam into the turbine casing when the unit is motor-driven.

The exhaust valve of a dual-drive turbine must be open at all times.

INSTALLATION

Foundation. A turbine does not require a massive foundation, and it is usually necessary only to have rigid support for the equipment. Foundation size and weight will depend on the unit being supported and whether it is on the ground or on a floor. If on the ground, the foundation should be isolated from the building floor. Small units are frequently mounted on concrete pads built into strong concrete floors. The floor and pad must be substantial enough to keep the turbine and driven machine in line.

Turbine units are often supported on steelwork. The structure design must not permit alignment of the machines to be disturbed by possible springing. Building a concrete pad under the unit base plate will add stiffness and help to absorb any vibration or noise.

Turbines may be mounted directly on concrete foundations, provided soleplates to go under them are set in the concrete. Steel plates with bolts extending down into the concrete are satisfactory, and sections of channel or I beam are used also. Accurate alignment can be obtained by putting shims between the turbine and the soleplate. Machines should be bolted and, after alignment, doweled to the soleplates. They should never be set directly on the concrete.

Foundation bolts to hold a base plate should be provided with pipe sleeves. These bolts should not be set rigidly in the concrete since some movement of the base plate will be required during alignment.

Alignment. High-speed machinery will not operate satisfactorily if the shafts are not in good alignment. Flexible couplings are not universal joints. Shafts must be lined up as exactly as possible, so the flexible coupling will only be required to compensate for the slight unavoidable misalignment which may occur during operation. Alignment of shafts can be determined by laying a straightedge across the rims of both coupling halves.

Units are lined up cold, and a turbine, when hot, will usually rise more than the driven machine. Therefore, a turbine is usually set lower than the driven machine, with the vertical distance between shafts depending on the drive and size of the unit. A boiler feed pump may be almost as hot as its driving turbine, so the two shafts should be more nearly in line when units are cold. In some cases the steam end of the turbine will rise more than the exhaust end, and it is necessary to allow for this tilting when lining up the units cold. This condition may occur with condensing turbines. The alignment should always be checked when the equipment is hot and any necessary final adjustments made then.

Clearances between coupling faces must be such that the two shafts will not bump. Normally, this clearance will vary between 1/8 and 1/4 in. depending on the machines and type of coupling. More clearance may be required with some equipment such as induced-draft-fan drives, for example, which operate with shafts at high temperature.

Sometimes a turbine and its driven machine are aligned on a common base plate at the manufacturer's plant, and the units are doweled in place. No matter how heavy it is, a base plate will deflect, and it is necessary to line up the units after the whole assembly is placed on the foundation. In such a case the base plate should be supported on the foundation by metal wedges, allowing about an inch for grouting. Foundation bolts should be in place but not tightened. Units should be uncoupled. The wedges can then be adjusted until the machined pads on the base plate are level. The alignment should then be checked at the coupling halves, and if not accurate, the wedges can be adjusted to bring the units into proper alignment. After this has been done, the base plate may be grouted in place. The foundation bolts should not be tightened until the grouting has set. A unit consisting of two or more machines on a common base plate must not be grouted in place until it is accurately lined up as indicated above.

Steam and Exhaust Piping. Turbines are furnished with standard inlet and exhaust connections, and steam pipes are larger or smaller than these depending on turbine steam requirements. Pipe sizes must be figured with allowances for pressure drop due to length of pipe, number of valves, fittings, etc. Turbines are rated with steam pressure at the turbine-inlet flange and back pressure at the exhaust outlet. Low initial steam pressure or high back pressure at the turbine, due to small steam pipes, will reduce power and increase water rate.

Steampipe. A throttle valve should be installed in the steam line near the turbine inlet. If the steam is moist, a steam separator should be placed in the steampipe close to the turbine. Excessive moisture in steam will cause rapid blade wear. All multistage turbines, all low-pressure turbines, and all turbines operating with high-pressure saturated steam (400 lb and above) should have a separator.

Exhaust Pipe. A shutoff valve should be installed in the exhaust line near the turbine, and to protect the turbine casing which will not withstand full inlet pressure, an atmospheric relief valve should be installed between the turbine and the shutoff valve.

Steam- and exhaust pipes should be blown out before they are connected to a turbine.

Pipe Strains. Pipes should be arranged and supported so that strains due to weight or expansion will not be imposed on the turbine. Where piping cannot be so arranged, an expansion joint must be provided next to the turbine. This is almost always required in a large exhaust pipe. Alignment should be checked when hot to make sure that the piping does not distort the turbine casing.

Small Auxiliary Piping. *Drains.* Drains must be provided in the steampipe ahead of the throttle valve and in the turbine casing. All turbine casings are drilled and tapped for a drain, and a short length of pipe with a valve at the end, which allows a free blow, is usually sufficient.

When steam is wet, the turbine casing should be trapped to prevent water accumulation during operation. Blades will wear rapidly and may be broken off if run in water; also, wheel forgings are likely to be damaged.

Water Cooling. If turbine bearings are provided with water cooling, the water inlet pipe must have a valve to control the flow, but the outlet should be free. It is customary to connect water jackets or coils in series.

Glands. Most mechanical drives employ carbon ring glands to prevent steam from leaking along the shaft (Fig. 8-221). When operated with back pressure, no sealing is required, and the leak-off pipe from each gland should be open to atmos-

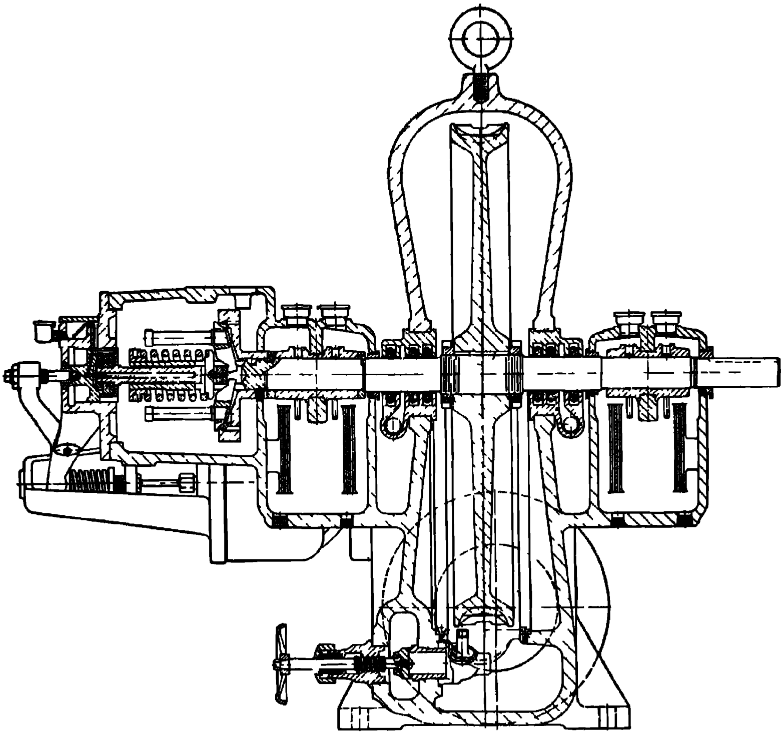

FIG. 8-224. Section through small single-stage turbine showing carbon ring glands and leak-off connections.

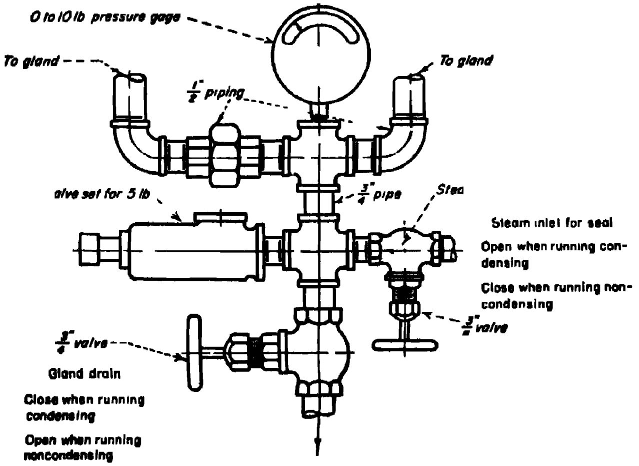

FIG. 8-225. Typical steam-seal piping arrangement for carbon ring glands on condensing turbine.

phere. A valve should not be installed in these lines, nor should they be connected to any other steam line which might cause pressure to build up in the glands and force steam out along the shaft and into the bearings.

Condensing turbine glands require steam sealing. Low pressure steam at not over 5 lb gauge pressure is connected to the leak-off space of each gland. It is desirable to control this pressure with a reducing valve or by a relief valve in the gland seal piping (Fig. 8-225).

OPERATION

Lubrication. A good turbine oil must be used. Turbine bearings run at higher temperatures than those on other types of equipment since they absorb heat from the shaft and the turbine casing in addition to that of the friction load. The manufacturer's recommendations should be taken, but in general, the following tabulation indicates the viscosity range for different bearing temperatures. Viscosities are given for ring-lubricated bearings and for forced-feed or pressure-lubricated bearings.

Table 8-65. Viscosity Ranges for Different Bearing Temperatures

Operating temperature of oil in bearing	*Viscosity SSU*
Ring Lubrication	
Up to 200°F	225–350 at 100°F
Over 200°F	115–150 at 210°F
Forced-feed Lubrication	
Without reduction gear	150–160 at 100°F
With reduction gear	
Up to 180°F	250–350 at 100°F
Over 180°F	100–580 at 100°F

For a turbine and gear unit with a common pressure-lubricating system the lubricant should be selected to suit the gear.

First Run. The manufacturer's instructions should be read carefully, so that the function of all essential parts is understood.

Before starting a new turbine, or one that has not been used for a considerable period of time, the machine must be thoroughly cleaned. All working parts should be wiped clean. The bearings, oil reservoirs, and any oil piping should be flushed with kerosene. Main bearings and other oil reservoirs, including flexible couplings of the lubricated type, should be filled with oil to the proper level. The machine should be rolled over by hand and the governor valve moved to make sure the rotor does not rub and the valve does not stick.

The exhaust valve and all drain valves should be opened. Water should be turned on for any water jackets or cooling coils. The throttle valve should be cracked open to warm the machine and to turn it over slowly. Drains may be closed as soon as water stops running from them. The oil rings should be inspected to make sure that they revolve. If there is a shaft-driven oil pump on the turbine, the pressure should build up quickly as the speed increases. If the unit appears to operate satisfactorily, the throttle valve may be opened gradually and the unit brought up to rated speed. Bearing temperatures should be checked frequently. If bearings run hot, the units may be improperly aligned, or there may be dirt in the bearings.

The speed should be checked frequently, and the governor should begin to operate when near rated speed. With no load, the unit will run from approximately three to six per cent above rated speed, depending on the type of governor. Not until the governor is controlling the speed of the unit should the throttle valve gradually be opened wide.

The emergency overspeed governor should be tested by overspeeding the machine. The trip valve should close at approximately ten per cent overspeed. This governor should immediately slow the machine down below its normal speed or stop it entirely when there is no load and the throttle valve is wide open. This governor should not be reset until the unit is at or below half speed as emergency governor parts may be damaged. Also, resetting this governor too quickly may affect the speed at which the governor will trip on the next run.

The emergency governor should be tested on a regular schedule or when the machine is shut down.

Normally the lubricating oil should be changed after a 2- or 3-day initial run. After this starting-up period, oil should be changed on a regular schedule, as required.

Regular Operation. When the machine is in regular service, the turbine should be warmed up gradually and turned over slowly before bringing it up to full speed, but in an emergency mechanical-drive turbines usually can be started very quickly. This is particularly possible if all parts are drained and if the exhaust valve has been left open to keep the machine warm. Operation of oil rings and governor should be checked each time the turbine is started.

Vibration. Vibration is sometimes caused by misalignment due to foundation settling and pipe strains, or bearings may be worn or loose in the bearing boxes. If the bearings are worn, a heavier oil may allow operation until they can be replaced. Also, the rotor may rust and get out of balance if a turbine is out of service for a considerable time with the casing not properly drained.

Flexible couplings may cause vibration. A lubricated type of coupling must have proper lubrication, or the driving and driven machines, in effect, will be rigidly connected with resulting vibration. A pin and bushing coupling, with worn or sticking parts, will have the same effect. Shafts cannot move freely, and thrust is transmitted from one machine to the other. A mechanical-drive turbine is not designed to take the thrust from its driven machine, so the turbine thrust bearing may run hot and perhaps burn out when couplings are not flexible. Couplings should be inspected on a regular schedule.

Best Efficiency. For best economy a turbine should be operated with as many hand valves closed as possible. However, enough valves should be left open to take care of load swings. Hand valves should be wide open or closed tight. They should never be partly opened, as valve seats will cut rapidly, and there is no improvement in efficiency.

Low Power. When a turbine will not develop enough power, there may be an overload, or the driven-machine efficiency may have decreased because of wear. Turbine initial steam pressure and temperature may be low or exhaust pressure high.

On the turbine itself the governor may be set low, the governor valve improperly set, the steam strainer clogged, one or more nozzles plugged, or the wheel blading worn.

A clogged steam strainer or improperly set governor valve will be indicated by a large differential between steam-line and steam-chest pressure at the maximum load that can be obtained.

The steam used and the power developed by a turbine can be accurately determined. The manufacturer keeps a record of the nozzle diameters, and he can calculate steam flow through the turbine and load being developed by it if he has the following information:

Steam pressure at the turbine inlet
Steam pressure in the turbine steam chest
Superheat or moisture in the steam
Number and position of any hand valves open or closed
Speed of the turbine
Back pressure at the turbine exhaust

Steam-pressure gauges must be calibrated. The manufacturer's figures are based on test data with new machines and do not allow for wear or improper adjustments.

Speed-reducing Gears. Gears furnished as part of a turbogear set are usually of the double-helical or herringbone type.

Installation and Starting. Gears should be installed and lined up in the same manner as a turbine installation. They run at comparatively low temperatures, so when they are lined up cold appropriate allowance must be made for this. They should be started after taking the same precautions as for a turbine. It may be necessary to prime the oil pump when starting up a gear for the first time.

Lubrication. Turbine gears are very carefully made and have rather close clearances. A medium oil with a viscosity at 100°F of about 250 to 350 SSU is usually the most satisfactory. If the gear is close fitting and runs at high speeds, better operation may be obtained with a lighter oil. This is particularly true if the gear tends to overheat. The temperature range of the oil should be from 125 to 175°F. Water cooling is usually supplied so that this range can be maintained. A regulating valve should be installed in the water-supply line, but the outlet from the cooler should be open and without a valve of any kind so that it will be impossible to put excessive water pressure on the cooling equipment.

Usually high-speed gears are not designed to dip in the oil, and they will overheat and foam if this happens. Generally, oil pressure should not exceed 15 lb gauge as higher pressure may cause the gear to heat up.

Bearings. When bearings become worn, they must be renewed in a short time or the gear teeth may be damaged because of internal misalignment. Gear bearings of the babbit-lined cast-iron-shell type should never be rebabbitted since the shells will warp in the process, and it is very difficult to scrape and fit bearings so that the alignment is correct in both horizontal and vertical planes. For the same reason bearing clearance never should be adjusted by planing the bearing horizontal joint as trouble is certain to occur. New bearings should be installed in such cases.

It is very important that shaft alignment be maintained and that the flexible couplings allow the shafts to float. If couplings become rigid through lack of lubrication or wear, load is not properly distributed on the gear teeth, and the teeth will wear and eventually will break. Couplings must never be driven on or off the shafts as the tooth surfaces may be injured.

Gears are operating properly if there is a uniform marking over the entire length of both gear and pinion helixes. If there is heavier marking or pitting on one part of the tooth face, it may have been caused by misalignment of the connected shafts, vibration, worn bearings, or poor lubricant.

ASH HANDLING AND DISPOSAL

BY B. C. BERRY

The Allen-Sherman-Hoff Company, Philadelphia, Pennsylvania

INTRODUCTION

An ash- or refuse-handling system is essential to the operation of any furnace burning solid fuel. The system may range in complexity from a hand shovel and a wheelbarrow to a modern hydraulic, pneumatic, or mechanical unit, or a combination of these.

TYPES OF SYSTEMS

The *manual system* utilizing a shovel, hoe, and similar hand-operated tools for the removal of ash from the pit and a barrow for transportation to a disposal point is so fundamentally uneconomical that its use should be considered only in the most unusual cases. It is conceivable that, with a combination of a very small installation, infrequent operation, and a low ash content of fuel, a manual system would best fit the needs and be the only one economically justified. Any such proposal should be critically viewed as to its soundness.

The *mechanical systems* include the screw type that continuously removes ashes from a V-shaped furnace bottom to a container for disposal. This type is usually applicable only to small furnaces of the household-heating-plant range or at the most to small industrial or institutional installations. The maximum size of furnace for which the screw type is ordinarily considered is one burning not over 20,000 lb of coal per day.

The *pneumatic system* should be used only on units burning not over 40,000 lb of coal per hr. If used on furnaces larger than this, the operating costs become excessive.

The pneumatic arrangement for an underfeed stoker-fired boiler should not be used. It is essential that the ashes discharged to ashpit from underfeed stokers be quenched in the pit. The application of the hydraulic system to this type of firing will be discussed.

The *hydraulic system* provides for greater flexibility in type of coal that can be burned. On units burning over 40,000 lb of coal per hr, the hydraulic system or a combination of hydraulic and pneumatic is most applicable.

For purposes of computing volume of ashes to be handled for any given problem, all coal will be assumed to contain 10 per cent ash, and coal consumption will be based on 10 lb of steam generation per pound of fuel burned.

Decision as to type of system to ensure minimum boiler outage and economy in operating costs, both power and labor, requires careful analysis of problem.

Flexibility in design is needed to permit use of varied types of coal which in turn will produce an ash ranging in fusing temperature from 1900 to 2600 to 2700°F.

Modern furnace-bottom and ash-hopper design for powdered-fuel-fired units covers two types of construction: (1) a completely dry bottom where no quenching water is introduced, as shown in Fig. 8-226, and (2) the submerged bottom which has in it a pool of water into which ash and slag are dropped and disintegrated, as shown in Fig. 8-227. The lining for each of these types is different not only in thickness but also in the materials used. In the first, a monolithic lining of thickness dependent upon temperature and type of operation is used, with or without insulation as determined by conditions. In the second, the lining is monolithic. For this type of hopper, a protection at the water line is also indicated in Fig. 8-227, and a method of cooling the protecting elements and keeping the water in the hopper quiescent so that continuous lapping along the sides cannot occur has been found to be the most effective method.

The hopper as shown in Fig. 8-226 should be selected only when furnace is to be a pulverized-fuel-fired unit of the dry-bottom type having large furnace volume with a low heat-release factor, thereby reducing to a minimum any possibility of slagging or fusing of the ash.

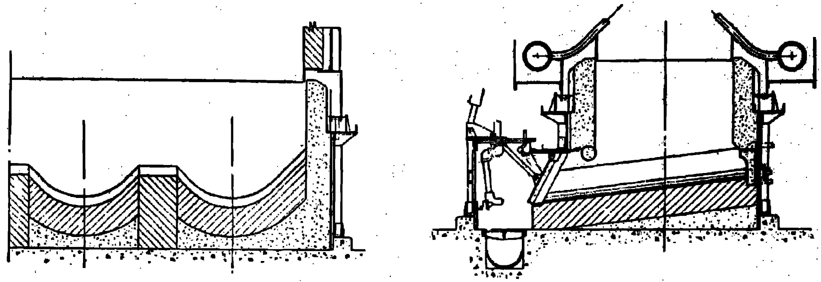

Fig. 8-226. Dry-bottom hopper.

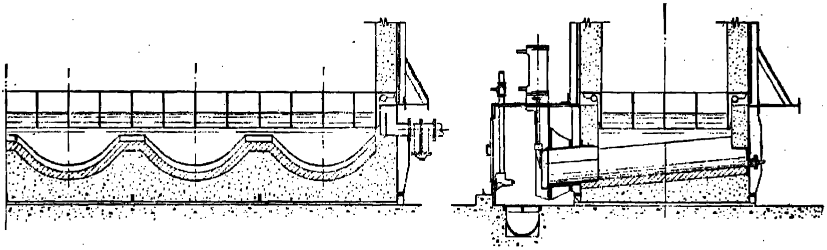

Fig. 8-227. Submerged type of hopper.

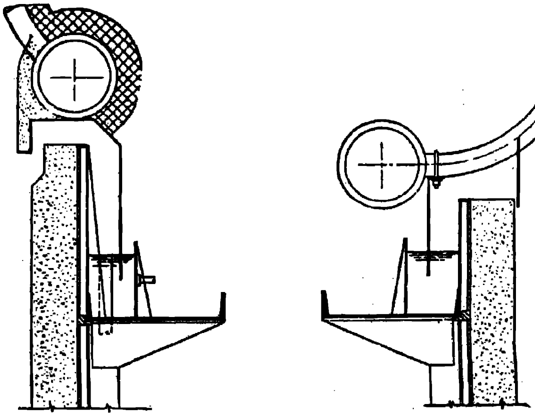

Fig. 8-228. Fluid-expansion joint.

Modern boiler design has also developed to a point where it is essential that all air necessary for combustion shall be introduced at controlled points. Leaks in the setting where excess air can infiltrate are no longer tolerated. It became necessary, therefore, to develop an expansion joint between the setting walls, whether they be refractory or waterwalls, and the furnace bottom or ash hopper so that no air infiltration is possible. This has been accomplished by the fluid seal shown in Fig. 8-228.

It may be a water seal, a sand seal, or of other material which will permit movement of the seal plate. In view of the fact that the four walls of a boiler setting may at times be on different elevations and each one expands both vertically and laterally a different amount, the development of the corners presented a problem, which was solved through the use of flexible material.

If it is a wet-bottom or slag-type steam generator, the wet hopper and hydraulic system must be used. If the ash hopper is to serve a stoker-fired boiler or steam-generating unit, the hopper can be lined with refractory shapes and equipped with quenchers as shown by Fig. 8-229.

In all these hoppers, nozzle arrangements are provided which will remove the ashes at a rate of 1 ton per min.

A powdered-fuel-fired unit of the continuous-slagging type requires a hydraulic system and the pool or submerged-type hopper, as shown in Fig. 8-227.

If the temperature in the furnace throat is high (1800°F or higher) and headroom from basement floor to waterwall headers is cramped, extra precautions must be taken at the water line. This can be done by installing alloy plates at the water line which are sprayed with water at the back of the plate. The plates are hung on the water-cooling header.

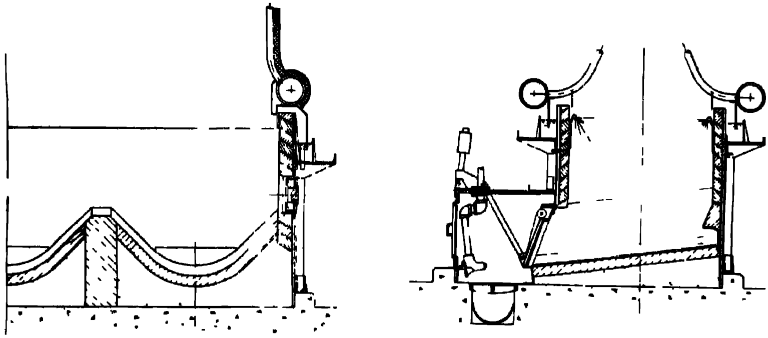

FIG. 8-229. Quenching-type hopper.

Another method of protecting the water line is to use a water-cooled hopper with either a poured- or molded-shape refractory lining.

If it is a cool furnace (throat temperatures below 1800°F), a good poured refractory lining will stand the service at the water line. A good molded shape will also perform well in this service if used on a cool furnace.

The junction of the hopper and pressure parts must provide for both vertical and lateral movement resulting from expansion. This can be done with the fluid seals as previously described, depending upon degree of air tightness desired.

If the system serves one or a number of boilers, the proper arrangement of sluice, sump, pumps, or jet is important. By proper arrangement is meant sump location which permits shortest run of sluice trenches and minimum sluice water requirements. In locating sump, thought should be given to future extension of plant to hold total water requirements down.

On stoker-fired units, the sluice and pump arrangement follows the same general design used for the powdered-fuel-fired units. This is also true for the dry-bottom powdered-fuel-fired units.

In all instances, it is good insurance to build the sump to provide for the installation of a clinker grinder which may be installed later if, owing to an excessive amount of oversize material, it is found necessary.

If it is required to discharge to fill at a distance and against a static head of any reasonable amount, the pump is the best medium for handling the material. If the total dynamic head is low, a jet can be used. The jet is not a very efficient unit, however, and does not permit much flexibility in extending the discharge line.

As the time element is a vital factor in the wear taking place on materials-handling equipment, it is important to handle the refuse in as highly concentrated volume as possible. This factor has a bearing on design arrangement.

In transporting ashes by pumping or jetting through closed pipe lines, the velocity should be maintained at not less than 9 fps on horizontal runs. If the arrangement of the line necessitates long vertical risers, the minimum pipe-line velocity is 11 fps.

The pump used in handling abrasive material should be a closed-impeller centrifugal-type assembly having a reasonably steep head-capacity characteristic. The impeller and volute must be made of abrasive-resisting material having a close grain structure and Brinnelling not less than 300. The design should incorporate sealing features to protect the packing gland and end plates against attack from abrasive-laden solution and also to eliminate short-circuiting of material around the suction shroud of the impeller.

First the ultimate disposal point should be decided upon. Will the refuse be discharged to permanent or temporary fill and at what distance from the plant? Can it be discharged to grab-bucket sump, or must it be stored for truck or railroad-car loading?

If ashes can be discharged to fill, the hydraulic system immediately takes a favorable position. This also holds true for the grab-bucket sump. If it is necessary to store the material on the property for truck or railroad-car loading, the system will incorporate the use of a storage bin into which the material can be pumped and then properly dewatered, leaving what is termed commercially dry ash or slag for loading.

In plants where the water supply is limited, the hydraulic system provides for recirculation of the water used as the transport medium. Recirculation of the water results in a closed system with no loss of water to overflow. This arrangement is practical only where the material is discharged to an overhead tank, grab-bucket sump, or specially arranged dike area located on the plant site.

In small plants requiring the removal of only a small volume of refuse each day, a simplified hydraulic arrangement can be adapted to the service, requiring no high-pressure sluicing water. The handling rate of this system is lower than the arrangements recommended for the larger plants but is suitable and economical for the small installations.

The problem of maintenance costs must be considered in determining the type of system to be used. The wear resulting from wet abrasion is less severe than that encountered from dry abrasives. The time element is also a decisive factor in maintenance costs. Therefore, in a plant where the volume of refuse to be handled in each 24-hr period is large, the materials-handling system selected should incorporate time-saving and wear-resisting features.

A recent development in furnace design on large steam-generating units provides for operating the furnace under positive pressure, thereby eliminating the necessity of using induced-draft fans.

This development requires that the furnace-bottom refuse be removed without disturbing furnace conditions through the use of a sealed hopper and sump arrangement. This requires highly specialized equipment and careful analysis of each project as it develops.

A short analysis of operating comparisons on the hydraulic system versus the pneumatic system follows.

Assume a plant with two boilers of the dry-bottom-furnace type burning pulverized bituminous coal and generating 600,000 lb of steam per hr per boiler, or a total of 1,200,000 lb per hr. The coal consumption will approximate 120,000 lb per hr. Assuming that the coal has an ash content of 10 per cent, the resulting refuse will total 12,000 lb per hr.

Of this total, approximately 40 per cent will be deposited in the furnace-bottom ash hopper. There will therefore be (0.4 × 12,000 × 24) 115,200 lb, or 57.6 tons, of ash to handle each 24-hr period.

The following is a comparison of operating costs of the hydraulic system versus the pneumatic systems:

Hydraulic

With a hydraulic system, material can be sluiced from hopper bottom at rate of 30 to 60 tons per hr. Using lower figure, system will operate 1.92 hr. Allowing for starting and stopping time, total operating time is 2 hr.

Pneumatic

In a pneumatic system, much of the material has to be manually fed into transport system with a hoe. A man can average about 4 to 5 tons per hr with a hoe. Using 5 tons per hr as the average, the system will operate 11.52 hr, plus starting and stopping time, or 11.6 hr per day.

CONCLUSION

If plant location permits depositing material to fill area, a hydraulic system should be selected.

If it is stoker-fired plant, a hydraulic system should be selected.

If boilers are of the slagging type, either intermittent or continuous, a hydraulic system should be selected.

If boilers are to be operated under positive furnace pressure, hydraulic system should be selected.

If water is scarce, the recirculating hydraulic system should be used.

If boilers do not burn in excess of 40,000 lb of coal per hr and heat release does not exceed 15,000 Btu per cu ft of furnace volume, the pneumatic system is applicable.

CHARACTERISTICS AND PROPERTIES OF REFRIGERANTS

BY R. J. THOMPSON

Director of Sales, Kinetic Chemicals Department, E. I. du Pont de Nemours & Co.

INTRODUCTION

Refrigeration has always been an essential in many industries, business enterprises, and in the home. Ice was the first and only refrigeration medium for many centuries, but there were so many disadvantages connected with its use that other means were sought, and it was found that a number of low-boiling liquids and compressed and liquefied gases could be used to produce refrigeration.

There are two principal methods in which refrigerants are employed: one, generally referred to as the indirect method, is the circulation of cooled water, brine, or chemical solutions; the other, the direct method, is the circulation and expansion of the refrigerant itself. Refrigeration either by the direct or indirect method was first employed almost entirely in industrial applications but was afterward extended to take the place of ice in commercial uses as well, and in the last 20 to 30 years has been adapted to industrial and comfort-cooling air-conditioning and household refrigeration equipment.

Unfortunately, there were certain inherent hazards in the use of the refrigerants employed, and while the hazards could be fairly well controlled in packing houses and ice-manufacturing plants because suitable precautions could be enforced, their control was not practicable in industrial, commercial, and household refrigerating and air-conditioning systems.

A refrigerant is a substance or medium used to produce refrigeration by absorbing heat in its expansion or vaporization. The word "refrigerant" is used broadly to refer to any primary refrigerating medium such as carbon dioxide, ammonia, methyl chloride, sulfur dioxide, or the Freon refrigerants, or, in another sense, to refer to a secondary cooling medium such as calcium chloride brine. As more commonly interpreted, the word "refrigerant" refers to any material used in mechanical refrigeration, by which process the refrigerant is evaporated, recovered, compressed, condensed, or liquefied and permitted to expand or vaporize again as distinguished from those processes in which the spent refrigerant medium is wasted, such as in the melting of ice or the change of state of carbon dioxide from a solid to a gas.

The requirements for the ideal refrigerant may vary in number and order of importance depending upon the particular requirements to be met or the desire of the designer, but it is believed that such requirements may be easily summed up by stating that

1. The refrigerant must be free of panic, health, fire, and property-damage hazard should it escape from the refrigerating or air-conditioning system.
2. The refrigerant must have chemical, physical, and thermodynamic properties which will be readily adaptable to and will permit its use in present-day designs of refrigerating and air-conditioning equipment and, at the same time, produce efficient service at a low initial and ultimate cost over a long period of operation.

CHARACTERISTICS OF REFRIGERANTS

In the following material will be given the desired properties for the ideal refrigerant and the characteristics or properties of all refrigerants that have been used up to the present time. The requirements that are given are all very important and are placed somewhat in an order of sequence which will show their relative importance or value.

The chief hazards were those of fire and explosion of the refrigerants themselves, health hazards due to the toxicity of the refrigerants, panic hazards brought about by the irritating and odoriferous nature of the refrigerant, the hazards due to chemical reactions resulting from accidental introduction of the refrigerant from the cooling system into the chemicals being processed or foodstuffs being refrigerated, and, in some cases, the hazards of extremely high pressures. All the refrigerants in common use prior to 1931 had one or more of these undesirable characteristics. A well-organized search continued for the ideal refrigerant, *i.e.*, one that was neither flammable nor toxic nor capable of entering into chemical reactions and which could be operated at relatively low pressures and which would be efficient and suitable for all types of systems whether for refrigerating or air-conditioning purposes.

Odor. A refrigerant must be odorless and nonirritating in any concentration in order to reduce or eliminate the possibility of a panic hazard occurring in event the refrigerant should accidentally escape from a system or leak out when the system was being repaired or being serviced.

Ammonia is an irritant, and $\frac{1}{30}$ oz in 1,000 cu ft of space imparts to the air a strong smell, and $\frac{1}{5}$ oz per 1,000 cu ft of space is the strongest dose bearable for $\frac{1}{2}$ hr. Concentrations of the odor of $\frac{1}{4}$ lb per 1,000 cu ft of space endured for $\frac{1}{2}$ hr produce blindness. This is an outstanding serious effect produced by ammonia.

Sulfur dioxide is a very irritating gas and is detectable in very small concentrations of $\frac{1}{125}$ oz per 1,000 cu ft of space, while $1\frac{1}{3}$ oz per 1,000 cu ft is suffocating.

Carbon dioxide is odorless, but its physiological effects when breathed in mild or moderate concentrations serve in a measure as a warning of its presence. In concentrations much above 11 lb per 1,000 cu ft, the physiological action may be too rapid in producing stupefaction or loss of consciousness to serve as adequate warning.

Since the odor of methyl chloride is not unpleasant and but faintly noticeable in small quantities, it probably presents a greater hazard than some of the toxic gases possessing distinct warning properties.

Methyl formate is an irritant and gives definite warning of its presence.

Suitable gas masks or oxygen helmets should be readily available when handling irritating or toxic refrigerants.

The vapors of all the Freon refrigerants are odorless at concentrations of less than 20 per cent by volume in air, which is equivalent to the release and vaporization of approximately 45 to 95 lb of liquid into a confined space of 1,000 cu ft. At concentrations higher than 20 per cent by volume in air the odors of the Freon vapors are very mild and somewhat ethereal, being similar to carbon tetrachloride, the commonly used fire-extinguishing fluid. The Freon vapors in all concentrations are nonirritating to the eyes, nose, throat, lungs, or skin. Thus, gas masks or refrigerant-absorbing materials are not required when handling any of these refrigerants.

When a toxic or flammable refrigerant is odorless or practically so, some suitable substance should be added which will not corrode the equipment but which will permanently maintain a distinctive odor. In such a refrigerating system, especially in public places, care should be taken in the addition of odorants as a small leak in the system might cause a panic that would do far more harm than the refrigerant itself. At the present time there are no irritants or odorants or warning agents that will satisfactorily serve such a purpose.

Warning agents are not required and are not even considered desirable for use in the odorless and nonirritating Freon-charged refrigeration equipment.

Toxicity. A refrigerant liquid or vapor must be nontoxic and nonpoisonous to eliminate all possibilities of a health hazard should the refrigerant escape from the system. Toxicity as referred to must not be confused with concentrations of refrigerant-air mixtures high enough to exclude sufficient oxygen to support life.

The Underwriters' Laboratories have found that $\frac{1}{4}$ lb of ammonia per 1,000 cu ft of space will kill or seriously injure with an exposure of $\frac{1}{2}$ hr.

Sulfur dioxide will cause throat irritation, coughing, constriction of the chest, nausea, irritation of the eyes, and is so acutely pungent as to cause a sensation of suffocation even with the first breath. The Underwriters' Laboratories have found that 18 to 19 oz per 1,000 cu ft will kill or seriously injure in 5 min.

Methyl chloride is an anesthetic when concentrated in closed spaces or on long exposure, and there is a definitely delayed toxic action. The Underwriters' Laboratories have found that from 2½ to 3¼ lb per 1,000 cu ft will kill or seriously injure in 2 hr.

It is a well-established fact that the Freon refrigerants as such are the least toxic refrigerants that have ever been discovered, and complete and detailed data on toxicity will be found in the Underwriters' Laboratories reports and Bureau of Mines reports.

The toxic properties of various refrigerants are shown in Table 9-1.

Table 9-1. Toxic Properties of Refrigerants

Underwriters' Laboratories group No.	Refrigerant	Formula	Cu ft per lb of refrigerant, 68°F, 1 atmosphere	Boiling point, deg F	Kills or seriously injures		
					Duration of exposure	Concentration in air

* Oxygen deficiency.

Flammability. A refrigerant must be nonflammable and nonexplosive in any concentration in order to eliminate all possibility of a fire or explosion hazard. The fact has been recognized that even a small amount of flammable or explosive vapor may be concentrated on the floor or in a confined space around a leak which may produce an explosive mixture, even though the small amount of refrigerant when evenly diffused to all parts of the room may not produce an explosive mixture. Thus all flammable and combustible refrigerants should be considered fire hazards regardless of the concentrations required or the amount of refrigerant permitted to escape from the system.

In the Underwriters' Laboratories reports and also the Bureau of Mines reports, it will be found that all the Freon refrigerants, sulfur dioxide, carbon dioxide, and methylene chloride have been classified as noncombustible and nonflammable. Formation of combustible mixtures by Freon 21 and Freon 113 under practical conditions, even at the higher temperatures, is extremely unlikely, and their fire hazards are, therefore, very small, as is the case with methylene chloride.

Explosive properties of the commonly used refrigerants are shown in Table 9-2.

Corrosion. A refrigerant must be noncorrosive to all metals or materials used in refrigeration construction in order to permit the refrigeration manufacturer a wide selection of materials with which to design efficient condensers, evaporators, bearings, pipe lines, control apparatus, etc.

Certain refrigerants are mildly corrosive to certain metals but actively corrosive to other metals. This calls for extreme care in the selection of iron, steel, brass, galvanized metal, acid-resisting bronze, monel metal, nickel, high-nickel alloys, and aluminum or for the trimming of iron valves with brass alloy, steel, or aluminum.

The Freon refrigerants are noncorrosive to all metals used in refrigeration apparatus, including steel, cast iron, brass, copper, tin, lead, zinc, silver, aluminum, etc.

Any type of system, regardless of the refrigerant used, should be dry, especially in the case of those refrigerants in which water is not soluble in order to eliminate the possibility of the moisture freezing out at the regulating valve, intercrystalline embrittlement of brass bellows or diaphragms under cyclic stress, shorting of field coils in hermetically sealed units, and the emulsification of the lubricating oil, any one of which might cause faulty operation of the system. It is to be pointed out that water which may be in a system together with air will cause oxidation of metal parts which must be distinguished as oxidation or rusting and is not due to corrosion by the refrigerant.

Table 9-2. Explosive Properties of Refrigerants

Refrigerant	Explosive range, concentration in air		Maximum explosion pressure, psig	Time of development of pressure, sec
	Per cent by volume	Lb per 1,000 cu ft		
Ammonia	16–25	7.1–11.05	50	0.175
Methyl formate	4.5–20.0	7.02–31.2	96	0.026
Methyl chloride	8.1–17.2	10.6–22.6	69	0.110
Dichlorethylene	5.6–11.4	14.1–28.7	76	0.095
Ethyl chloride	3.7–12.0	6.12–20.1	87	0.028
Sulfur dioxide		Nonflammable		
Carbon dioxide		Nonflammable		
Methylene chloride		Nonflammable		
Freon 11		Nonflammable		
Freon 12		Nonflammable		
Freon 21		Nonflammable		
Freon 22		Nonflammable		
Freon 113		Nonflammable		
Freon 114		Nonflammable		

Stability. A refrigerant must be stable, and over long years of service it has been found that the Freon refrigerants will withstand repeated evaporations, compressions, and condensations without dissociation, and these refrigerants do not form high-boiling or solid compounds.

Certain refrigerants such as ammonia show evidence of some disintegration in both compression and absorption systems due to reaction of moisture with metals, due to disassociation, and due to unsaturated hydrocarbons in the mineral lubricating oil which necessitates constant purging of the foul gases, which are constantly recreated, in order to obtain economic operation. Foul gases are dangerous in many systems when building up test pressures with air in case some refrigerant is present because certain of the disassociation products can be readily detonated when present in the proper mixtures. Disassociation of a refrigerant in a system will also cause high condensing temperature, high current consumption or high cost of operation, and noncondensable vapor lock in h-p float-valve chambers.

Inertness. A refrigerant must be inert with respect to compounded materials such as stuffing-box and valve-stem packing, gasket materials, cotton-covered windings, insulating varnishes, etc.

Most of the refrigerants have solvent action on many materials and composition gaskets with the result that such materials must be carefully tested and selected before use. In general, such gasket materials should not contain natural rubber, but instead neoprene should be obtained from the rubber companies which are in position to supply materials of the proper characteristics. Pressed fibers, including asbestos, with a number of insoluble binders may be used as may also metallic gaskets. Cotton on motor windings must be properly cleaned and degummed, and insulators and varnishes must be selected with proper regard to the solvent properties of the particular refrigerant.

Effect on Materials. A refrigerant must have no effect on any materials being refrigerated, such as food, flowers, furs, or fabrics, or any materials that may be exposed to the refrigerant vapor or liquid.

Certain refrigerants such as ammonia and sulfur dioxide cause mild to serious contamination to plant life, food products, textiles, or other materials with which they may come in contact, and excessive exposure of fruits, vegetables, meats, and liquids will cause rot, scald, and burns or make them so unpalatable as to prevent their consumption.

The Freon refrigerants, either liquid or vapor, are not absorbed by and have no effect on any materials being refrigerated, and the vapor has no effect on the odor, taste, color, or structure of dairy products, meats, or vegetables. The Freon vapors have no effect upon the odor, color, continued blooming, or structure of flowers or plant life, and the liquid or vapor has no effect upon the color or structure of furs or fabrics.

Leak Detection. A leak of refrigerant must be capable of being easily detected and located.

Leaks of ammonia, aside from odor, are detected and located by ammonium sulfite (white fog or fumes) resulting from burning sulfur sticks in the presence of the refrigerant or determined by the alkaline reaction on moistened litmus paper or phenolthalein.

Leaks of sulfur dioxide, aside from odor, are detected and located by ammonium sulfite resulting from exposure to 28 per cent ammonia in water in the presence of the refrigerant.

Many odorless and/or flammable refrigerants, such as methyl chloride, methylene chloride, carbon dioxide, isobutane, ammonia, and methyl formate, are not easily detected or located, owing to their relatively high chemical stability, and other methods of leak detection must be resorted to, such as the application of soap and water solution at all suspected points or observation of oil spots or leaks. It is quite obvious that such methods are not entirely satisfactory in dark, confined, or inaccessible spaces or locations.

Owing to the fact that the Freon refrigerants are stable and inert, the usual visual method called the "smoke" test cannot be used to determine leaks as there is no known chemical compound that will react with the refrigerants to produce a visible vapor.

The best known method of detecting and locating a leak of Freon vapor is by means of an alcohol or gas-burning halide torch. Owing to the combustion of the fuel in the burner, a draft of from 2 to 3 fps is created through a steel tube which is inserted in the burner at the base of the flame. A flexible rubber hose is placed on the end of the steel tube, and the open end of the rubber exploring hose is then passed around all possible sources of leak. Any air suspected of containing Freon vapor is conducted through the hose and tube into the burner and over metallic copper. Should there be any Freon vapor in the air being tested, the high-temperature flame will cause the refrigerant vapor to break down and form a volatile copper halide. This will cause the flame color to change from the normal colorless to a bright green if the air contains Freon vapor.

A leak of Freon vapor may be definitely located by means of a halide torch or lamp even when the leak occurs in a dark or confined space. Leaks at the rate of 1 oz of Freon per month (0.06 per cent) may be readily detected, although these detector torches will detect leaks as low as 0.01 per cent, which is equivalent to the escape of Freon at the rate of 1 oz in 6 months. Leak-detector torches of nonferrous metal burners or of a pump-up type are not recommended, as the color change of the flame will not be sufficiently rapid and fully serve the purpose of the lamp. The use of odorants or chemicals to produce reactions for a smoke test are not recommended. Leak-detector lamps of the type now on the market should not be used for locating leaks of flammable or combustible gases used as refrigerants.

The rate of leakage of a refrigerant gas is dependent on such factors as pressure, capillarity, viscosity, density, rate of diffusion, and molecular weight, but a very good measure of this rate of leak may be expressed as being inversely proportional to the square root of molecular weight, assuming the pressure to be the same in all cases.

Thus for the same pressure it will be found in Table 9-3 that the Freon vapor or gas leakage will be less than the leakage of any of the other compressed gases used as refrigerants.

Table 9-3. Rate of Leak

Refrigerant	Molecular weight	Square root of molecular weight	Rate of leak (same pressure)
Freon 113	187.39	13.69	0.68
Freon 114	170.93	13.00	0.71
Freon 11	137.4	11.63	0.80
Freon 12	120.9	11.0	0.85
Freon 21	102.93	10.16	0.92
Freon 22	86.48	9.3	1.00
Methylene chloride	84.92	9.21	1.01
Sulfur dioxide	64.07	8.0	1.16
Methyl formate	60.03	7.75	1.20
Isobutane	58.8	7.63	1.22
Methyl chloride	50.48	7.11	1.31
Carbon dioxide	44.0	6.64	1.40
Air	29.0	5.38	1.73
Ammonia	17.03	4.13	2.25

Surface-wetting Ability. A refrigerant must have good surface-wetting characteristics so as to release refrigerant vapor or gas bubbles or vapor film from the heat-transfer surfaces of the evaporator and condenser to make such surfaces more effective and efficient.

The various refrigerants have different characteristics or properties for wetting heat-transfer surface as the gas bubbles of one type spread out on the unwetted surface, thereby drawing the free edge of the bubble into a fine wedge between the refrigerant liquid and the heat-absorbing surface and holding it fast against the action of buoyancy. In such a case the bubble becomes rather large before being detached and replaced by a new bubble.

In the case of gas bubbles in an evaporator using a surface-wetting refrigerant, the liquid refrigerant tends to push away and to sheer off the bubble, which rests at only one point and becomes globular or oval and leaves the surface while still very small. Very complete information on the subject appears in various engineering journals and technical papers.

The chlorinated hydrocarbon refrigerants and the halo-fluoro Freon refrigerants are excellent in this respect. They have very good surface-wetting characteristics, release gas bubbles immediately and uniformly when formed, and eliminate the use of an ebullating surface, which places the liquid refrigerant directly in contact with heat-transfer surface which increases the heat-transfer efficiency and prevents superheating and violent blasting out of the gas through the liquid refrigerant in the evaporator.

Vapor Density. Low vapor density is at times considered desirable by certain engineers in order to obtain high gas velocity through valves, fittings, and small suction and discharge lines without causing excessive pressure drop.

Regardless of the refrigerant used, consideration must be given to the elimination or reduction of restrictions in suction and discharge lines, compressor valves, and fittings in order to permit free passage of refrigerant vapor. This consideration has made necessary the redesign of compressor intake and discharge valves with close study of pressure-volume diagrams, with the result that the present-day systems have shown greatly increased operating efficiency and reduced valve noise without excessively large or costly installation and without engineering difficulties.

Densities of refrigerant vapor in pounds per cubic feet at saturated pressures and standard ton temperature conditions are shown in Table 9-4.

Table 9-4. Densities of Refrigerant Vapors

Refrigerant	Vapor density lb per cu ft	
	5°F	86°F
Carbon dioxide	3.741	21.09
Freon 22	0.8034	3.213
Freon 12	0.6735	2.569
Freon 114	0.2369	1.159
Methyl chloride	0.2209	0.930
Isobutane	0.156	0.658
Sulfur dioxide	0.1558	0.844
Ammonia	0.1227	0.564
Freon 21	0.1095	0.577
Freon 11	0.0815	0.446
Freon 113	0.0370	0.257
Methyl formate	0.0212	0.141
Methylene chloride	0.202	0.15

Table 9-5. Density of Liquid Refrigerants

Refrigerant	Density lb per cu ft 86°F	Specific gravity (water = 1)
Freon 113	96.96	1.559
Freon 11	91.38	1.468
Freon 114	89.91	1.443
Freon 21	84.52	1.360
Sulfur dioxide	84.4	1.358
Methylene chloride	83.3	1.340
Freon 12	80.63	1.297
Freon 22	73.36	1.177
Methyl formate	61.0	0.982
Methyl chloride	55.8	0.898
Carbon dioxide	37.4	0.602
Ammonia	37.2	0.598
Isobutane	34.1	0.549

Liquid Density. Density or gravity of liquid refrigerant concerns only the calculations for buoyancy of float valve, but when calculations are made consideration must be given to the density or gravity of the refrigerant-oil mixtures rather than only the liquid refrigerant.

Density or gravity is of minor importance when calculating pressure drop in liquid lines as the liquid velocities are of a very low order. Density of liquid has influence on the volume of liquid refrigerant that may be required in the system but density alone is of secondary importance when selecting the ideal refrigerant. Refrigerants of high density or gravity are now being used quite widely in preference to refrigerants of low density and gravity.

The density of liquid refrigerants in pounds per cubic foot is shown in Table 9-5.

Critical Temperature and Pressure. The refrigerant must have a high critical temperature to permit high operating efficiency when using either high-temperature water or air as a condensing medium. The critical temperature is the temperature above which the refrigerant can exist only as a gas, and the pressures at those tem-

Table 9-6. Critical Temperatures and Pressures

Refrigerant	Critical temperature deg F	Critical pressure psia
Methylene chloride	421	640
Methyl formate	418	607

Ammonia	107.9
Sulfur dioxide	98.9
Carbon dioxide	-69.9
Freon 113	-31.0

peratures are shown in Table 9-6. It will be observed that, with the exception of carbon dioxide, all refrigerants have critical temperatures well above condensing-medium temperatures that will be experienced in refrigeration practice.

Freezing Point. The refrigerant must have a low freezing point which should be well below any temperature that may be encountered in machine operation. Table 9-7 shows the freezing points of the various refrigerants, all of which are lower than any temperature upon which they are called upon to produce under normal operating conditions.

REFRIGERANT SYSTEM LUBRICATION

A refrigerant must be miscible with mineral lubricating oils in order to simplify the lubrication problem and permit the most efficient lubrication of the compressor under all operating conditions.

Practically all refrigerants are more or less miscible with mineral lubricating oil, which reduces the viscosity of the oil, but the miscibility is dependent on temperature and pressure of the solution, base of the oil, viscosity of the oil, and design of the compressor and lubricating system. Certain refrigerants are miscible with oils to a very slight degree, while other refrigerants are completely miscible when under pressure and low temperature conditions. This question of miscibility should not be considered a serious determining factor as refrigerants that are highly miscible, such as methyl chloride, ethyl chloride, isobutane, methylene chloride, Freon 12, Freon 11, Freon 21, Freon 22, Freon 113, and Freon 114, have been used with complete satisfaction. Refrigerants that are considered relatively immiscible with mineral lubricating oil are ammonia, carbon dioxide, sulfur dioxide, and methyl formate, although the question of immiscibility was not the reason that prompted their use.

Many refrigerants are not soluble or are soluble only to a limited degree in mineral lubricating oil which will permit the heavier fractions of the oil, wax, or gum to separate or deposit on the cold heat-transfer surface of the evaporator or condenser, with the result that they will greatly reduce heat transfer or prevent return of all the oil to the compressor where it is needed.

The chlorinated hydrocarbon refrigerants and the halo-fluoro Freon refrigerants which dissolve in the mineral lubricating oil will automatically remove the heavy oil, wax, or gum with the result that heat-transfer efficiency is greatly improved.

All chlorine-bearing compounds greatly assist in the lubrication of refrigeration compressors because they act as a carrier for the oil causing wetting of the bearing surface. The Freon refrigerants do not react with any of the mineral lubricating oils used in refrigeration apparatus.

The advantages of using a refrigerant which is miscible with lubricating oil are as follows:

1. The oil foam or fog will permit return of the oil to the compressor from the evaporator.
2. Positive return of oil from evaporator.
3. Boiling point of refrigerant-oil mixture changed but very little even with large quantities of oil present.
4. Refrigerant a good carrier of oil to moving parts ordinarily difficult to reach.
5. Simplified construction of oil return.
6. No problem of oil separation and return from liquid receivers, evaporators, or high-side float chambers.
7. Good heat-transfer characteristics due to eliminating insulating film of oil.
8. Solubility lowers pour point of the oil in low-temperature evaporators

Considerable data have been developed which show the solubility of the Freon refrigerants in mineral lubricating oil at various pressures and temperatures. Other data have been developed which show the boiling point of the Freon refrigerants and oil solutions and also the viscosity of Freon oil solutions at various temperatures.

The various curves show a reduction in the viscosity of the oil when diluted with the Freon refrigerants, especially at low oil temperature, but relatively small change in viscosity at the higher oil temperatures which will exist in the bearing under operating conditions. It is not believed that one should be directly concerned with the solubility of Freon in oil, as the curves show that the addition of 5, 10, or possibly 15 per cent of Freon in oil under actual operating conditions does not greatly reduce the viscosity. In other words, the reduction in oil viscosity when using Freon at temperatures of from 160 to 180°F is not greatly changed from that of the oil itself.

The experience of the refrigeration and air-conditioning industries has shown that Freon refrigerants do not cause injury to the lubricating properties. It is true that bearings may be scored at times, but invariably it will be found that the damage to the bearings had been caused by the presence of factory dirt, oxide, or scale, foundry sand, or other foreign matter which had been removed from the casting or pipe owing to the cleansing properties of Freon refrigerants.

TYPE OF COMPRESSOR

The evaporator temperature to be obtained and the type and size of compressor to be used will determine the selection of the refrigerant to be employed.

Under normal temperature conditions, it will be found that refrigerants with boiling points of less than approximately 15°F are adaptable to reciprocating-type compressors. Refrigerants with boiling points of between approximately 10 and 90°F are adaptable to rotary-type compressors of fractional-horsepower size and of hermetically sealed design. Refrigerants with boiling points higher than 35°F are adaptable to centrifugal-type compressors of larger than 50 tons' capacity.

Low-boiling-temperature refrigerants have higher pressures and can best be used in low-piston-displacement reciprocating-type compressors operating under positive pressures on the low side of the system and with pressure differentials of approximately $3\frac{1}{2}$ atmospheres (50 psi) and higher.

Medium-boiling-temperature refrigerants are used in medium-vapor-displacement rotary-type compressors operating at or near atmospheric pressure, such as 2 lb abs on the low side of the system and with pressure differentials of $1\frac{1}{2}$ to $3\frac{1}{2}$ atmospheres (20 to 50 psi).

High-boiling-temperature refrigerants are used only in large-vapor-displacement high-speed centrifugal-type compressors operated under negative pressures of as low as 1 lb abs on the low side of the system and with pressure differentials of up to $1\frac{1}{2}$ atmospheres (22 psi).

Thus under normal temperature conditions found in the average refrigerating or air-conditioning system, it will be found that reciprocating-type compressors require the use of carbon dioxide, ammonia, Freon 22, Freon 12, methyl chloride, isobutane, and sulfur dioxide. Fractional-horsepower rotary-type compressors require the use of isobutane, sulfur dioxide, Freon 114, Freon 21, Freon 11, and methyl formate. Centrifugal-type compressors require the use of Freon 11, methylene chloride, and Freon 113.

Any refrigerant can be used in any type of compressor provided that proper cognizance is given to evaporator and condenser temperatures, pressures and pressure differentials, density and volume of refrigerant vapor, and other factors. For example, Freon 12 or Freon 22, both of which have high vapor density, may be used in a centrifugal-type compressor for producing extremely low temperatures (−150°F) provided that the difference in pressure between the high and the low sides of the system is held within $1\frac{1}{2}$ atmospheres, or approximately twenty-two pounds per square inch. Condensing of the Freon 12 or Freon 22 will need to be taken care of by means of a second centrifugal-type compressor using Freon 11 or Freon 114. This would be known as a cascade type of system. Freon 12 or Freon 22 may be used in reciprocating-type compressors for producing very low temperatures (−100 to −150°F) provided a two- or three-stage compressor is employed to hold the compression ratios between stages as low as possible.

Isobutane, sulfur dioxide, and methyl formate are limited to fractional-horsepower reciprocating- or rotary-type compressors only. Such systems were used only in household units but have long since been discontinued

Refrigerant Heat Values. The heat values of refrigerant liquid and vapor in refrigerating effect per pound must be considered with the liquid refrigerant volume in order to establish a value for the refrigerant itself. A refrigerant must not be judged only by the fact that it has a high or low refrigerating effect per pound, but the volume per pound of the liquid refrigerant must also be taken into account in order to arrive at the volume of liquid refrigerant to be vaporized per unit of time and a given load.

The Freon refrigerants have relatively low refrigerating effects per pound, but this must not be considered a disadvantage as it merely indicates that more liquid refrigerant must be metered to the evaporator in order that the desired amount of refrigeration be produced. Actually it is a decided advantage to circulate a large volume of liquid refrigerant through the expansion or float valve as the large volume of liquid refrigerant required will simply call for a large orifice diameter, which will permit the use of less sensitive, more accurate, and more positive operating and regulating devices with less critical adjustment.

Refrigerants with high heat values or refrigerating effects are not desirable, especially for use in the smaller size of systems owing to the small amount of liquid refrigerant in the system and the difficulty encountered in accurately controlling the flow of such small volumes of liquid refrigerant through the valve orifice that is required. For small systems, the adjustment of the regulating-valve orifice is most delicate when using refrigerants with high heat values.

The heat values, weight, and volume of liquid refrigerant to be metered through the regulating valve under standard ton conditions are shown in Table 9-8.

Table 9-8

	Heat content, Btu per lb		Btu refrigerating effect per lb	Lb liquid refrigerant evaporated per min	Cu ft liquid refrigerant per lb, 86°F	Cu in. liquid refrigerant to be evaporated per min
	Vapor, 5°F	Liquid, 86°F

Carbon dioxide	102.14	45.45	56.69	3.528	0.0267	162.8

Compressor Vapor Displacement. A refrigerant should have such vapor volume per pound that it will permit low compressor displacement and make possible small, compact compressors of relatively low-speed reciprocating type or of high-speed centrifugal type.

Under standard ton conditions, the displacement of the compressor will be dependent upon the refrigerating effect per pound, the weight of liquid refrigerant to be evaporated, as given in Table 9-9, and the volume per pound of refrigerant vapor.

The vapor displacement required by the compressor is almost directly related to the boiling point of the refrigerant at atmospheric pressure as shown in Table 9-9. In other words, the lower the boiling point of the refrigerant, the lower will be the displacement required, or rather the higher the boiling point of the refrigerant, the greater will be the vapor displacement required.

Pressure. The condensing and evaporator pressures should be positive and as close as possible to atmospheric pressure to permit lightweight construction, low initial cost, lower power consumption, and compactness of the compressor unit, as well as to reduce the leakage of the refrigerant to a minimum, to assist in detecting and locating leaks, and to avoid the leakage of moisture-laden air into the system.

Table 9-9

Refrigerant	Boiling point, deg F	Lb liquid refrigerant evaporated per min	Vapor volume per lb, 5°F	Cu ft displacement per min
Carbon dioxide	−108.4	3.528	0.2673	0.943
Freon 22	−41.4	2.887	1.246	3.596
Ammonia	−28.0	0.4215	8.150	3.436
Freon 12	−21.6	3.916	1.485	5.815
Methyl chloride	−10.76	1.331	4.471	5.95
Isobutane	13.6	1.794	6.41	11.497
Sulfur dioxide	14.0	1.414	6.421	9.084
Freon 114	38.4	4.640	4.221	19.587
Freon 21	48.0	2.237	9.132	20.427
Freon 11	74.7	2.961	12.27	36.33
Methyl formate	89.2	1.056	47.25	49.9
Methylene chloride	103.7	1.492	49.9	74.45
Freon 113	117.6	3.726	27.04	100.76

In Table 9-10 will be found the pressures of the various refrigerants and compression ratios when under standard ton conditions

Operating head pressures will vary with the temperature of condensing medium, type of condenser used, whether air- or water-cooled, design and condition of the condenser, operating back pressure, superheat from the compressor, and other factors Such pressures that may be observed will correspond to a temperature of approximately 10 to 15°F higher than the corresponding temperature of condensing medium for a good design of water-cooled condenser and as much as possibly 25° higher than the condensing air temperature for small air-cooled condensers. The temperature will also depend on the degree of air circulation

Table 9-10

Refrigerant	Gauge pressure psi		Compression ratio
	86°F	5°F	
Carbon dioxide	1,024.3	319.7	3.11
Freon 22	159.8	28.33	4.05
Ammonia	154.5	19.57	4.94
Freon 12	93.2	11.81	4.07
Methyl chloride	80.83	6.19	4.57
Sulfur dioxide	51.75	5.87*	5.63
Isobutane	44.8	3.3*	4.55
Freon 114	21.99	16.14*	5.42
Freon 21	16.53	19.25*	5.98
Freon 11	3.58	23.95*	6.20

Freon 113	13.93*	27.92*	8.01

* Inches of mercury below atmospheric pressure.

REFRIGERANT DATA

Superheat. Complete superheat data are not available for many of the refrigerants as superheat values has never been developed for them Thus all comparisons cannot be made for performance in high-temperature locations High superheat values mean high temperatures, carbonization of oil, damage to discharge values, and large condenser surface for the removal of superheat. It is interesting to note in Table 9-11 that the temperatures of compression for the Freon refrigerants are quite low under standard ton conditions of 5°F evaporator, 86°F condenser, 9°F superheat of vapor, and 9°F subcooling of liquid.

Horsepower. The theoretical indicated horsepower per ton of refrigeration is substantially the same for all refrigerants with the exception of carbon dioxide under a given set of temperature operating conditions.

Engineering design and many times sales, installations, service, and operation are responsible for the wide variation in actual horsepower per ton required. It has been found from practice that, regardless of the C_p, C_v, C_p/C_v ratio, ratio of differential heat of liquid to latent heat, specific heat of liquid, coefficient of performance, power loss due to liquid expansion and compression, superheat, etc , Freon-charged systems operate with less brake horsepower than any other of the commonly used refrigerants when using compressors of a type designed to handle the particular refrigerant. The use of heat exchangers for the Freon refrigerants accounts for quite noticeable gains in efficiency.

Cost. The selection of a refrigerant for all types of installations must be based upon its over-all utility rather than influenced by its cost alone. The cost of a refrigerant loses its so-called importance when the particular refrigerant is nonhazardous under all habitable conditions, where it permits simplicity of construction, operates quietly, is lightweight and compact, and allows use of a wide variety of metals and materials of only moderate construction, and in addition, eliminates secondary brine systems, makes possible high operating efficiency, makes obtainable greater flexibility of application and automatic operation, and lends itself to perfect lubrication and greater reliability of automatic controls and expansion valves, and, most important of all, permits low initial and ultimate cost of complete installation over a long period of satisfactory and adequate refrigeration service, whether it be for household, commercial, industrial, or comfort-cooling air-conditioning and refrigeration purposes.

Not only do the Freon refrigerants make application of refrigerating systems safe and efficient, but in the smaller sizes they have permitted a production and installation cost of practically half that of systems of similar capacity charged with refrigerants that have been used in the past.

Use of Warning Agents. The unanimous opinion of chemists and manufacturers who have worked on this problem is that, although several substances are very good warning agents in some respects, each one has some very objectionable properties. There appears to be no warning agent that will satisfactorily serve such a purpose. Therefore, use of irritants or odorants is not advised in connection with Freon-charged apparatus. Various reasons such as insufficient warning power, toxicity, instability, corrosiveness, and low volatility have served to eliminate from consideration the use of warning agents with the Freon refrigerants.

Use of Antifreeze. We do not believe it advisable to add any liquid or solid compound to any refrigerating system with the hope of eliminating moisture troubles or destroying any water that might be present because in many cases very objectionable and corrosive compounds will be formed, especially when such compounds are improperly used and their properties not fully understood. Instead of adding such a compound to a system we believe it to be much more advisable to remove the water from the system and eliminate the cause of the difficulty rather than to add such a material as a "crutch" or "cure-all," which certainly will not improve the refrigerating effect of the system.

It should be the proper practice to remove the moisture and other impurities from the refrigerating system and the lubricating oil rather than to add any new compounds which of themselves may contain water or other impurities. In other words, it is believed that a cure should be effected by removing the moisture from the system rather than merely to seek temporary relief by adding impurities to the system.

It is an indisputable fact that a system should be thoroughly dried to prevent all possibilities of oxidation and corrosion ever occurring or the freezing out of the moisture at the regulating valve. The recommended drying agents to be used for the removal of water from a Freon-charged system are silica gel, activated alumina, or calcium sulfate.

HANDLING REFRIGERANTS

One of the important requirements of a refrigerant is that it be handled with complete safety, not only by the owner or operator of the refrigerating system but also by the installation and service men.

It is not required that the Freon and other of the nontoxic and inert refrigerants be discharged into a water, acid, or an alkali solution when disassembling or servicing an installation. Such refrigerants may be discharged into the atmosphere as no damage will be caused to any materials being stored in the refrigerator or any injury or damage to flowers, plants, shrubbery, or family pets. Ammonia should be discharged into water, and sulfur dioxide should be discharged into an alkali solution in order that such refrigerants be absorbed or neutralized.

Freon 12, Freon 22, methyl chloride, carbon dioxide, and isobutane should be discharged slowly so that the liquid refrigerant is permitted to vaporize before it comes in contact with any materials so as to eliminate the possibility of freezing. Of course, any of these refrigerants may be pumped down or discharged into clean cylinders for reuse.

Inasmuch as the Freon refrigerants are nonirritating and nontoxic, it is not necessary to wear a gas mask when servicing such equipment. However, it is essential that proper protection be afforded the eyes by the use of goggles or large-lensed spectacles to eliminate the possibility of low-boiling-point liquid refrigerant coming in contact with the eyes and possible damage due to the freezing of the moisture in the eye. Should the low-boiling-point refrigerant come in contact with the eyes, the person suffering the injury should be taken at once to a good eye specialist. Rubbing or irritating the eyes should be avoided, and the following first-aid treatment should be given immediately:

1. Drops of sterile mineral oil should be introduced into the eyes as an irrigant.

2. The eyes should then be washed with one of the following if the irritation continues at all:

   a. A weak boric acid solution.

   b A sterile salt solution not to exceed 2 per cent sodium chloride.

Should the liquid Freon gas come in contact with the skin, the injury should be treated the same as though the skin had been frostbitten or frozen.

First aid for persons exposed to sulfur dioxide consists of taking the patient into fresh air and, if the case appears serious, calling a physician

The first aid for persons exposed to ammonia fumes is as follows:

Summon a doctor promptly. If patient is unconscious, keep up artificial respiration. If eyes are affected, hold the lids open and pour water or 2 per cent boric solution over the eyeballs and lids washing thoroughly for 5 min then allow two drops of liquid petrolatum to fall on the eyeball

If the skin is affected, strip ammonia-saturated clothing from the body. Wash with water, then paint burned surfaces with a saturated solution of picric acid (use boric acid near the eyes). Do not cover burns with clothing or dressings.

If the nose and throat are affected, have patient snuff boric acid solution up nose and rinse mouth thoroughly.

Encourage patient to drink large amounts of water. Ammonia gas is lighter than air, therefore, keep head as low as possible in presence of escaping ammonia. Keep near the floor in going to rescue of one overcome by ammonia, and keep a wet sponge or cloth over the mouth and nostrils Keep the following on hand in clean, easily accessible containers for first-aid purposes:

1. One-gallon bottle 2 per cent boric solution
2. One-quart bottle saturated aqueous solution of picric acid
3. One-pound sealed package of absorbent cotton
4. One ounce liquid petrolatum and medicine dropper

In cases of exposure to methyl chloride, the patient should be removed to fresh warm air and a doctor called. The following first-aid treatments may be used by properly trained persons:

1. Remove patient immediately from gas-contaminated air.
2. Administer artificial respiration if necessary.
3. Administer a mixture of 93 per cent oxygen and 7 per cent carbon dioxide. Such a mixture is commercially available in cylinders. An H. H. inhalator may be used.
4. Give by mouth sodium bicarbonate in water.
5. Administer aromatic spirits of ammonia as a stimulant.
6. Subsequent treatment to be prescribed by attending physician.

PROPERTIES OF REFRIGERANTS

The physical and thermodynamic properties of saturated vapor and liquid refrigerants will be found in Tables 9-12 to 9-24.

CENTRIFUGAL REFRIGERATION MACHINES

BY E. P. PALMATIER

Research Project Engineer, Carrier Corporation

HISTORY

The centrifugal compressor as a means of pumping and compressing air and gases was originated in Europe in 1902. In this year, a crude air blower was built to the designs of the famous French engineer, Rateau. The first machine resembling to any great extent modern design was an air compressor built by Brown, Boveri & Co., Ltd., Baden, Switzerland, in 1906. The German firm of C. H. Jaeger & Co., Leipzig, entered the field in 1908 and was selected by W. H. Carrier in 1920 to build the first centrifugal refrigeration compressor.

At that time all the common refrigerants except carbon dioxide were irritating or toxic and therefore constituted a hazard if used in public places in conjunction with air-conditioning systems. As a solution to this problem Carrier selected the low vapor pressure, relatively high molecular weight substance, dichloroethylene, as a suitable refrigerant and at the same time recognized that this gas was ideally suited to centrifugal compression. It was in this way that the centrifugal refrigeration machine was originated.

In the 27 years which have elapsed since the first machine was built and sold commercially, several other manufacturers have entered the field, and about 2,400 machines have been installed in the United States. Because of the relatively large size of this equipment the total installed capacity of the above machines, expressed in horsepower, is probably close to 750,000 hp.

ELEMENTS AND PRINCIPLES

Compressor. The manner in which a centrifugal compressor develops pressure is usually not entirely clear to those unfamiliar with this type of equipment. Obviously, if any material, liquid or gas, is rotated at high speed, it will tend to be thrown outward from the center of rotation by centrifugal force. If this flow is in any way restrained, the centrifugal force will produce pressure within the material which increases with increasing distance from the center of the rotation.

This describes, in simple terms, the way in which a pressure rise is produced in the impeller of a centrifugal compressor. But additional pressure rise is developed in stationary parts of the compressor.

When the gas leaves the impeller of a centrifugal compressor, it has a high velocity V (see Fig. 9-1) relative to the compressor casing. By directing this high-velocity gas into suitably designed stationary passages called diffusers, a considerable portion of the energy equivalent of this high velocity can be converted to pressure.

There are three basic types of diffusers:

1. The open or vortex type
2. The volute type
3. The vaned type

All three types are in current use in refrigeration compressors.

It may be said, then, that pressure is developed by a centrifugal compressor through the action of dynamic forces on the gas particles in two ways:

1. In the impeller, by the action of centrifugal force
2. In the diffuser, by the conversion of kinetic energy of the gas leaving the impeller to energy of compression

In most cases the greater portion of the total compression takes place in the impeller.

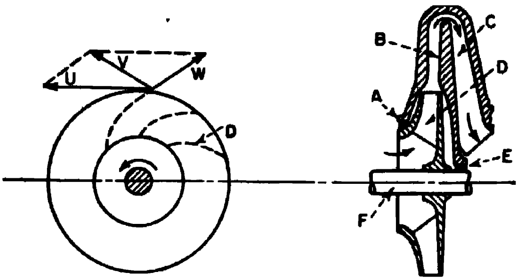

FIG. 9-1. Major components and velocity diagram of centrifugal compressor. (*A*) Inlet ring labyrinth; (*B*) diffuser passage; (*C*) return channel to following stage; (*D*) impeller blading; (*E*) shaft labyrinth; (*F*) shaft; (*U*) impeller-tip speed; (*V*) velocity entering diffuser, (*W*) relative velocity leaving impeller.

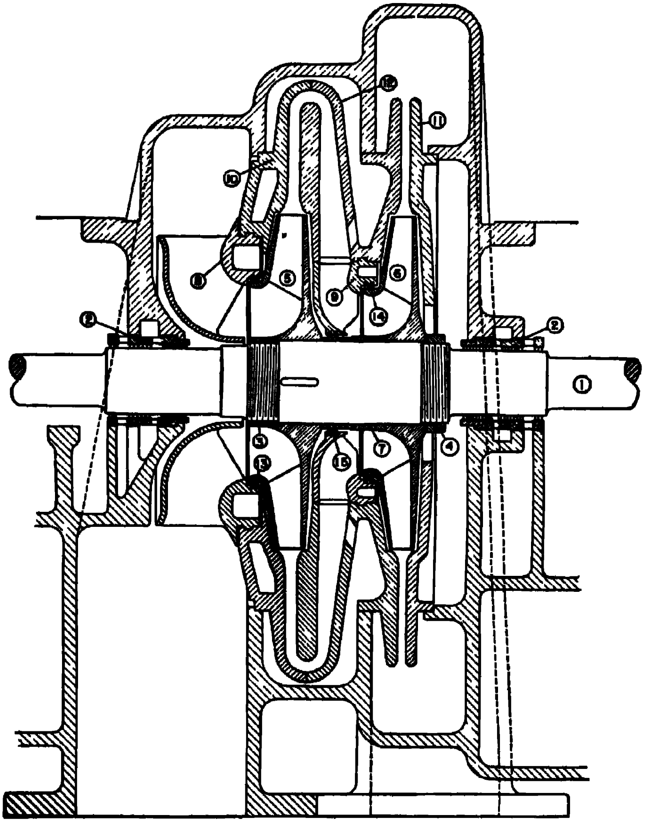

FIG. 9-2. Centrifugal compressor details. (1) Shaft; (2) shaft labyrinth, either end; (3) impeller lock nut, suction end, (4) impeller lock nut, discharge end, (5) impeller, first stage; (6) impeller, second stage; (7) impeller spacer; (8) inlet guide vane, first stage; (9) inlet guide vane, second stage; (10) intake wall; (11) discharge wall; (12) diaphragm, first stage; (13) inlet labyrinth, first stage; (14) inlet labyrinth, second stage; (15) spacer labyrinth.

In a centrifugal compressor the gas is in no way completely enclosed within definable walls and squeezed into a smaller volume as in the case of so-called "positive-displacement" compressors, whether of the reciprocating or rotary type. There are no major rubbing surfaces except shaft and thrust bearings and no close clearances except the labyrinth packings used to reduce interstage leakage in multistage machines (see Fig. 9-2). This fact makes it possible to segregate the lubrication system from the stream of gas passing through the compressor and practically eliminates contamination of the refrigerant by oil.

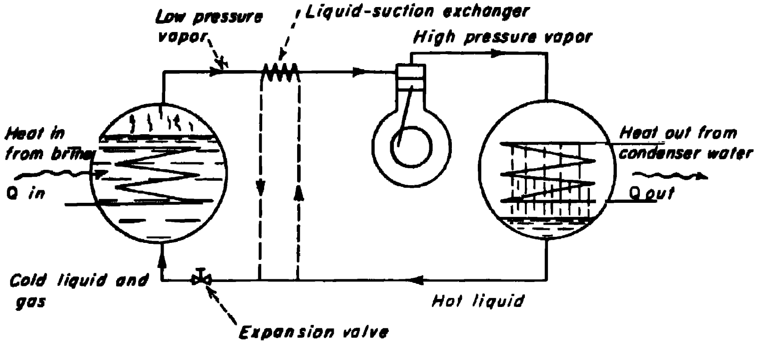

FIG. 9-3a. Simple refrigeration cycle.

Cycle. The simple single-stage refrigeration cycle shown in Fig. 9-3a is undoubtedly familiar. The only important variation is the optional use of a liquid-suction heat exchanger (indicated by dotted lines) for cooling the liquid returning to the evaporator at the expense of heating the compressor suction gas. In either case relatively warm liquid is throttled directly from condenser to evaporator pressure. Since this liquid must be cooled to the evaporator temperature, a definite fraction must be evaporated before any useful refrigeration can be produced. The resulting gas must be pumped back to the condenser through the total pressure ratio of the cycle.

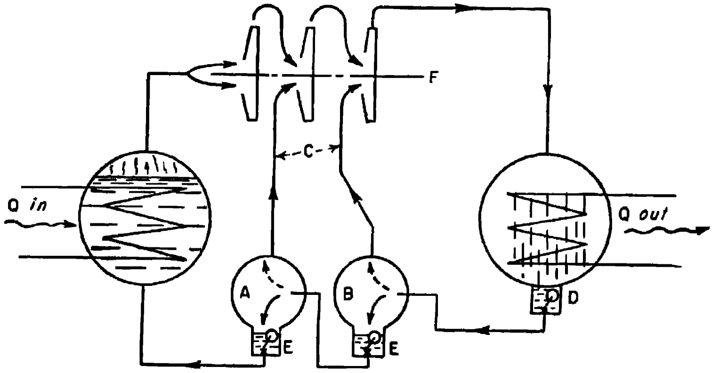

FIG. 9-3b. Refrigeration cycle with interstage liquid flash cooling. (A) Low-temperature economizer; (B) high-temperature economizer; (C) economizer gas lines; (D) condensate return trap; (E) economizer traps; (F) three-stage compressor.

Centrifugal refrigeration cycles almost always employ one or more stages of liquid "flash cooling" as shown in Fig. 9-3b. Instead of returning the condensate immediately to the evaporator, it is passed through one or more expansion chambers, or "economizers," which are connected to intermediate stages of the compressor. Means are provided in these chambers for separating the gas generated from the liquid and for passing the latter on to the next lower pressure. In this way all the useless evaporation necessary to cool the liquid from the condenser to the evaporator temperature does not occur at the lowest pressure. For the cycle shown, roughly a third of the total gas is compressed through the entire pressure range, another third is handled by the last two compressor stages, and the remainder passes through only the last wheel.

The use of intermediate liquid flash cooling in centrifugal refrigeration cycles results in important power savings, particularly when the temperature range (condenser minus evaporator temperature) of the cycle is large.

Evaporators or Brine Coolers. Centrifugal refrigeration machines almost invariably are designed with close-coupled evaporators or brine coolers because it is usually less expensive to pipe the load (either directly or by the use of a secondary refrigerant or brine) to the machine than to pipe the refrigerant to and from the load.

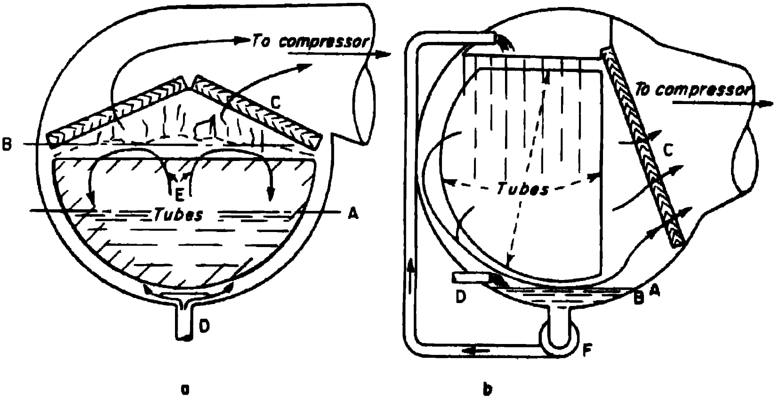

Fig. 9-4. Two common types of evaporators (*A*) Shutdown refrigerant level; (*B*) operating refrigerant level, (*C*) entrained liquid eliminator, (*D*) liquid return connection; (*E*) circulation during operation; (*F*) refrigerant pump

Two types of shell and tube evaporators are commonly used, the flooded type and the pump type, shown schematically in Figs. 9-4*a* and 9-4*b*, respectively. Flooded coolers are used whenever the loading of the heat-transfer surface and evaporator pressure is great enough to cause a violent boiling condition in and around the tube bundle. With low-vapor-pressure refrigerants like Freon 11, it is necessary to use a very compact type of finned tubing to develop the proper degree of circulation and assure high heat-transfer coefficients.

At low evaporator pressures the weight of the body of liquid refrigerant raises the pressure and hence the boiling temperature in the bottom of the shell to such an extent that the subsurface formation of gas and resultant agitation of the refrigerant is suppressed. The same result occurs if the heat-transfer coefficient on the brine side (inside tube surface) of the tube bundle is low. In either case the refrigerant-side heat-transfer coefficient and effectiveness of the surface are improved by distributing the liquid over the tube bundle with a pump as in Fig. 9-4*b*.

Condensers. The condensers of centrifugal refrigeration equipment differ only slightly from those used in other systems of equal capacity. Since the majority of machines use low-vapor-pressure refrigerants like Freon 11, the gas volumes entering condensers are relatively large, and more space must be provided within the shell for distribution of gas to the condensing surface.

The evaporator pressure of most centrifugal machines is subatmospheric. Any leaks which occur will therefore result in air, water, or brine entering the refrigerant system rather than escape of refrigerant. Condenser design must therefore provide means to collect and evacuate larger amounts of air and moisture than would normally occur in using refrigerants of higher vapor pressure.

The coexistence of air, water vapor, and Freon refrigerants in the condenser air-collection system introduces certain unique corrosion problems which must be considered in any successful design of these elements.

Purge Systems. The condenser pressures of centrifugal refrigeration units using low-pressure refrigerants may at times be subatmospheric. The system used to evacuate air and moisture must be designed accordingly. Details of the purge systems furnished by various manufacturers differ, but all normally provide the following essential functions:

1. Primary air and water-vapor concentration in the condenser shell
2. Means for transferring these gases to the purge unit
3. Additional concentration of the foul gases by condensation of some refrigerant and water vapor
4. Separation of water and liquid refrigerant and return of the latter to the machine
5. Relief of air and residual refrigerant and water vapors to the atmosphere

Besides its obvious duty of maintaining efficiency of the condensing surface on the refrigerant side, frequent observation of the purge system will reveal the incidence of any significant air, brine, or water leaks into the machine.

COMPRESSOR PERFORMANCE CHARACTERISTICS

The displacement or cubic feet per minute handled by a centrifugal compressor is not closely associated with speed. In fact, a machine running at constant speed will handle widely varying volumes with little change in pressure ratio but with a corresponding change in power requirement. This is indicated clearly in Fig 9-5. The three curves in each half of the figure apply to three different speeds, N_1, N_2, and N_3, and a constant or nearly constant suction temperature and density. The vertical coordinates are the ratio of condenser pressure to evaporator pressure or pressure ratio (lower) and input horsepower (upper).

Since the refrigeration or the cooling effect produced is almost proportional to the pounds of refrigerant circulated, the horizontal coordinate can be considered as the load in tons or Btu per hour which is imposed on the machine. The shape of the characteristic curve indicates that a considerable range of capacity can be handled at constant speed with relatively minor change in compression ratio.

The factors that influence the maximum compression ratio produced by a compressor are

1. The speed at which it is driven
2. The molecular weight of the gas handled. A higher pressure ratio is developed per stage with high-molecular-weight gases.
3. The number of wheels or stages
4. The diameter of the compressor wheels

The effect of items 1 and 4 is to establish a certain impeller "tip speed" (peripheral velocity). The compression ratio developed is closely related to this velocity (U in Fig. 9-1).

Capacity Control. The operating engineer should become familiar with the displacement-pressure ratio-power characteristics of this type of machine because they serve as a guide to operating procedures. For example, the characteristic in Fig. 9-5 indicates the relative performance obtained with different methods of control. In most instances the demand on the compressor is one of reducing pressure ratio with reducing load as represented by the line OA. This type of demand may be brought about by an interrelation between condenser water temperature and load, as in the case of air-conditioning applications. (Low outside temperature reduces both the load and condenser water temperature.) Or it may be that the only reduction in pressure ratio comes about by the reduced temperature difference required on the heat exchangers (brine cooler and condenser) at reduced load In any case, with a load-pressure ratio demand curve like OA, the lowest power will be required if the speed of the compressor is reduced. For this reason centrifugal refrigeration machines are usually driven by a variable-speed motor or turbine.

If a constant-speed driver such as a synchronous motor is used, practically equal power economy will result by interposing a slip coupling of either the hydraulic or magnetic type between driver and compressor.

If variable compressor speed is not provided, either suction throttling or condenser-water throttling may be used to balance the capacity with the demand. Suction throttling requires less power and is therefore used almost to the exclusion of the latter method.

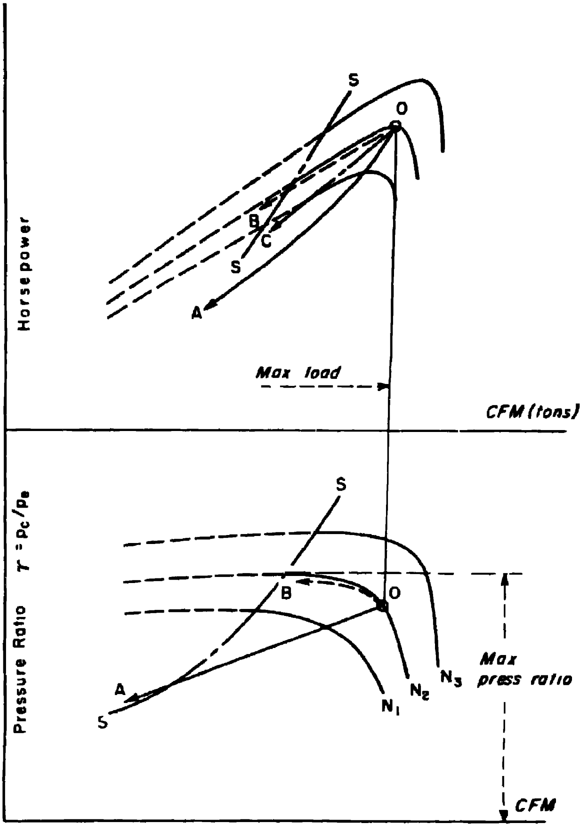

Fig. 9-5. Compressor and load characteristics.

It will be remembered that the characteristic curves shown in Fig. 9-5 are for a fixed-suction gas temperature. At higher suction temperatures the compression ratio at a given speed and cubic feet per minute will be lower. If the machine in question is designed to deliver water or brine at a constant temperature, the evaporator refrigerant temperature required will be higher at reduced loads. Since throttling does not materially alter the gas temperature, the cubic feet per minute-pressure-ratio characteristic when suction-damper or condenser-water control is used will be similar to that represented by the dotted curve *OB* in the lower part of Fig. 9-5.

The horsepower cubic feet per minute characteristic for condenser-water control will be as indicated by the dotted curve *OB* in the upper diagram. The power curves *OA* and *OB* can be compared directly because they refer to the same suction density and therefore to equivalent weight flows and approximately the same refrigeration load at particular cubic feet per minute.

The power–cubic feet per minute curve for suction throttling would only lead to confusion if placed on the same diagram because the effect of the suction damper is to reduce the pressure and density entering the compressor. The suction cubic feet per minute handled per unit of refrigeration is increased at part loads to such an extent that the operating point on the lower diagram moves back and away from point *O* very little as load is reduced. However, the weight flow of refrigerant reduces, and the power falls off accordingly.

If curves *OA* and *OB* are taken as the horsepower vs. tons characteristics for variable-speed and condenser-water control, respectively, the corresponding curve for suction-damper control will fall between them as indicated by the dash-dot line *OC* in the upper part of Fig. 9-5.

It will be realized, of course, that certain power losses result in variable-speed (slip-ring) motors and in slip couplings, and these losses must be included in any realistic power-consumption comparison. Even though these losses are added, it will be found that variable-speed drives are normally the most economical for centrifugal refrigeration units. In some instances, however, either the power saving does not justify the more costly motor, or the savings which may accrue from power-factor correction supplied by a synchronous motor offset the control losses.

Referring again to the cubic feet per minute -pressure-ratio characteristic in the lower half of Fig. 9-5, the reader will notice a line marked *SS* which cuts across the characteristic curves at their points of maximum compression ratio. To the left of this line the delivery of the compressor will be intermittent. The operation is often referred to as being unstable or surging. Generally, if the load is only slightly less than that required for stable operation, the frequency of the surge will be long. If the load is very light, the surging will be rapid or more like a flutter.

Surging is a normal characteristic of practically all centrifugal compressors. It has no detrimental effect on the compressor as long as the machine is rugged in design and the energy in the surge is limited. In the case of air or gas compressors, discharge check valves are usually installed to limit the intensity of the periodic reversal of flow through the compressor. Fortunately, in refrigeration applications the condenser (to which the compressor is usually closely coupled) acts like a check valve. The process of continuous condensation of the refrigerant leaves only a small amount in gaseous form on the discharge of the compressor at all times. The only danger normally associated with unstable operation of centrifugal refrigeration compressors is that overheating may occur at very light loads (15 to 20 per cent full load) if extended operation is undertaken. Overheating will be evidenced by abnormal temperatures of the bearing lubricant. A by-pass from condenser to evaporator is usually supplied on machines that must operate continuously at very light loads. It is not necessary to by-pass enough gas to stop the surge. This would be wasteful of power. Only that amount necessary to maintain normal bearing temperatures need be by-passed.

In some applications the sound of the surge may be objectionable. In such circumstances it is advisable to select the type of control which will reduce the point of instability to as low a load as possible. If load and condenser-water temperature fall off together or if light loads occur only in periods of low condenser pressure, variable-speed control will usually reduce surging almost to the vanishing point. This is indicated by the low-load intersection of lines *OA* and *SS* in the lower diagram of Fig. 9-5. With variable-speed control and this type of load characteristic surging occurs only at reduced compressor speeds where it is very mild in energy level.

If low loads may occur during periods of high condenser pressure and consequently high pressure ratio, a suction damper is most effective in suppressing the incidence of instability. For this reason a damper is often supplied even on machines equipped with variable-speed drives.

Capacity Range. As in the case of other types of compression refrigeration equipment, the capacity of centrifugal machines depends on their compressor displacement, the characteristics of the refrigerant used, and the operating-temperature level. Of the several Freon refrigerants, Freon 11 is normally used in machines for water cooling and for brine cooling down to about −20°F. For ultralow temperature applications, down to as low as −120°F or lower, and for large-capacity duty at higher temperature levels, Freon 12 is used. As Freon 22 becomes more available it may replace Freon 12 to some extent because of its slightly higher cycle efficiency.

Centrifugal refrigeration compressors are built for a range of displacements from about 2,000 to 20,000 cfm. Using Freon 11 for water-cooling duty, this range is equivalent to the capacity range of from 125 to 1,200 tons. Equipment of the same displacement but capable of higher compression ratios will produce from 40 to 400 tons on 0°F brine-cooling duty. The use of Freon 12 in similar machines designed for the higher pressure refrigerant results in capacities between five and six times those obtained with Freon 11. Freon 12 is, of course, used for ultralow temperature work. The relatively large displacements of centrifugal compressors make capacities of as high as 300 tons available in a single unit at −100°F suction temperature.

OPERATION

Centrifugal refrigeration equipment is relatively simple to operate. The inherently flat pressure ratio-volume characteristic for a given speed results in the tendency to maintain nearly constant evaporator and delivered brine temperatures under varying load conditions. This means fewer adjustments during operation. Turbine-driven or motor-driven units with hydraulic or magnetic slip couplings are easily provided with controls to maintain a constant delivered brine temperature by automatically adjusting compressor rpm. Machines with suction dampers can also be made automatic by the use of controlled damper positioners.

Normally there are no valves in the refrigerant circuit to be opened or closed. The equipment is usually started in the following sequence:

1. Brine and condenser-water circulating pumps
2. Refrigerant-condenser purge system unless it is designed for automatic operation
3. Lubricant cooling-water flow
4. Centrifugal compressor

If the brine is warm and condenser is free of air, the compressor will not surge when started and may be increased in speed to the limit of the safe input for the driver. Motor current should be observed and maintained below the full load rating either by the speed control or by closing the suction damper.

If the brine is cold and condenser water is warm (as in cases where several machines are operated in parallel) or if air in the condenser causes an abnormal elevation of the condenser pressure, the compressor will not pump any gas and therefore will not produce any refrigeration until its speed is increased to a point where the compression ratio it develops exceeds that established by the evaporator and condenser pressures. A rapid surge and low power demand are indicative of such conditions. Sometimes if machines have been opened for inspection or repair, large concentrations of air will be mixed with the refrigerant vapors. This has the effect of reducing the average molecular weight of the gas handled by the compressor and hence reduces the maximum ratio which can be developed. In such circumstances it may be impossible to get the machines to absorb load until the air concentration has been reduced by the purge equipment.

Shutdown equipment is normally stopped in the following sequence:

1. Compressor
2. Brine and condenser-water circulating pumps
3. Purge equipment unless it is designed for automatic operation
4. Lubricant cooling-water flow

ROUTINE SERVICING AND TROUBLE SHOOTING

In centrifugal refrigeration equipment the item of mechanical wear is reduced almost to the vanishing point. The major danger to bearings and other internal parts is corrosion. Annual inspection of the thrust and shaft bearings is advisable.

Besides the routine duty of maintaining heat-exchange surface (evaporator and condenser) in a clean and efficient condition, the operator's major concern should be to prevent as far as possible the contamination of the refrigerant with air, water, and oil. The presence of air and water in Freon refrigerant systems is the primary cause of corrosion. Since inward leakage of air always carries with it some water vapor and since even the most effective purge-recovery system must discharge some refrigerant with purged air, the operator who maintains his equipment "vacuum tight" will reduce both internal corrosion and refrigerant loss. *Machines should be checked periodically for inward air leakage and water or brine leakage from the heat exchangers into the refrigerant. The purge system should be maintained in good condition* so that it can remove air and water from the system if it enters and hence serve to indicate trouble.

Ordinarily the capacity and efficiency of centrifugal compressors are not directly related to the hours or years of operation. It is not unusual for a machine to maintain its original performance for 10 years or more with only minor servicing of auxiliaries and maintenance of heat exchangers. In fact, the only circumstances which can alter the performance of a centrifugal compressor are the development of excessive by-passing of gas between stages or the formation of deposits of scale or other foreign material in the gas passages of impellers and diffusers.

Interstage by-passing can result from increased clearances at the labyrinth packings caused by whipping of the rotor shaft. If no violent vibration has ever been noticed during operation, it is unlikely that labyrinths have been damaged. Likewise the deposit of foreign materials in the gas passages will eventually result in noticeable unbalance. Hence, abnormal vibration originating in the compressor is a sign of trouble, and inspection of the compressor rotor and diffusers is advisable. Otherwise the compressor assembly should require no servicing.

The gas-temperature rise from intake to discharge is an approximate indication of the power per pound used to compress the refrigerant. An unusually high discharge temperature, therefore, indicates poor performance and possibly internal recirculation. Compressor efficiency normally varies so much with load and speed, however, that only expert interpretation and careful measurements can definitely establish the facts. However, a cool or cold discharge temperature is indisputable evidence that entrained liquid refrigerant is entering the compressor with the vapor either from the evaporator or the economizers. Limited entrainment has no material effect on power requirement. In fact, liquid injection is sometimes used to limit discharge temperatures at high compression ratios. Excessive entrainment will increase power consumption and may be the cause of dirt or scale deposits in impeller and diffuser channels. The causes of a cold discharge temperature should, therefore, be located and corrected.

Centrifugal compressors should use very little, if any, oil. Absorption of Freon refrigerants in the oil will increase its volume and cause foaming at the beginning of operation. Observation of oil level should only be made at the end of operating periods when oil is warm and comparatively free of refrigerant. Oil should be added only when absolutely necessary, and excessive consumption (more than 3 or 4 qt per year) should be investigated.

APPLICATIONS

Centrifugal refrigeration equipment is applicable to practically all types of commercial and industrial services. Machines may be applied for cooling water brines, and liquids in processes of all sorts, and for the direct condensation and cooling within the evaporator of hydrocarbon vapors, ammonia, chlorine, and other industrial gases.

Such equipment may also be applied as a "heat pump" where fuel is scarce but electric power is available. The heat-pump principle involves the extracting of low-level heat (42 to 70°F) by the evaporator from the atmosphere or river and the delivery as high-level heat (120 to 150°F) from the condenser. Many such applications have been made on the European continent.

In general, centrifugal refrigeration machines are most applicable in sizes above 100 hp, although for ultralow-temperature applications this figure might be reduced.

A type of application that should not go unmentioned is to be found in the petroleum and chemical industries. Here a cooling effect is often produced by the direct evaporation, compression, and condensation of the materials in process or of a solvent injected for specific reasons. Centrifugal compressors are applicable to such processes which may be generally classified as autorefrigeration or solvent-recovery cycles.

Although all forms of commercial drive equipment may be used for centrifugal refrigeration compressors, the rotative speed and other characteristics of the steam turbine are ideal. Furthermore, in industrial applications where by-product steam is required or is available (breweries, meat-packing plants, refineries, etc.) the item of operating cost chargeable to refrigeration can usually be reduced by fitting the refrigeration turbine into the over-all steam-power balance of the plant.

RECIPROCATING COMPRESSION SYSTEMS

BY H. B. POWNALL

President, Freezing Equipment Sales, Inc.

The purpose of this subsection is to describe briefly the component parts and equipment making up a reciprocating compression refrigeration system. It is not the intent to go into detailed design but merely to describe the basic pieces of equipment as well as to discuss their operating characteristics.

RECIPROCATING COMPRESSORS

Reciprocating compressors may basically be subdivided into two classes, *viz.*, vertical- and horizontal-type compressors. In vertical compressors the center line of the cylinders is perpendicular to the floor, whereas horizontal compressors have the center line of the cylinders parallel to the floor. These two classifications may be again subdivided into single- and double-acting compressors. In a single-acting compressor the piston compresses gas during only one part of the stroke, whereas a double-acting compressor will compress gas in both ends of the cylinder.

These compressors may also be classified as being enclosed or semienclosed, depending on the way the gas is taken into the machine. In an enclosed-type compressor, the crankcase will be equalized to the low side pressure, and the lubricating oil is in contact with the refrigerant at all times. On a semienclosed machine a crosshead design is used so that the stuffing box is between the cylinder and the piston rod with the result that the crankcase can be equalized to atmospheric pressure. The most common compressor would be the enclosed type wherever it can be used since, having less moving parts, it is the more economical to build. It is necessary in some instances to use a semienclosed compressor where the refrigerant will break down the oil in the crankcase or where considerable foreign material is expected to flow back to the compressor.

The recent trend has been to design towards multicylinder, high-speed compressors. These compressors can be made either in line, radial, or in blocks forming Vs and Ws.

The capacity of reciprocating compressors will vary from a small fraction of a ton, such as the 1/6- and 1/8-hp compressors used on the domestic refrigerators, to several hundred tons capacity such as will be found in compressors of 14-in. bore by 13½-in. stroke, four cylinders in a line. From practical considerations, the top limit of bore and stroke is around 20 in. For single-stage compression where pressure differentials may approach 200 psi, the bearing pressures become excessive for larger bores, and good design in piston speeds will force the rotative speed of the compressor down. By using multicylinder radial or V-W compressors, the cylinder bore and stroke may be kept small, which allows high rotative speeds with resultant large increments of capacity.

TYPE OF REFRIGERANTS

The type of refrigerant to be used in conjunction with a reciprocating compressor must be carefully chosen. First, the refrigerant must have thermodynamic characteristics such that the volume of gas handled, commonly referred to as cubic feet per minute per ton, is maintained within the range of capacity of a positive-displacement type of compressor. The pressure differential of the refrigerant must be such that reasonable bearing loadings will be obtained. The density of the refrigerant will control the necessary valve area needed. The polytropic expansion coefficient must be such that reasonable discharge temperatures will be obtained with ratio of compressions as high as 8 to 1 and 9 to 1. It is also necessary to consider the characteristic mixtures which are obtained between lubricating oil and the refrigerant.

Making a brief comparison between ammonia and Freon 12, it might first be stated that the cubic feet per minute per ton required for ammonia is approximately 50 per cent less than that required for Freon 12. However, the pressure differential, when working from a constant evaporator temperature to a constant condensing temperature, is approximately 50 per cent greater for ammonia than for Freon 12. It is for this reason that on ammonia compressors designers will generally pick cylinder dimensions of equal bore and stroke such as 10- by 10-in. compressors. In designing this compressor for Freon 12, it is possible to go to a larger cylinder diameter for the same stroke and maintain the same bearing loading. Thus, it will generally be noted that on Freon 12 compressors the bore is generally larger than the stroke.

Since Freon 12 gas is approximately five times as heavy as ammonia gas, it is necessary to handle considerably more pounds per minute through the ports to the compressor with the result that considerably more valve area is required in a Freon 12 compressor than in an ammonia compressor.

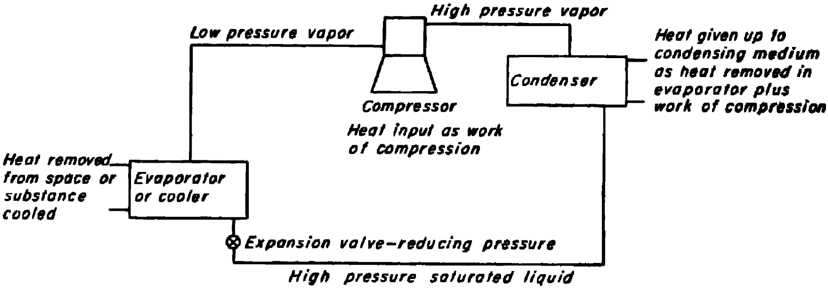
The solubility of ammonia gas in oil is practically negligible. Thus the crankcase oil is almost always pure and has very little tendency to foam upon reduction of pressure. Ammonia liquid and oil are also insoluble, and therefore, the oil, being heavier than the ammonia liquid, will separate and go to the bottom when a quiescent condition exists.

Freon 12 gas is soluble in all proportions in oil. There is a very definite pressure-temperature relationship established over oil and Freon mixtures. This solubility results in considerable foaming upon sudden reduction of pressure, and so it is very difficult to keep Freon oil in the crankcase of Freon compressors when the suction pressure is suddenly reduced.

Freon liquid and oil are also soluble and follow the same equilibrium curve as the Freon gas and oil. This means that, as the oil concentration builds up in Freon 12 liquid, the oil will not separate but tends to raise the boiling point of the refrigerant.

REFRIGERATION CYCLE

Figure 9-6 shows a schematic mechanical refrigerating system. It should be noted that the compressor is acting merely as a heat pump in that it forces heat to flow from a low temperature level to a high temperature level. This is accomplished by removing vapor which is formed by evaporating liquid on the low side of the system. This liquid is evaporated by the heat which it removes from the space or fluid to be cooled. The compressor raises the pressure of this vapor sufficiently high so that, when discharged into a condenser, this heat may be rejected to the atmosphere or cooling water by condensing the high pressure vapor to a liquid where it is again returned to the evaporator through a throttle or expansion valve.



High pressure vapor
Low pressure vapor
Heat given up to condensing medium as heat removed in evaporator plus work of compression
Condenser
Compressor
Heat input as work of compression
Heat removed from space or substance cooled
Evaporator or cooler
Expansion valve—reducing pressure
High pressure saturated liquid

FIG. 9-6. Schematic mechanical refrigerating system.

Without going into too much detail it can readily be seen from such a cycle that, the lower the evaporator pressure, the more inefficient this system will become when operating at a constant condensing pressure. This condition is easily explained since, as the evaporator pressure is reduced, the vapor created becomes rarer with the result that the compressor in handling a constant volume will handle less total pounds of the vapor. The refrigeration effect is naturally a function of the number of pounds of refrigerant evaporated in the evaporator. Thus, it can be said that, as the suction pressure of a compressor is lowered, the refrigeration effect will decrease approximately proportional to the absolute suction pressure; the total brake horsepower driving the compressor will also decrease; however, the brake horsepower per ton of refrigeration required by the compressor will increase.

The condensing pressure is controlled by the temperature of the cooling medium used, such as water or air. Generally speaking, a decrease in condensing temperature will increase the capacity of the refrigeration system and will decrease the total brake horsepower required by the compressor. Likewise, an increase in condensing temperature will decrease the refrigeration effect of the compressor and will generally increase the total brake horsepower required by the compressor.

TYPES OF CONDENSERS

Air-cooled Condensers. Air-cooled condensers are quite common on small commercial condensing units for capacities up to and including approximately two tons of refrigeration. They are seldom used for capacities greater than this since they require too much surface and air circulation to be economical. When using an air-cooled condenser, the condensing temperature corresponding to pressure can be as high as 130°F, with an air temperature as high as 100°F entering the condenser. For this reason air-cooled condensers are generally used only with refrigerants that have relatively low vapor pressures. For example, Freon 12 will have a corresponding vapor pressure of 180 psi at 130°F, whereas the corresponding ammonia would be approximately 315 psig. Thus, air-cooled condensers are very rarely used for ammonia applications.

Evaporative-type Condensers. Evaporative-type condensers are a combination of air-cooled and water-cooled condensers. Water is sprayed over the condensing surface while a fan pulls air through the condensing surface with the result that the condensing-surface temperature is maintained at the approximate average wet-bulb temperature between the leaving and entering air. Entering dry-bulb temperature has very little effect upon the operation of an evaporative-type condenser This is true since the entering air will saturate itself almost immediately upon coming in contact with the water. These condensers are becoming quite popular for both Freon 12 and ammonia use since they use approximately the same amount of water as a cooling tower, which consists of the theoretical $\frac{1}{4}$ lb per min per ton of refrigeration plus losses, as well as the fact that they combine the benefits of a cooling tower and water-cooled condenser into a single unitary piece of apparatus.

Water-cooled Condensers. Water-cooled condensers can be subdivided into vertical open types and horizontal closed types. In either case all heat removed is given up to the water flowing through the condenser. The vertical open-type condenser allows the water to flow down through the tubes by gravity, and as the name implies, the tubes are open on both ends which allows them to be cleaned during normal operation.

The horizontal closed-type condenser is generally a multipass condenser to enable high water velocities with resultant optimum heat transfer regardless of water quantity. The increasing popularity of extended surface tubes is responsible for the industry developing smaller and smaller shell sizes for a given capacity in the line of horizontal multipass condensers. This type of condenser must naturally be used either with city water, well water, or, on larger installations, cooling-tower application. The main disadvantage of the new highly efficient small multipass condensers is that, in areas having bad scale-forming water, the condenser tubes must be cleaned frequently.

TYPES OF EVAPORATORS

The subject of evaporators for refrigeration plants is one which in itself could be responsible for several volumes. Basically, the main purpose of an evaporator in a refrigeration plant is to boil the liquid refrigerant from a liquid phase into a vaporous phase. The refrigerant, in changing state, absorbs heat from the space or object to be cooled. The most common types of evaporators could be classified as follows:

1. Room pipe
2. Brine and water coolers
3. Air-cooling coils

METHODS OF CONTROL IN REFRIGERATION PLANTS

Most refrigeration plants today require quite a few automatic controls. These plants may be classified either as automatic or semiautomatic. Semiautomatic plants will have a considerable number of automatic controls in an effort to simplify operation but will require the attendance of an operator for such duties as to add oil to the compressor crankcase and make various minor adjustments. Commercial refrigeration has developed fully automatic plants which require no attention other than periodic inspection and cleaning.

Capacity Control of Reciprocating-type Compressors. Capacity control of reciprocating-type compressors can generally be accomplished in one of the following manners:

1. Speed control of the compressor is by nature the best type of control which can be used. This is true since the efficiency of the compressor is maintained when operating at reduced capacity as well as the fact that the percentage capacity reduction will be directly proportional to the speed reduction regardless of operating conditions. The disadvantage of speed control is the method of obtaining it, since the majority of installations today are electric drive, with the result that multispeed motors must be used which considerably complicate the electrical side of the plant. It is necessary to use two-speed motors or slip-ring motors in conjunction with resistance banks.

2. The use of multiple compressors is another way in which capacity control can be gained since compressors may be cut on and off the line to match plant capacity. This method of control, while thermodynamically efficient, is generally undesirable from a cost standpoint when more than two or three steps of capacity reduction are required. With this type of control on automatic plants, the crankcase of the compressors must be equalized. This sometimes presents a considerable problem.

3. Capacity control may be achieved automatically through the use of gas by-pass. Compressors of one design have a so-called "partial by-pass" which means that a portion of the gas pumped by the cylinder is by-passed back into the suction main. This method has the advantage that there is always some gas flowing through the cylinder in order to absorb some of the frictional heat.

An external by-pass from the high to low side may be used for capacity reduction, provided that some means of cooling the gas entering the suction of the compressor is used. This method is the least efficient since full compressor horsepower is required regardless of capacity.

4. Clearance pockets may be used to reduce capacity by designing some mechanical means of increasing the clearance in the cylinder. This type of capacity reduction is highly efficient, provided the clearance can be obtained without wire drawing. The only objections are purely mechanical, in that it is difficult to obtain sufficient clearance to give necessary capacity reduction.

It is of prime importance to design the controller actuating the capacity-reduction means so that there is sufficient time lag between steps of capacity to allow the plant to rebalance. It should be remembered that, wherever finite steps of capacity reduction are taken, the temperature difference between the initial and final temperature of the fluid being cooled will decrease by the amount of the capacity reduction. This means that either a very insensitive instrument will have to be used, which is objectionable because of the lack of control, or else sufficient time lag must be placed in the control circuit either to allow the compressor to rebalance under the reduced capacity condition or slowly cycle back and forth between two steps of capacity. Short cycling of refrigeration plants due to improper setting or application of controls can be very annoying from the standpoint of dependable operation as well as maintenance costs for repairs at the end of the year.

PLANT OPERATION

One of the most important requirements in the operation of a reciprocating-compressor type of refrigeration plant is to be sure that the compressor is handling dry gas on the suction side of the machine. Suction superheat is theoretically the measure of dryness, but it is not always possible to use. When using flooded-type evaporators where the vapor disengages from the body of liquid, with no superheating surface between the evaporator and compressor, this suction gas can enter the machine at saturation temperature. If the gas is carrying considerable quantities of liquid with it, the suction temperature will still remain at saturation. It is also possible on plants operating with refrigerants having high latent heat, such as ammonia, to have small quantities of liquid rolling along the bottom of the suction line with superheated gas flowing over top of the liquid, since insufficient time of contact was allowed for equilibrium conditions to be reached. In the above two cases suction-gas temperature is not a true measure as to whether liquid is returning to the compressor.

The discharge temperature from a refrigeration compressor is probably one of the best indications of liquid slop-over as well as one of the most important readings to be watched in any refrigeration plant. Normally the discharge temperature from a compressor should run 20 to 30°F higher than the expected adiabatic discharge temperature. It is possible to run at the expected adiabatic temperature for most compressors without danger, although this is generally an indication of wet compression. When discharge temperatures are running lower than adiabatic, it means that certain amounts of liquid are entering the cylinder and cooling the gas during compression but that this liquid is completely evaporated at the end of the compression stroke.

A continuous log of discharge temperature on a compressor is generally the best indication of trouble occurring in the machine. A valve breakage or any blowback from high pressure to low pressure within the machine will be apparent by a partial increase in the actual operating discharge temperature.

The presence of air or other noncondensable gases is a detriment to the operation of a refrigeration system in that, for a given cooling-water temperature, the presence of air results in an increased condensing temperature which results in lowered capacity and over-all plant efficiency. Air normally collects in the condensing or high-pressure side of the system and is purged at this point either by hand or by automatic purge devices. The presence of noncondensable gases in the condenser may be detected by checking the temperature of the condensate liquid against the temperature corresponding to pressure in the condenser. Normally, under stand-by conditions, if the temperature of the liquid condensate is more than 3 or 4°F below that corresponding to saturation at the observed pressure, air is present, and purging is necessary. Whenever the evaporator side of the system is operating in a vacuum, particular attention must be given to prevent possible air leakage through valve packing, stuffing boxes, etc.

For good operation, it is essential for the condenser tubes to be free of scale. The presence of scale in an air-free condenser is noted by an increase in the temperature difference between the water and the saturation temperature corresponding to pressure. Whenever this temperature increases appreciably over that for known clean conditions, the tubes should be cleaned.

AMMONIA-ABSORPTION REFRIGERATION SYSTEMS

BY W. H. BICKFORD

Chemical Engineer, York Corporation

The continuous ammonia-absorption refrigeration system performs the same basic function as the reciprocating compression system but in a somewhat different manner. In the absorption system the transfer of refrigerant from evaporator pressure to condensing pressure is by virtue of the solubility relationships between ammonia and water.

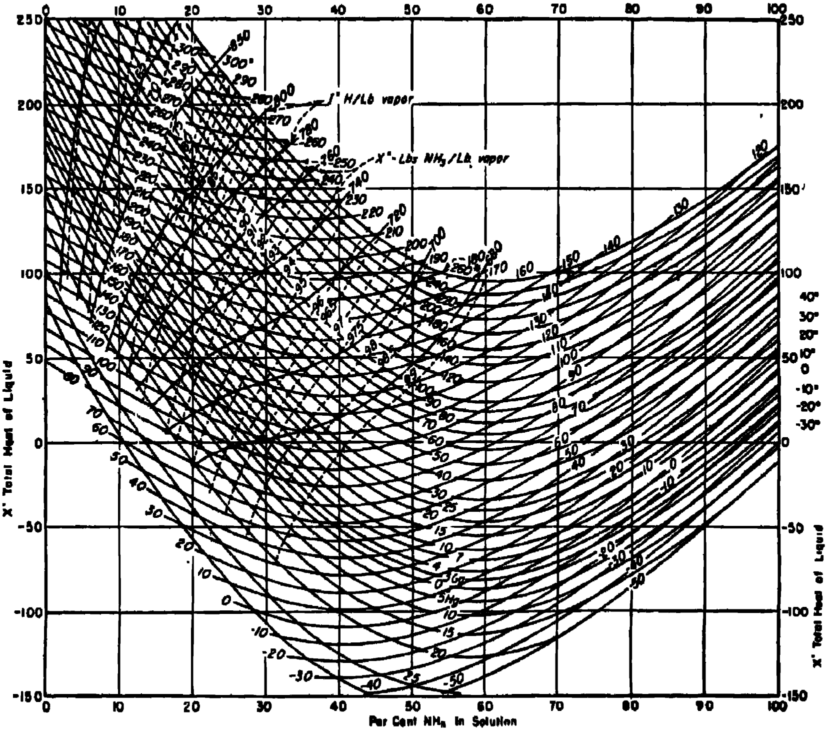


FIG. 9-7. Thermal properties of ammonia-water solutions (copied from A. B. Stickney chart).

The thermal properties of ammonia-water solutions are shown in Fig. 9-7 from which it may be seen that

1. At constant pressure the quantity of ammonia in a solution decreases with an increase in temperature.
2. At constant temperature the quantity of ammonia in a solution decreases with a decrease in pressure.
3. Heat must be removed for a solution to absorb more ammonia at constant pressure.
4. Heat must be added to decrease the concentration of a solution at constant pressure.

In a typical system (Fig. 9-8), the ammonia refrigerant is vaporized in the evaporator, and the vapor passes to the absorber and is absorbed in a weak solution of ammonia and water (weak aqua) forming a strong solution (strong aqua). The strong aqua is transferred to the generator through exchanger by means of aqua pump. In the generator the refrigerant vapor is boiled out of solution through the bubble column to condenser where the vapor becomes liquid. The weak aqua solution formed in the generator passes under condensing pressure through exchanger, undergoes a reduction in pressure, and enters absorber at essentially evaporator pressure. In the exchanger heat is transferred from the hot weak aqua leaving the generator to the cool strong aqua from the absorber, decreasing the amount of heat-transfer surface required in absorber and generator as well as generator heat and over-all cooling-water requirements.

The rectifier is used to remove water carried by the refrigerant vapor leaving the generator, thus ensuring essentially pure ammonia vapor to the condenser. A small amount of condensed liquid, known as reflux, is returned to the rectifier for this purpose.

Each piece of equipment in the cycle has a part in the *plant heat balance* as follows:

Generator—Heat is added at high temperature.

Evaporator—Heat is added at low temperature.

Pump -- Heat is added in the form of work performed.

Absorber--Heat is removed by water

Condenser—Heat is removed by water.

Rectifier—Heat is exchanged between liquid ammonia reflux and hot vapor from the generator.

Exchanger--Heat is exchanged between strong and weak aqua.

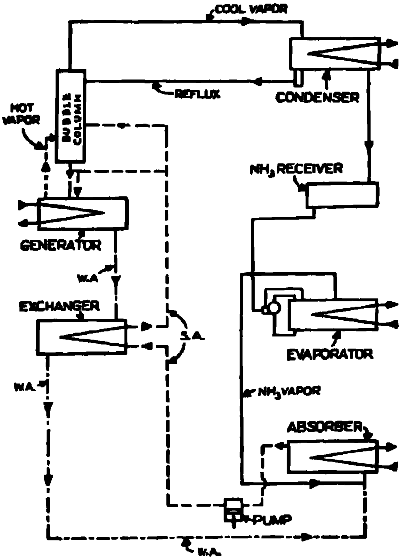

FIG. 9-8. Absorption-system flow diagram.

The heat exchanged in rectifier and exchanger is of internal nature and, while affecting the over-all plant balance, is not considered as a separate item.

In a typical system, the heat quantities per pound of refrigerant supplied to the evaporator are

Q_G = heat supplied to generator

Q_E = heat removed in evaporator

Q_P = heat equivalent of pump work

Q_A = heat removed from system by absorber water

Q_C = heat removed from system by condenser water

Q_L = heat losses from system through radiation, etc.

Neglecting losses and incorporating heat equivalent of pump work into generator heat supplied, the heat balance is as follows:

$$Q_G + Q_E = Q_A + Q_C$$

The above quantities may be evaluated through use of table of thermodynamic properties of ammonia, steam, and ammonia-water solutions.

The absorber load Q_A is comprised of three factors: (1) the heat of condensation of ammonia vapor, (2) the heat of solution as the ammonia is absorbed, and (3) the heat removed in cooling the weak aqua solution to absorber temperature. Obviously, once the evaporator, condenser, and absorber loads are known, the generator load may be obtained by difference. Approximate values of absorber and condenser loads may be obtained from Table 9-25.

Table 9-25. Approximate Values of Absorber and Condenser Loads

Aqua concentration, per cent NH_3 by weight		Load, Btu/lb ammonia evaporated							
		Condenser				Absorber			
		Pressure, psig				Pressure, psig			
Strong	Weak	205	185	165	145	40	30	20	10
45	35	593	590	587	584	807	815	820	830
44	36	598	595	592	590	795	804	810	818
43	37	603	600	598	591	775	784	790	798
40	30	623	620	610	614	844	851	859	866
39	31	630	627	624	621	830	840	846	855
38	32	638	635	632	628	811	820	826	835
35	25	666	662	658	654	880	887	895	904
34	26	677	673	668	665	867	875	883	891
33	27	689	685	680	676	845	855	862	865
30	20	730	725	718	714	915	925	932	940
29	21	747	742	735	729	905	913	920	930
28	22	765	759	751	745	885	893	900	910

Current preference in equipment is toward the use of horizontal shell and tube construction for condensers, absorbers, generators, and distillation column-type rectifiers. Centrifugal-type aqua pumps are preferred with either motor or turbine drive.

From an operating viewpoint, the primary requisite is the avoidance of sudden changes. Adjustments to operating variables should be made gradually.

For correct economical operation it is necessary that proper balance be maintained throughout the unit. The heat input to the generator increases as the aqua solution decreases in strength. Therefore, the aqua concentrations should be held as high as possible regardless of the load on the system. The amount of heat input to the generator also increases with an increase of "compression ratio," so the absorber pressure should be maintained as high as possible while doing refrigeration at the required temperature.

The concentration of the strong aqua is dependent upon the amount and concentration of the weak aqua supplied to the absorber, together with the amount of vapor that is absorbed. Therefore, in order for the system to operate at best conditions, the quantity of weak aqua circulated should be in proportion to the amount of vapor from the evaporator. If the full-load quantity of aqua is circulated when the load is decreased, the final concentration of the strong aqua from the absorber is decreased from the design condition. This results in a lower absorber pressure, and unless the evaporator pressure is controlled by throttling the vapor, the evaporator pressure will also decrease. If the evaporator temperature is controlled by a valve causing a pressure drop between the evaporator and the absorber, the system operates on a lower aqua concentration than necessary, with the result that the heat input to the generator is excessive.

The evaporator pressure may be controlled by increasing the concentration of the weak aqua from the generator by lowering the steam pressure. However, with this control, the full amount of aqua in circulation must be heated from exchanger temperature to the final generator temperature, thus requiring more steam than if the aqua quantity were reduced to correspond with the reduction in refrigerating load.

The quantity of aqua circulated should be decreased as the load decreases on the unit, with the aqua flow being decreased a little more rapidly than the decrease in the amount of vapor going to the absorber from the evaporator. This gradually changing ratio between the quantity of aqua circulated and the quantity of vapor to the system is difficult to maintain accurately either with manual operation of the plant or by the use of automatic control, so that in most cases the aqua flow is reduced in direct proportion to the reduction in quantity of vapor being absorbed.

Loss of capacity in an absorption system may be attributed to any of the following causes:

1. Presence of noncondensable gases in absorber and condenser as indicated by temperature-pressure relationships
2. Insufficient cooling water supply to condenser and absorber
3. Excessive fouling of absorber and condenser tubes
4. Insufficient refrigerant or aqua charge in plant. (Proper levels should be maintained in all equipment.)
5. Unsteady steam pressure. (The generator should have even source of heat.)
6. Accumulation of condensate on steam side of generator. (Tubes must drain properly.)

The concentration of the strong and weak aqua solution may be obtained with fair accuracy from temperature and pressure conditions in the absorber and generator, respectively, provided the system is purged of noncondensibles. Exact determination of solution concentration may be made by chemical analysis of samples withdrawn from the system.

The operating conditions for a given evaporator pressure are fixed by the steam pressure and cooling-water temperature. Generally, it may be stated that, for optimum operation, steam and water conditions should allow at least an 8 per cent difference in concentration between the strong and weak aqua streams, although it is quite possible to operate systems with larger or smaller concentration differences.

The absorption refrigeration system finds its chief application where a sufficient quantity of waste heat is available in the form of steam. hot oil, etc. Systems may be designed to operate single or double stage, with series or parallel flow of cooling water through condenser and absorber, allowing considerable flexibility when properly operated.

The quantity and temperature level of the generator heat supply as well as the temperature and quantity of cooling water to absorber and condenser is largely a function of design. The most advantageous applications are in cases where suitable amounts of waste or low-grade heat are available. This heat may be available as exhaust steam, quench oil, or similar heat which might normally be lost but which could be used to produce refrigeration.

Table 9-26. Steam and Water Rates per Ton of Refrigeration

(Single-stage—steam and water rates are based on series flow of water through condenser and absorber, 85°F H_2O on condenser and 8 per cent aqua split)

Absorber pressure, psig	Steam pressure, psig	Steam rate, lb/hr/ton	Cooling-water rate, gpm/ton
5	46.5	37.7	5.40
10	35.0	34.3	5.06
15	27.5	32.0	4.84
20	21.5	29.8	4.66
25	16.5	28.3	4.52
30	12.3	27.0	4.39
35	8.6	25.8	4.28
40	5.8	24.7	4.18

Table 9-26 gives typical values of steam and cooling-water rates for several absorber pressures with fixed cooling-water temperatures.

Industrial absorption refrigeration machines have been designed and operated for refrigeration loads from 100 to 2,000 tons. Where suitable cooling water is available, usually below 85°F, water may be used in series, passing first through condenser and then absorber, realizing an appreciable saving in pumping costs, etc.

Two-stage absorption machines may be used where refrigeration is required at different temperature levels, as well as for single low-temperature loads with heat source below that allowable for single-stage operation.

The absorption machine should not be overlooked where waste heat is available. Unlike reciprocating compression machines, which are limited by volumetric displacement, the absorption machine can maintain capacity at lower back pressures by increasing the flow of heat to the generator. A further advantage is that the absorption machine may be located outdoors, requiring no special building. With the application of suitable controls, these machines operate with a very small amount of attention.

ABSORPTION AND ADSORPTION DEHUMIDIFYING SYSTEMS

BY GILBERT A. KELLEY

Chief Engineer, Air Conditioning Division, Surface Combustion Corporation, Toledo, Ohio

Dehumidification is the removal of moisture from air or other gases. The term "dehumidification equipment" is usually applied to equipment whose primary function is removal of moisture from a gas, usually air. This is a contrast to the conventional refrigeration systems where moisture is removed from a gas by condensation simultaneously with the reduction in sensible heat of the gas by spray or surface cooling with the cooling medium below the dew point of the gas. *There are two general types of dehumidifying systems, viz.*, absorption systems and adsorption systems.

Absorption systems are those in which moisture is removed from a gas with a change, either physical or chemical or both, of the absorption medium during the process. The absorption medium may be either solid or liquid. Calcium chloride is an example of a solid absorbent, and aqueous solutions of lithium chloride, lithium bromide, calcium chloride, and solutions of the ethylene glycols are examples of liquid absorbents.

Adsorption systems are those in which moisture is removed from a gas without any physical or chemical change of the adsorbing medium during the process Silica gel, activated alumina, and activated bauxites are examples of solid materials having this adsorbing property.

ABSORPTION SYSTEMS

Principle of Operation. The liquid absorbent or hygroscopic solution has the property of absorbing moisture from, or adding moisture to, the air depending upon the vapor-pressure difference between the air and the solution. The equilibrium vapor pressure of the solution is dependent upon the temperature and the concentration of the solution. The liquid absorbent is capable of either dehumidifying or humidifying the air, depending upon the requirements on the system, by control of the temperature or the concentration of the solution.

Air saturated in contact with an aqueous solution of lithium chloride will contain approximately one-eighth as much water as air saturated in contact with water. In other words, air in equilibrium with a concentrated aqueous solution of lithium chloride would have a relative humidity of approximately 12 per cent since the relative humidity of the air is the amount of moisture in the air compared to the amount of moisture the air would contain if it were saturated with water vapor at the same temperature.

In most of the commercial equipment of this type, it is usual practice to maintain the concentration of the solution constant for a given application and to cool the solution where it is desired to remove moisture from the air and to heat the solution when it is desirable to add moisture to the air.

The heat of absorption, owing to moisture being absorbed from the air by an absorbent liquid, is given up to the surface of the liquid. This heat will cause the absorbent liquid to rise in temperature so that it is necessary to cool it. Otherwise the whole body of absorbent liquid would rise in temperature to such a point that the loss of the sensible heat to the air by conduction and radiation would equal the gain in latent-heat absorption of the water vapor by the liquid.

As contrasted with adsorption systems, the dry-bulb temperature of the air from an absorption dehumidifier is not a function of the amount of water removed from the air but is dependent upon the temperature of the absorbent liquid. If the temperature of the absorbent liquid is lower than the dry-bulb temperature of the air entering the dehumidifier, the air will be cooled as well as dehumidified in passing through the dehumidifier. If the temperature of the liquid absorbent is higher than the dry-bulb temperature of the air, the air will tend to increase in temperature while passing through the dehumidifier.

Liquid-absorbent Summer Operating Cycle. The operating cycle of a liquid-absorption system with an external solution cooler and heater is shown in Fig. 9-9 For summer operation the strong hygroscopic solution is pumped from the sump of the unit through a solution cooler. The solution is continuously cooled in the heat exchanger with city, well, refrigerated, cooling-tower water, or in some instances with an evaporative cooler. The quantity of water required is a function of the water temperature and the total heat, either sensible, latent, or both, removed from the air by the hygroscopic solution.

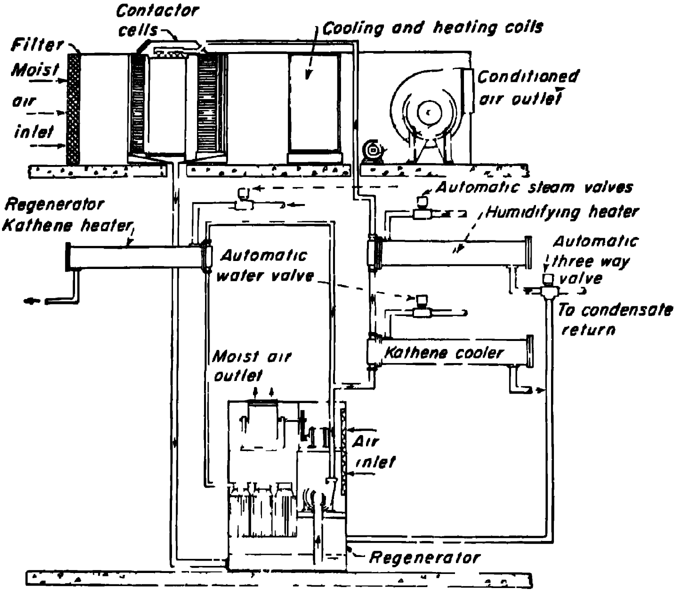

FIG. 9-9. Flow chart for liquid-absorbent system with external liquid cooler and heater.

The hygroscopic solution at the required temperature and concentration is brought into intimate contact with the air to be dehumidified in the contactor chamber of the unit The moisture is absorbed from the air by the solution owing to the vapor-pressure difference between the air and the solution The amount of water vapor removed from the air is usually controlled by automatically regulating the flow of water through the cooler with a modulating water valve

The dry-bulb temperature of the air leaving the liquid-absorbent contactor is dependent upon the temperature of the liquid absorbent and the amount of contact surface between the air and solution. In most commercial equipment, the dry-bulb temperature of the air leaving the dehumidifier will be within 1 to 5° of the liquid-absorbent temperature. If the temperature of the absorbent liquid is lower than the dry-bulb temperature of the air entering the dehumidifier, the air will be cooled as well as dehumidified in passing through the dehumidifier If the temperature of the liquid absorbent is higher than the dry-bulb temperature of the air, the air will increase in temperature.

Cooling and heating coils are installed in the duct work if cooling or heating of the air from the dehumidifier is required.

In absorbing moisture from the air, a certain amount of heat is generated which is the heat of condensation of the water vapor in the solution. This consists of the latent heat of condensation of water vapor and the heat of solution or the heat of mixing. The heat of mixing varies with the liquid absorbent used and with the concentration and temperature of the absorbent. It is 120 Btu per lb of water vapor absorbed for an aqueous solution of lithium chloride at 95°F temperature and at the concentration used for air-conditioning applications.

The temperature of the liquid absorbent will increase owing to the heat of condensation of the water vapor absorbed from the air by the solution. The concentration of the liquid absorbent is lowered because of the dilution of the liquid with water absorbed from the air. The warm dilute solution flows from the contactor cells to the sump.

The liquid absorbent is maintained at the proper concentration for moisture removal by automatically removing water from the liquid. A small percentage of the solution, usually 10 to 20 per cent of the flow to the contactor cells, is passed through a heater where the liquid is heated to 200 to 235°F, depending upon the steam pressure available. At this temperature the vapor pressure of the liquid absorbent is considerably higher than that of outside air. The hot solution at the relatively high vapor pressure is then contacted with outside air in the regenerator, where water is absorbed from the solution by the outside air owing to the vapor-pressure difference between the outside air and the hot solution. The solution is cooled as well as concentrated in the regenerator because of the absorption of water from the solution and the sensible cooling effect of the outside air. The process in the regenerator is the reverse of the absorption process in the contactor cells where the air is dehumidified. The hot moist air from the regenerator is discharged to the outside.

The majority of the absorption dehumidifier systems are controlled by a float control in the sump of the unit. This control holds a constant level of liquid in the sump. Since no salt is added or removed, a constant level or volume in the system represents a constant concentration. The volume of liquid absorbent in the unit and the level of the liquid in the sump will rise as water is absorbed from the air. This rise in level actuates the float which opens the steam valve and admits steam to the regenerator heater to remove water from the solution until the control level is reached. The float then turns off the steam to the regenerator heater, and no further regeneration takes place until there is another rise in level.

The hot concentrated liquid absorbent from the regenerator mixes in the sump with the warm diluted liquid from the contactor cell. The mixture, which is at the proper concentration for dehumidification, is pumped through the cooler where the cycle is repeated.

Liquid-absorbent Winter Operating Cycle. The operating cycle of a liquid-absorption system for winter operation is shown in Fig 9-9. The hygroscopic solution is pumped through a humidifying-solution heater where the solution is continuously heated in proportion to the humidifying load.

The hygroscopic solution at the required temperature and concentration is brought into intimate contact with the air to be humidified. The moisture is given up to the air by the solution owing to the difference in vapor pressure between the air and the solution. The amount of water vapor added to the air is usually controlled by automatically regulating the flow of steam through the heater with a modulating steam valve. The water valve for summer operation is automatically closed when humidification is required.

The temperature of the solution will decrease because of the heat of evaporation of the water absorbed by the air from the solution. The concentration of the solution will increase owing to the removal of water from the solution. The cool concentrated solution flows from the contactor cells to the sump.

The solution is maintained at the proper concentration by adding steam condensate or distilled water to the solution to replace the water given up to the air. The addition of city or well water to the chloride or bromide solutions is not recommended because of the possible effects of minerals in the water.

The density control for humidifying operation controls the addition of water to the solution by operating a valve in the make-up water line to maintain a constant concentration. The condensate from the humidifying heater is usually used for make-up water as shown in Fig. 9-9. The density control operates the three-way valve to pass condensate into the sump when make-up water is required and to pass the condensate into the condensate-return line when no make-up water is required.

Liquid-absorbent Equipment. *Absorbents.* Absorbents for liquid dehumidifying systems should have the following characteristics:

1. Suitable vapor-pressure characteristics. The absorbent should not crystallize at temperatures 10 to 15° below the temperature range used in the operating cycle
2. Noncorrosive
3. Odorless
4. Stability. It will not break down over range of use or vaporize
5. Low viscosity, good heat-transfer characteristics
6. Nontoxic and noninflammable
7. Capable of being regenerated at temperatures obtainable with l-p steam
8. Widely available and economical to manufacture

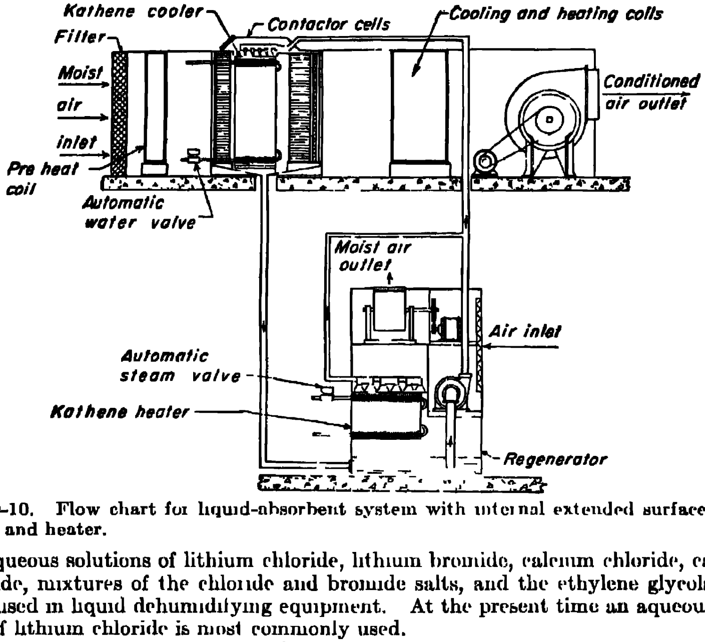

FIG. 9-10. Flow chart for liquid-absorbent system with internal extended surface liquid cooler and heater.

Aqueous solutions of lithium chloride, lithium bromide, calcium chloride, calcium bromide, mixtures of the chloride and bromide salts, and the ethylene glycols have been used in liquid dehumidifying equipment. At the present time an aqueous solution of lithium chloride is most commonly used.

Contactors. The contactor is that part of the apparatus in which the air to be dehumidified is brought in contact with the liquid absorbent. The contactor should have a high water-removal efficiency per vapor-pressure difference between the air and absorbent with a relatively low resistance to the flow of air. It should be relatively light, compact, and inexpensive. It should retain its original characteristics after extended use.

The contactor may consist of an atomized spray of the liquid absorbent, but most equipment has a contact surface providing a large area of the absorbent exposed to the air. This extended surface contactor provides higher water-removal efficiency per volume of space and eliminates atomization of the liquid. This simplifies the removal of entrained drops of the absorbent from the air stream.

An extended surface fin coil is used as the contactor in most of the standard absorbent dehumidifiers. The cooling medium, usually water, flows inside the tubes, and the air and liquid absorbent flow over the external surface of the coil as shown in Fig. 9-10. This arrangement combines the plate-contact surface and the cooler shown in Fig. 9-9 in one assembly. This arrangement is less expensive, more compact, and is more adaptable for packaged units assembled in the factory.

The plate-contact surface usually consists of a series of parallel plates made of metal or glass. The air passes between the plates in contact with the liquid flowing over the surface of the plates. The solution is precooled as shown in Fig. 9-9. This type of contact surface is usually used in heavy-duty industrial applications in which the individual parts of the system are built at the factory and installed in the field

Regenerators. The regenerator is that part of the apparatus in which water is removed from the liquid absorbent. The regenerator requires the same performance and physical characteristics as the contactor.

An extended surface fin coil is used as the regenerator in most of the standard absorbent dehumidifiers. The heating medium, usually steam or hot water, flows inside the tubes, and the liquid absorbent and air flow over the external surface of the coil as shown in Fig 9-10. This arrangement combines the plate-regenerator contact surface and the solution heater shown in Fig. 9-9 into one assembly

Some heavy-duty regenerators are constructed with a series of parallel plates

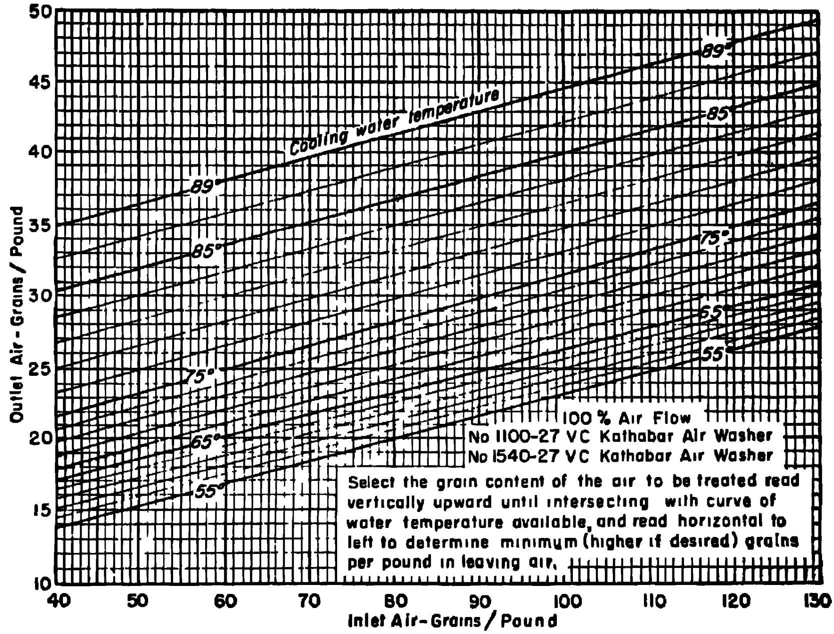
Selection of Lithium Chloride Equipment. *Given:* a five-story office building in Houston, Texas, with 595,150 cu ft of space to be air conditioned. There are 685 occupants in the building



Select the grain content of the air to be treated read vertically upward until intersecting with curve of water temperature available, and read horizontal to left to determine minimum (higher if desired) grains per pound in leaving air.

FIG 9-11 Performance curve of lithium chloride dehumidifier (*Surface Combustion Corporation*)

A *Design data*

1 Outside design
   - *a* 130 grains of moisture per lb of dry air for latent load
   - *b* 95°F DB for sensible load

2 Inside design—80° DB and 50 per cent relative humidity, 77 grains per lb. absolute humidity

3 Utilities
   - *a* 85° cooling-tower water
   - *b* 20 psi steam pressure

4 216,000 Btu hr—internal latent load from people and infiltration

5 Fresh-air requirements
   - *a* 15 cfm of fresh air per person has been specified for ventilation.

$$15 \times 685 = 10{,}275 \text{ cfm fresh air for ventilation}$$

B *Cfm through the dehumidifier*

In general, the dehumidifier is applied to the fresh air only for comfort installations of this type The general pattern is to place the dehumidifier in a penthouse of the building to be air conditioned and to discharge the dehydrated air to individual cooling units The entire external and internal latent load is ordinarily removed in the dehumidifier

1 Try removing the internal and external latent-heat loads with all fresh air through the dehumidifier

$$\frac{216{,}000}{0.68^{*} \times 10{,}275} = 31.0 \text{ grains per lb difference required between maintained air and fresh air from the dehumidifier}$$

From performance curve Fig. 9-11, for lithium chloride dehumidifier with 85° water, the air will be reduced from 130 grains per lb to 45 grains per lb. Since the entire latent load can be absorbed by the fresh air passing through the dehumidifier, the 11,000-cfm unit is selected to handle 10,275 cfm of fresh air. If the required outlet-air grains were lower than could be obtained with the dehumidifier, it would be necessary to obtain a lower cooling-water temperature or mix some recirculated air with the fresh air and pass more air through the dehumidifier in order to assume the latent load.

In this problem, the calculations will be based on reducing 10,275 cfm of air from 130 to 45 grains per lb.

C. Dry-bulb temperature of outlet air

From Table 9-32, the outlet-air dry-bulb temperature from the dehumidifier will be 101°F.

D. Regenerator selection

$$\frac{10{,}275 \times 0.075 \times 60 \times (130 - 45)}{7{,}000} = 560 \text{ lb per hr water removed from the air}$$

The regenerator capacity for 20 lb steam pressure from Table 9-29 is 86 per cent of the rated capacity.

$$\frac{560}{0.86} = 651 \text{ lb per hr rated selection required for 560 lb per hr removal at 20 lb steam pressure}$$

From Table 9-28 select a No 66 regenerator which will remove 660 lb per hr of water at 25 lb steam pressure. At 20 lb steam pressure, the water-removal capacity will be 0.86 × 660 = 568 lb per hr.

E. Total heat to be removed by the 85° water

1. Sensible heat. From step *C* the air enters dehumidifier at 95° and leaves at 101°.

$$10{,}275 \times 1.08^{\dagger} \times (101 - 95) = 66{,}600 \text{ Btu/hr sensible-heat addition to the air}$$

2. Latent heat. From step *D* 560 lb per hr of water are removed from the air.

$$560 \times 1{,}170 = 655{,}200 \text{ Btu/hr latent heat to the water}$$

NOTE. Average latent heat of condensation of 1 lb of water in lithium chloride is 1170 Btu for concentration used in air-conditioning equipment.

3. Heat load from regenerator. From Table 9-30 the *D* factor is 8.34 × 1000 Btu per hr. The heat load from the regenerator will be

$$8.34 \times 1000 \times 66 = 550{,}000 \text{ Btu per hr.}$$

655,200 Btu per hr- latent heat from air
550,000 Btu per hr - heat load from regenerator
1,205,200 Btu per hr.
66,600 Btu per hr sensible heat to the air
1,138,600 Btu per hr— total heat to be removed by the cooling-tower water

---

* Factor $0.68 = \frac{0.075 \times 60 \times 1.055}{7{,}000}$ from formula

Latent Btu/hr $= \frac{\text{cfm} \times \text{specific volume } (0.075) \times 60 \times 1{,}055 \times \text{grains per lb removed}}{7{,}000 \text{ (grains in 1 lb)}}$

77 grains per lb in space
31 grains per lb required grain difference for 10,275 cfm of air
46 grains per lb required outlet air from dehumidifier to remove total latent load.

† Factor 1.08 = 60 × 0.075 × 0.24 from formula

‡ Sensible Btu per hour = cfm × 60 × 0.075 × 0.24 × temperature difference

F. Operating data

1. Gpm of cooling-tower water. From Table 9-33, for 85° water and 45 grains per lb outlet air, the gpm of water per 1,000 Btu per hr of heat absorbed by the water is 0.092. From step *E*, the total heat to the water is 1,138,600 Btu per hr.

$$0.092 \times 1{,}138.6 = 104.8 \text{ gpm of } 85^\circ \text{ water}$$
$$1{,}138{,}600/8.34 \times 60 \times 104.8 = 21.8^\circ \text{ water-temperature rise}$$

2. Steam requirements. From Table 9-31 the maximum steam demand is 2.63 lb of steam per lb of water removed from the air for 20 lb steam pressure.

$$560 \times 2.63 = 1{,}475 \text{ lb per hr of steam for maximum load.}$$

Note: The steam rate is proportional to the load. At half load the steam requirements will be 50 per cent of the steam rate for full load.

3. Electric requirements. A 3-hp motor for the pump from Table 9-27 and a 3-hp motor for the regenerator fan from Table 9-28.

G. Humidifying operation for winter cycle

1. Fresh air from the lithium chloride dehumidifier to be discharged to the local zone units at 72° DB and 30 grains per lb.
2. The air will be preheated in a preheating coil to 89° DB. All the heat for humidification is supplied in this type of unit with the preheating coil. Assuming outside air at 0° DB, the air from the preheating coil will be 89° DB—53.3° WB. Neglecting the radiation and conduction losses, the air from the lithium chloride humidifier will be 72° DB and 30 grains per lb. The amount of humidification is controlled by automatically regulating the steam input to the preheating coil.

H. Sensible-heat removal for summer operation

The internal and external (fresh-air) latent loads are removed with the dehumidifier. The cooling coils for the individual-zone cooling units will be selected for sensible heat removal only and will operate without condensation of water vapor on the coil surface. The refrigeration system will be selected in the conventional manner for the sensible cooling load. The flow chart for this problem is shown in Figure 9-12.

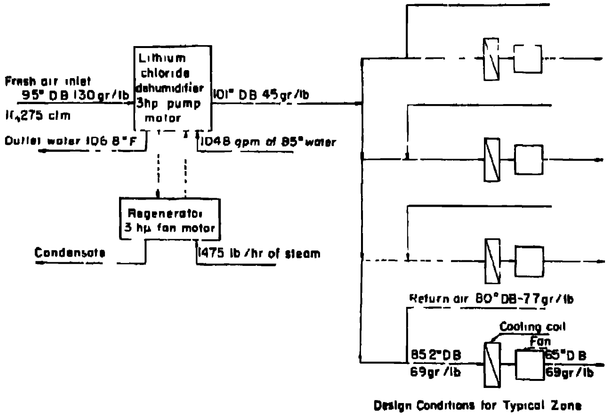


Fig. 9-12. Flow diagram for problem using liquid-absorbent dehumidifier.

Control of Absorbent Dehumidifiers. There are two basic control methods used with absorbent dehumidifying systems, *viz.*, constant solution temperature and variable solution temperature.

Constant Solution Temperature. The liquid-absorbent temperature is held constant regardless of the load imposed on the unit. The temperature is such that, at full load on the unit, the air emerging will be at the desired moisture content. At any load less than 100 per cent, the air from the unit will be dryer than the required design conditions. The density control inside the unit maintains the absorbent concentration constant.

In general, constant solution-temperature control is suitable for comfort conditioning and for process work where a lowering in leaving air dryness from the liquid-absorbent unit is not important. The majority of dehumidifying applications are of this type.

Constant solution-temperature external controls for this control method are as follows:

1. Immersion thermostat in the liquid absorbent which is set at the proper control temperature. For installations such as shown in Fig. 9-9, this thermostat would be placed between the solution cooler and the contactor cells. For an installation in which the contactor unit and the cooler are combined in one assembly, as shown in Fig. 9-10, the immersion thermostat would be placed in the path of the solution from the extended surface contactor.
2. Modulating valve in the water line to the solution cooler. If humidification is required, a modulating valve is also placed in the steam line to the humidifying heater. The two valves are controlled by the immersion thermostat.

Variable Solution Temperature. The liquid-absorbent temperature is varied over a range with varying loads so that, regardless of the load imposed on the absorbent unit, the air to be controlled will be at a constant moisture condition. In general, variable solution temperature is suitable for process and industrial applications where a constant condition of moisture must be maintained and where any fluctuation would be detrimental.

The following controls are required for this control method:

1. A master wet-bulb stat, humidistat, or dew-point control installed at the control point.
2. A submaster immersion solution thermostat placed in the liquid absorbent The location would be the same as for the immersion thermostat under constant solution-temperature control
3. Modulating valve in the water line to the cooler and a modulating steam valve in the steam line to the heater.

The master wet-bulb thermostat with this control arrangement resets the submaster liquid-absorbent-temperature thermostat to vary the absorbent temperature in accordance with the load. It is important with this type of control always to include a submaster thermostat in the control circuit. In addition to the above absorbent external controls, a dry-bulb thermostat should be placed at the control point for most applications to control the dry-bulb temperature through an afterheating coil or an aftercooling coil, or both, if required The solution concentration si maintained at a constant value with the internal density control.

ADSORPTION SYSTEMS

In an adsorption system, water vapor is condensed on the surface of the adsorbent and drawn into the interior of the adsorbent by capillary attraction. The adsorbent continues to adsorb water vapor from the air until an equilibrium condition is reached where the internal vapor pressure of the water in the pores of the material is in equilibrium with the vapor pressure of the air passing through the material.

For a given adsorbent material, the moisture adsorption is dependent upon the adsorbent-bed temperature, the moisture content of the air or gas to be dehumidified, and the flow rate through the adsorbent bed.

The air passing through the adsorbent dehumidifier increases in temperature owing to the conversion of latent heat to sensible heat resulting in a rise in temperature of the air. The rise in temperature of the air passing through the dehumidifier is somewhat higher than the theoretical rise computed from the transformation of latent heat into sensible heat This extra heat is from the residual heat in the bed and structural parts owing to the reactivation process. An approximate figure for the rise in the temperature of the dehumidified air caused by the adsorption heat is 0.75°F rise for each grain of moisture removed per pound of air. The actual temperature rise of the air in the adsorbent dehumidifier for a specific application should be obtained from manufacturer's rating tables.

Additional capacity may be obtained from the adsorbent dehumidifier by precooling the air before it goes through the dehumidifier when the air to be dehumidified is warm. Precooling of the air serves to lower the adsorbent-bed temperature and thus increase the performance. Some manufacturers install cooling coils in the adsorbent beds or stage the adsorbent bed with a cooling coil between two beds in order to obtain additional capacity and lower the working temperature of the bed.

The moisture is removed from the adsorbent by heating the bed to approximately 300 to 450°F. The exact temperature of the air for reactivation depends upon the type of adsorbent used. The reactivation air containing the water given up by the adsorbent is discharged to the outdoors. After the water has been removed from the adsorbent, outdoor air is usually passed over the bed to reduce the temperature of the bed before it is switched to the dehumidifying cycle.

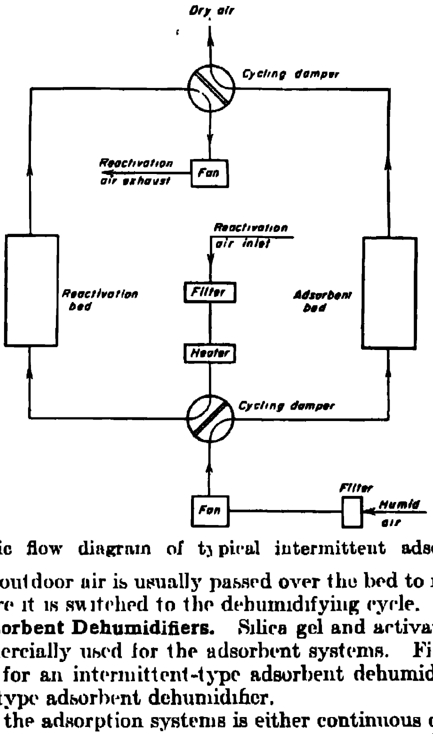

FIG. 9-13. Schematic flow diagram of typical intermittent adsorbent dehumidifier.

Operation of Adsorbent Dehumidifiers. Silica gel and activated alumina are the two materials commercially used for the adsorbent systems. Figure 9-13 is a schematic flow diagram for an intermittent-type adsorbent dehumidifier, and Fig. 9-14 shows a continuous-type adsorbent dehumidifier.

The operation of the adsorption systems is either continuous or intermittent. In order to provide continuity of moisture removal, there are two adsorbent beds in the intermittent equipment, as shown in Fig. 9-13. While one bed is being reactivated and purged, the other bed or adsorbing bed is removing moisture from the air. After the adsorbing bed has adsorbed water vapor to the point where it will not continue efficiently to remove moisture from the air, dampers are switched in the air stream so that the adsorbing bed which now contains a relatively large amount of water vapor is put on the reactivating cycle. At the same time, the air to be dehumidified is switched to the other bed which has been reactivated and purged. This is accomplished automatically in most equipment with time relays.

In a continuous-adsorption dehumidifier, the unit is separated into two compartments with dividing seals located on the inside and the outside of the drum. Figure 9-14 shows the details of construction of a continuous-adsorbent dehumidifier. The air entering the right-hand portion of the drum is dehumidified and discharged through the right-hand fan, while at the same time the left-hand portion of the drum is being reactivated.

Water vapor is adsorbed by a given particle of the adsorbent as it rotates counterclockwise from *Z* to *X*. The adsorbent particle moves into the reactivation compartment at position *X* where the water vapor previously adsorbed is driven out of the material.

The adsorbent in the reactivation compartment is in contact with air heated by the gas burner. The products of combustion from the burner are mixed with the air drawn in through the reactivation air inlet. The temperature of the mixture is high enough to drive the water vapor from the adsorbent. This temperature is 325 to 350°F for the silica gel equipment of one manufacturer. The water vapor is discharged to the outdoors by the reactivation fan. High-pressure steam may be used for heating the reactivation air by placing steam coils in the reactivation air supply to the unit.

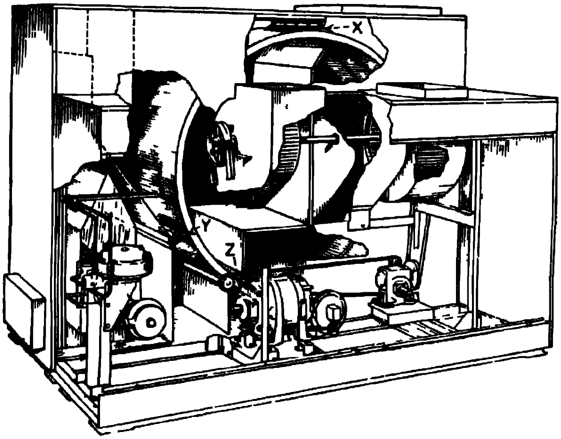

FIG. 9-14. Rotary-type silica gel adsorbent dehumidifier. (*Bryant Heater Company*)

The unit as shown in Fig. 9-14 is designed so that the water vapor has been driven out of the adsorbent when it reaches point *Y*. Outdoor unheated air is pulled through the segment *YZ* by the reactivation fan to reduce the temperature of the bed before it enters the adsorption compartment.

Equipment Ratings. Figures 9-15, 9-16, and 9-17, represent equipment ratings of standard silica gel adsorbent units commercially available.

Selection of Silica Gel Dehumidifier. *A. Problem.* A laboratory 72 by 30 by 12 ft is to be air-conditioned. Ground floor is concrete. One outside wall is constructed of 13 ft brick and plaster with three coats of vaporproof paint. All windows are sealed and caulked. Inside walls and ceiling are coated with three coats of vaporproof paint on both sides. One door 6 by 8 ft is to be air-locked. There are 10 people in the laboratory. One pound per hour of water is evaporated in the laboratory.

B. Design data

1. Outside design
   a. 122 grains of moisture per lb of dry air for latent load
   b. 95° DB, for sensible load
2. Inside design
   85° DB and 28 per cent relative humidity—52 grains per lb
3. Utilities
   a. 85° water for the dehumidifier
   b. 1000 Btu natural gas

4. 11,900 Btu per hr, internal latent load from people, infiltration, and product
5. Fresh air
   a. $72 \times 30 \times 12$ ft = 25,920 cu ft volume of space

$$25{,}920/60 = 432 \text{ cfm} = 1 \text{ air change per hr}$$

One and one-half changes per hr of fresh air will be discharged to the space.

$$1.5 \times 432 = 648 \text{ cfm of fresh air, say } 650 \text{ cfm}$$

The amount of fresh air discharged to the space through the dehumidifier is usually estimated from experience.

C. Cfm through dehumidifier

In applications of this type, it should first be checked to see if the latent load can be removed by passing fresh air through the dehumidifier. If the entire internal and external latent-heat loads cannot be removed with fresh air, some recirculated air is mixed with the fresh air, and the mixture is circulated through the dehumidifier.

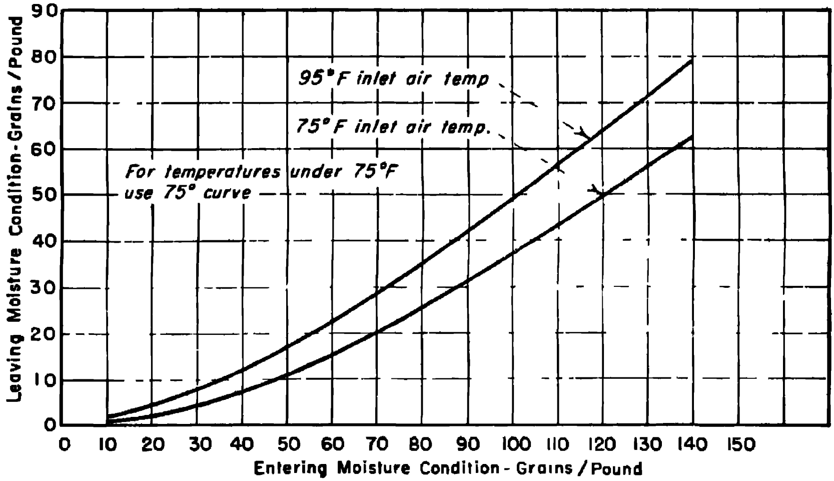

Fig. 9-15. Effluent moisture curve for rotary adsorbent dehumidifier. (*Bryant Heater Company.*)

With air entering at 122 grains, the outlet air from Fig. 9-15 will be higher than the maintained condition of 52 grains per lb, so it will be necessary to treat a mixture of fresh and return air through the dehumidifier.

Try 1,300 cfm of air through a No. 14 unit. The mixture of 650 cfm fresh air and 650 cfm return air will be at 90° DB and 87 grains per lb. From Fig. 9-15 the outlet air will be 37.5 grains per lb.

$$11{,}900/0.68^{*} \times 1{,}300 = 13.5 \text{ grains/lb rise on } 1{,}300 \text{ cfm of air}$$

52 grains/lb = maintained condition

13.5 grains/lb = required diffusion grain/pound difference between maintained condition and air from dehumidifier with 1,300 cfm of air

38.5 grains/lb = required air from dehumidifier

Since the dehumidifier will deliver air at 37.5 grains/lb, use No. 14 unit with 1,300 cfm of air. If the moisture removal could not have been obtained with 1,300 cfm of air, it would be necessary to use more return air and a larger unit or precool the fresh air.

D. Dehumidifier after-cooling coil selection

From Fig. 9-16 the air from the adsorbent dehumidifier will be 134°F for air entering at 90° DB and 87 grains per lb. The cooling coil is selected in the conventional manner. A 7° approach to the water temperature would be an economical selection. 1,300 × 1.08* × (134 − 92) = 58,968 Btu per hr to be removed by the water. Assuming a 14° temperature rise, the water quantity would be 8.4 gpm of 85° water, leaving the coil at 99°.

---

* See page 666 for derivation of factor 0.68.

E. Gas consumption

From Fig. 9-17 the full-load gas consumption is 145,000 Btu per hr. From Fig. 9-17 with 87 grains per lb inlet air at 90° DB, 85 per cent of the full-load gas consumption will be required.

$$0.85 \times 145{,}000 = 123{,}250 \text{ Btu/hr gas consumption}$$

F. Operating data

8.4 gpm of 85° water from step *D*

123,250 Btu/hr, gas consumption from step *E*

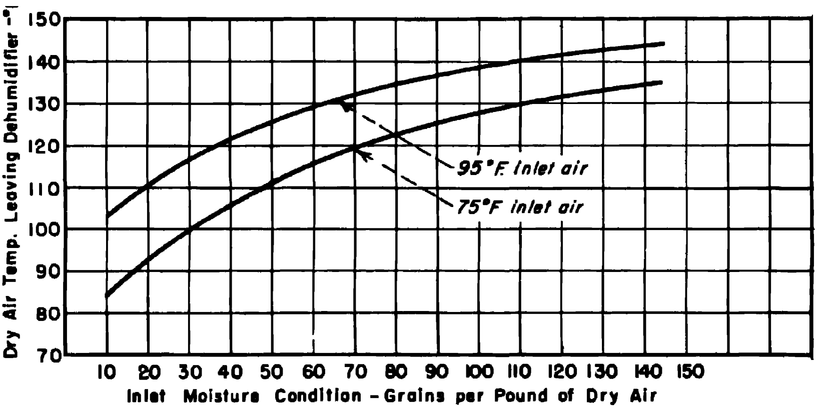

FIG. 9-16. Temperature of effluent dry air from rotary adsorbent dehumidifier. (*Bryant Heater Company.*)

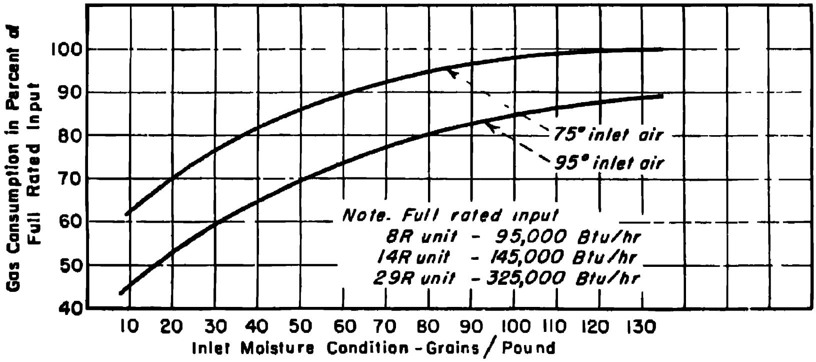

Note. Full rated input
8R unit - 95,000 Btu/hr
14R unit - 145,000 Btu/hr
29R unit - 325,000 Btu/hr

FIG. 9-17. Gas consumption on rotary adsorbent dehumidifiers. (*Bryant Heater Company.*)

A 1-hp motor is supplied with this unit for the fan handling the main air supply and the reactivation air. The motor size varies with the depth of the bed and the air flow. The flow chart for this problem is shown in Fig. 9-18.

Control of Adsorbent Dehumidifiers. *Variable Control of Reactivation of Steam-fired Adsorbent Dehumidifiers.* A wet-bulb thermostat, humidistat, or dew-point stat is placed at the control point to operate a modulating damper in the reactivation air supply to the dehumidifier. The moisture-removal capacity of the dehumidifier is controlled by regulating the amount of activation-heat input into the dehumidifier by controlling the volume of reactivation air with a modulating damper control. The dehumidifier operates continuously with this arrangement, and the equipment is modulated to meet the varying moisture-removal loads.

---

* See page 666 for derivation of factor 1.08.

The control equipment required consists of the following:

1. Wet-bulb thermostat, humidistat, or dew-point thermostat placed at the control point
2. Damper with modulating damper motor in the reactivation air supply between the steam-reactivation coil and the dehumidifier under control of the humidistat

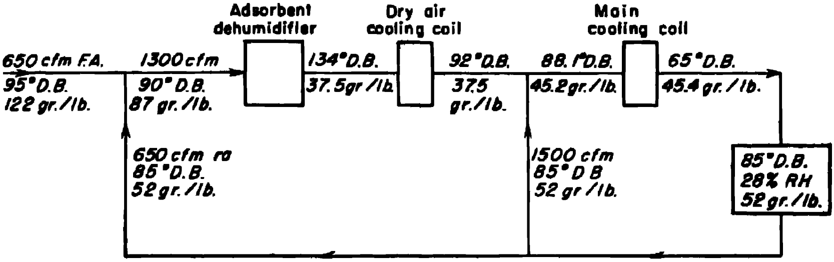

FIG. 9-18. Flow chart for adsorbent dehumidifier problem.

Variable Control of Reactivation of Gas-fired Adsorbent Dehumidifiers. The humidistat with the gas-operated dehumidifier controls the gas input to the dehumidifier. The operation and controls are the same as the above with the exception that the modulating control is placed on the gas input to the dehumidifier, and the modulating damper in the reactivation air supply is eliminated.

Face and By-pass Damper Control. In certain applications, the modulating control is obtained with adsorbent dehumidifiers by placing face and by-pass dampers around the dehumidifier. Face and by-pass dampers are installed in the dehumidified air stream under the operation of the humidistat or wet-bulb thermostat controller. The controls and equipment are designed so that, under maximum load, all air passes through the dehumidifier. At less than maximum load, the humidistat operates the face and by-pass dampers to by-pass a certain amount of air around the dehumidifier in order to modulate the capacity of the dehumidifier to the load requirements.

Off and On Control. In certain applications, the adsorbent dehumidifier is cycled from a wet-bulb thermostat or humidistat in the controlled space. This type of control is chiefly used in comfort installations and other installations where some variation in the relative humidity is permissible.

APPLICATION OF ABSORBENT AND ADSORBENT DEHUMIDIFIERS

Absorbent and adsorbent dehumidifiers are employed where it is desirable to control the removal of moisture from the air independent of the dry-bulb temperature of the air. Dehumidifiers are used for this purpose in industrial processing air conditioning and in comfort air conditioning in combination with refrigeration.

Dehumidifiers are favorably applied to remove moisture from outside air in applications requiring delivery of air at low relative humidities. Figure 9-19 is an interesting application of dehumidification equipment with refrigeration for aftercooling the air. This arrangement is applied to a pharmaceutical plant where it is necessary to maintain various spaces at different relative humidities and dry-bulb temperatures.

The dehumidifier reduces the fresh air to an outlet condition of 97° DB and 40 grains per lb. This air is distributed to the various air-conditioned spaces through booster units. Small booster dehumidifiers are provided for those departments or spaces requiring greater dehumidification than that supplied by the main air supply. Cooling coils and heating coils are provided when control of the dry-bulb temperature of the air in the various spaces is required.

Dehumidifiers are applied to many industrial drying problems where low relative humidities are required for the processing, manufacturing, and storage of various materials. Figure 9-18 is a typical arrangement of equipment for control of a space or drying tunnel at relative low humidities. A cooling coil or heating coil is usually applied after the dehumidifier for dry-bulb-temperature regulation.

Dehumidification equipment is employed to advantage in air-conditioning problems requiring low relative-humidity control and no temperature control. The preservation of inactive naval vessels by holding the interior of the ship at a relative humidity below 30 per cent to prevent mold, corrosion, and other moisture damage is an example of low-humidity control with no temperature control.

The application of dehumidification equipment to comfort air conditioning in combination with refrigeration for aftercooling provides the following advantages without the use of reheat:

1. Independent control of relative humidity and temperature with varying latent- and sensible-heat loads. The humidistat or wet-bulb thermostat directly controls the moisture removal in the dehumidifier, and the sensible cooling is controlled by the thermostat regulating the amount of refrigerating effect.

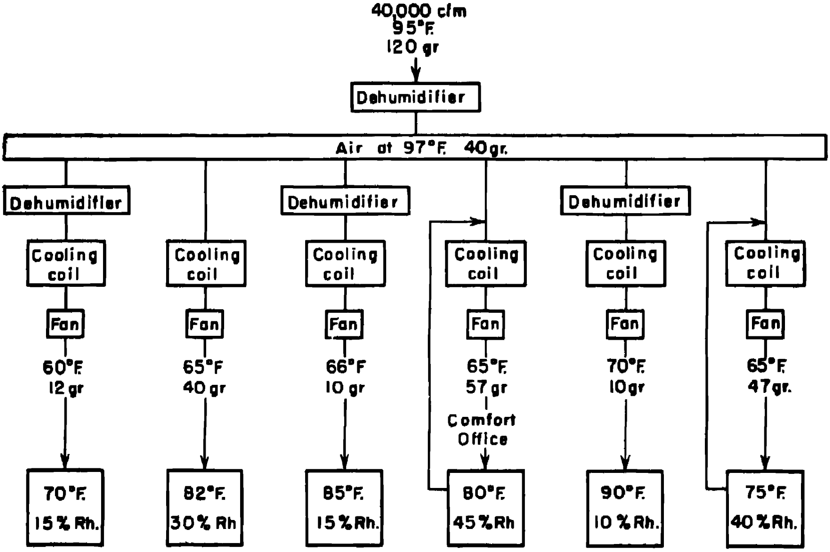

Fig. 9-19. Flow chart for central system dehumidifier with booster units.

2. Operation of the refrigeration equipment at higher evaporator temperatures for most applications owing to the use of refrigeration equipment for only sensible cooling.

3. The first cost and operating cost of a combination system compared with a straight conventional refrigeration system is dependent upon the design air conditions, the size of the installation, the ratio of latent heat to total heat load, the amount of fresh air, the relative cost of steam or gas and electric power, and the cost of cooling water. In general, it may be said that the operating cost tends to be lower for a combination system, and the first cost tends to be higher.

INDUSTRIAL INSTRUMENTATION AND CONTROL

BY DOUGLAS M. CONSIDINE

Manager of Technical Section, Brown Instruments Division of Minneapolis-Honeywell Regulator Co., Philadelphia, Pennsylvania

The importance of industrial instrumentation to the daily activities and responsibilities of the plant and process engineer has increased manyfold in the past few years. Continuous manufacturing and processing techniques, plus new and improved methods of measurement and control, are principally responsible for the rapid strides made in instrumentation. In hundreds of industrial organizations, instruments have created many new departments and jobs. Instrument Department and Instrumentation Engineer are becoming familiar phrases in plant terminology.

Because of the tremendously wide field embraced by industrial instrumentation, it is impossible thoroughly to cover or even mention all phases of the subject. The phases covered have been selected because of the significance which they bear to plant and process engineers. A list of excellent references is included at the end of the section. Broad coverage of other phases of instrumentation is contained in the sources listed.

Since plant and process engineers frequently must present valid and convincing reasons to management for proposed expenditures, including those for instrumentation, the basic answers to the question, "Why measure and control?" are quite important. A part of the section is devoted to this consideration. While many plant engineers have a very detailed knowledge of many instruments or controls, it has been found that an over-all understanding of the process variables, their nature and relation to one another, is often lacking. An especial effort has been made here to classify, compare, and discuss the nature of the variable. Measurement is an extremely important part of instrumentation since accurate control can be based only upon reliable measurements. Fundamental measuring means are discussed here in a broad, informal manner. The approach is designed to convey how certain very basic criteria are utilized for the measurement of many different variables. Detailed considerations of measurement must be obtained from references specifically covering this subject. Particular stress has been placed here upon the newer measuring means, such as those for determining chemical composition, dew points, etc., which are not yet thoroughly covered in the literature. Automatic control is a very broad and complex subject, and volumes have been devoted to it alone. Here only the fundamentals of the subject can be presented. To stress the practical application of measuring and controlling instruments, a section on automatic-control-system applications has been included. And finally, a subject of interest to most plant and process engineers, *viz.*, instrumentation costs, is briefly covered.

WIDE SCOPE OF INSTRUMENTATION

Few products of modern industry escape passage through some process environment which must be controlled within rather narrow limits. Temperature, pressure, humidity, flow, and other factors, commonly referred to as *process variables*, literally govern the environment to which a product is exposed and often will determine whether the product will be of high quality or a reject. Wherever stabilization of a process variable will increase product quality, decrease wastes or rejects, save steam or fuel, or enable an operator to do a better job in less time, instruments and automatic controls should be considered. Since there are several process variables of major importance and since these variables are encountered in hundreds of different industries, the scope of instrumentation is extremely wide.

WHY MEASURE AND CONTROL?

In the final essence, most advantages claimed for instrumentation can be resolved in terms of economics. Instruments and controls intelligently applied generally will enable the manufacture of a better product at a lower cost. Instruments are also applied widely in the interest of safety to personnel and equipment.

Product Quality. Most industrial products are manufactured to meet certain specified physical or chemical properties. As the quality of a product goes up, the tolerances governing deviation from these properties become narrower. And, as tolerances grow narrower, the need for instruments and automatic controls generally increases.

Thousands of examples of how final product quality is tied in with manufacturing conditions could be cited. Only a few can be mentioned here. In the examples given, the critical process variables are in italics.

The hardness, ductility, resistance to corrosion, and several other properties of a metallurgical product are representative of the care exercised in (1) proportioning, by *weight*, of the original ingredients and (2) maintaining the proper operating *time* and *temperature* in melting, refining, pouring, and heat-treating.

The purity of a chemical product may depend upon (1) the proper proportioning of original ingredients by *weight* or *flow* (volume), (2) holding the *pressure* of the reaction vessel constant for a specified *time*, and (3) adjusting the *pH* of the final product through addition of a corrective agent.

The weight, strength, and other properties of a paper product are partly the result of (1) digesting the pulp at the proper *temperature* or *pressure* and for a specified *time*, (2) regulating the *liquid level* of the head box, (3) adjusting the *pH* of the pulp, (4) maintaining the proper *speed* of the paper machine, (5) drying the paper at the desired *temperature* and to the proper *moisture content*, and (6) storing the paper at the most desirable *humidity*.

Product quality and uniformity can result only when processing conditions are held closely from hour to hour and from day to day. Automatic controls not only eliminate the drudgery of manually maintaining these conditions but eliminate the risks of human errors and carelessness. At the same time, the operator is freed to do other important tasks.

Direct Materials Savings. By consistently maintaining product quality, the number of rejects produced is cut to a minimum, thus effecting savings of raw materials as well as the productive time of machinery and men. These savings in time and material cut over-all manufacturing costs which means greater profits and a lower selling price to the consumer.

Instrumentation has done an outstanding job in cutting the nation's fuel bill and in so doing has contributed to conservation of our natural resources. Automatic controls through eliminating overheating of ovens, furnaces, driers, kettles, and other processing equipment have cut to a minimum the number of Btu going up the stack. Heating controls are generally based upon temperature measurement, and there is no human fireman or operator who can sense temperature with the accuracy and sensitivity of a thermocouple or thermometer bulb. Fuel savings through instrumentation, then, are not difficult to understand.

Conditioning of trade wastes is another example of where instruments have effected large savings in materials Often the wastes from a plant are dumped into a public stream. Frequently, these wastes contain objectionable materials, such as acids, which destroy fish and other wildlife. To avoid these harmful results, many operators add some corrective agent such as lime to the wastes to neutralize the objectionable effects. By measuring the pH of the treated wastes, considerable savings can be realized through elimination of overdosage of corrective agent.

Cost Accounting. Cost accountants are helpless without reliable data upon which to base their studies. Recording and integrating instruments comprise one of the accountant's principal tools in collecting data. Flowmeters are used widely to measure steam, water, fuel, and other utilities used by various departments in a plant. Where solid materials are involved, scales are used to measure the transfer and consumption of materials of interest to the accountant.

Product Testing. Most manufacturers perform certain physical and chemical tests on all products made, or at least upon representative samples taken from the production lines. Such testing could not be carried out without the aid of modern instruments. Viscosimeters, X-ray spectrometers, checkweighing scales, hydrometers, and refractometers—these are but a few of the instruments in daily use for product testing.

Plant Safety. Most plants have one or more areas where fire, explosion, poison, or other hazards are present and would be disastrous unless carefully watched and controlled. A gas-fired oven, a solvent-recovery area, a paint spray booth—these are examples. Fortunately, modern instruments are available to detect the presence of dangerous concentrations of gases and vapors, of flame failure in combustion units, and similar conditions. These instruments not only detect the existence of dangerous conditions but sound visual or audible alarms and in many cases immediately institute protective measures automatically, such as shutting off fuel supplies, closing fire doors, or starting auxiliary ventilating systems. Instruments have saved many lives.

Advantages—ad Infinitum. A complete delineation of the advantages of instrumentation cannot be given here. One other advantage which is often overlooked, however, is that which enables many complex processes to exist. This is the advantage of practically instantaneous coordination. With the hundreds of valves and dampers which must almost continuously be adjusted in many processes, it is difficult to comprehend how the process could operate manually, even with a man at every control valve. Possibly, one man with a hundred hands and the brain to coordinate those hands could control such a process. But certainly, a hundred men, each with two hands and a brain, but without the instantaneous coordination required, could not tackle the control of such a process.

PROCESS VARIABLES

The process variables are extremely difficult to classify. They can be grouped, however, with some logic. One method of grouping is followed here.

Energy Variables. Energy variables are so termed because they are related to the energy content of a process stream or piece of process equipment. While these variables are large factors in determining the final properties of a product, they are unimportant once this product has been made. Energy variables include (1) temperature and (2) pressure (positive and vacuum).

Temperature. The existence of three states of matter—solid, liquid, and gas—is convincing proof that temperature vitally affects every substance at at least two points on the temperature scale. Advantage of the changing state of substances at definite temperatures is taken in processing, wherein freezing and boiling points constitute the basis for separating materials. Two substances or different boiling points, for example, can be separated by distillation. Temperature also affects the rate of chemical reaction between substances, the rate of reaction increasing two- or threefold for each 10°C rise in temperature. The solubility of solids in liquids and of gases in liquids is also dependent upon temperature. In general, the solubility of solids in liquids increases with an increasing temperature, while the solubility of gases in liquids increases with a decreasing temperature. Thus, it should be obvious why temperature is so important a factor to the chemical operations, crystallization and absorption. The relationship between crystallization of solids and temperature explains the need for accurate temperature control in many heat-treating operations. The rate of bacterial and enzyme action is also critically affected by temperature. The range over which fermentation and other biochemical actions occur, therefore, is relatively narrow. Since there are few substances which are unaffected by temperature over a wide range, the measurement and control of temperature constitutes the largest field of application for industrial instruments.

Pressure. Under many conditions encountered in industrial processing, pressure and temperature are interlocked by nature so that one variable is fixed by the other. Often the plant or instrumentation engineer will be presented with making a decision as to which variable should be selected as the basis of control for a piece of process equipment. Pressure, like temperature, markedly affects the boiling points of substances and, to a lesser degree, freezing points. Pressure also affects the rate of chemical reaction, especially where the products of reaction are gases. Where the reactants and products of reaction are solids or liquids, however, pressure is relatively unimportant. Pressure control is extremely important to boiler operation where the safety of personnel and equipment depends upon maintaining pressure within prescribed limits. Recent advances in both extremely h-p and high-vacuum techniques have accentuated the importance of pressure measurement and control.

Quantity and Rate Variables. Under quantity and rate variables are variables that bear a direct relationship to the quantities and flow rates of materials in a process They include (1) fluid flow rate, (2) liquid level, (3) weight and weight flow rate of solids and liquids, (4) thickness and other dimensions of solids, and (5) speed of processing machinery. Unlike the energy variables, these variables do not affect the properties of the substances being processed so much as they determine the efficiency and operation of the process itself. For example, the physical properties of water flowing at the rate of 20 gpm are the same as those of water flowing at 2,000 gpm. On the other hand, an item of processing equipment designed to handle 20 gpm will be quite incapable of handling 2,000 gpm.

Flow. Although flow rates of single components in a process do not affect the properties of the components, the rates of flow of two or more components to form a mixture, or of two or more constituents to form a chemical compound, do greatly affect the results obtained. For example, in proportioning a heavy oil to a light oil, the flow rates of both components will determine the viscosity of the mixture. Since substances react chemically in definite proportions one to the other, accurate flow proportioning is required to avoid the presence of excess reactant in the final product. The importance of flow measurement to continuous processing, where equipment is designed to operate at maximum efficiency at certain production rates, cannot be overemphasized. Similarly, the importance of flow measurement to the gathering of statistics for plant cost accounting cannot be overlooked. It is interesting to note that flow often is a dependent variable fixed by a key variable, such as temperature or pressure. The flow control of steam or of cooling water to a heat exchanger to maintain a desired temperature is an example of this latter situation.

Liquid Level. Like flow, liquid level in itself does not affect the properties of a substance being processed. Nevertheless, it must be measured and controlled so that processing equipment will not run dry or overflow, with possible disastrous results.

Weight. While of principal concern to the proper proportioning of solid or liquid ingredients to a process, weight is also a specific property of a substance which may be desired to be held within definite limits. In extruding tire tread or tubes, for example, it is desired to obtain a definite weight per running foot of the extruded material, since this weight is vital to the balance, weight, and physical dimensions of the finished product. Measurement of weight in various stages of manufacturing is also frequently done as an aid to plant cost accounting. Counting large numbers of parts by weight, for example, is widely practiced.

Thickness. Thickness and other physical dimensions of substances being processed often have a definite bearing upon the final product. For example, sheet steel is rolled to a definite gauge; pipe is extruded to a definite bore; and paper is calendered to a definite caliper.

Speed. Speed is quite similar to flow rate in that it determines to a large degree the rate of production or processing. In itself, speed does not affect the properties of a substance. For example, paper running at 300 or 1,500 fpm on a machine is not affected by the speed itself. It is affected by the time with which it is in contact with the drying cylinders, however, and that time will be affected by speed. Since processing equipment, such as a paper machine, is designed to operate at a certain speed, control of speed is important. Too fast a speed on a paper machine, for example, will result in wet, improperly dried paper, while too slow a speed will result in overdried paper.

Substance Property Variables. Substance property variables are definite, specific properties of substances and include (1) density and specific gravity; (2) viscosity and consistency; (3) pH or hydrogen-ion concentration; (4) electrical conductivity;

(5) thermal conductivity; (6) calorific value; (7) explosibility and flammability; (8) humidity; (9) color, opacity, smoke density, and turbidity; (10) moisture content; and (11) actual chemical composition.

Several of the above variables are of principal importance in determining, partly or wholly, the chemical composition of a substance. These variables include electrical conductivity, thermal conductivity, and specific gravity. Electrical and thermal conductivity, for example, are relatively unimportant physical characteristics of most substances (insulating materials would be an exception). On the other hand, electrical conductivity is used widely as an index of the moisture content of a substance, while thermal conductivity is used to measure the composition of gases.

To illustrate how difficult a classification of the process variables really is, it is interesting to note that weight and thickness, classified previously as quantity or rate variables, may just as logically be classified here as substance property variables.

Density and Specific Gravity. Density and specific gravity are particularly important to evaporating and crystallizing operations where a liquid solution must be evaporated to a certain concentration before crystals will begin to form. Where reasonably pure substances are involved, a measurement of the specific gravity proves to be a useful index to concentration.

Viscosity and Consistency. Lubricating oils are the most fitting examples of substances which are produced having viscosity as one of the final specified properties. Viscosity is also extremely important to the production of paints and varnishes. Consistency, closely related to viscosity, is of especial importance to paper production. This variable property of paper pulp greatly affects formation of the sheet on the paper-machine wire.

pH or Hydrogen-ion Concentration. As a measure of the effective acidity or alkalinity of a process liquor, pH is of significant importance to many of the chemical unit operations, including precipitation, coagulation, neutralization, and fermentation. Usually the pH of the final product is not nearly so important as the pH of the various liquors during production. For example, certain organic solvents and compounds are produced by the action of living enzymes or molds. These living organisms usually yield a maximum quantity of the desired substance at a definite pH value, and, therefore, close control over pH is important. On the other hand, the actual pH of the finished product is not usually of particular significance.

Electrical Conductivity. Electrical conductivity finds limited value as an index to chemical composition of liquids and also as a measure of the moisture content of such substances as paper and textiles. With the exception of wire and electrical insulators, electrical conductivity is not a particularly significant property of a final product.
